The child or adolescent's family, school life, peer interactions, and social activities often have a direct impact on the child's success in overcoming his or her difficulties. The psychological education and cooperation of a child or adolescent's family are essential ingredients in successful application of treatment recommendations. Communications from clinicians to parents and family members that balance the observed positive qualities of the child and family with the weak areas are often perceived as more helpful than a focus only on the problem areas. Finally, the most successful treatment plans are those developed cooperatively between the clinician, child, and family members during which each member of the team perceives that he or she has been given credit for positive contributions.

▲ 31.3 Intellectual Disability

Intellectual disability, formerly known as mental retardation, can be caused by a range of environmental and genetic factors that lead to a combination of cognitive and social impairments. The American Association on Intellectual and Developmental Disability (AAIDD) defines intellectual disability as a disability characterized by significant limitations in both intellectual...
functioning (reasoning, learning, and problem solving) and in adaptive behavior (conceptual, social, and practical skills) that emerges before the age of 18 years. Wide acceptance of this definition has led to the international consensus that an assessment of both social adaptation and intelligence quotient (IQ) are necessary to determine the level of intellectual disability. Measures of adaptive function assess competency in social functioning, understanding of societal norms, and performance of everyday tasks, whereas measures of intellectual function focus on cognitive abilities. Although individuals with a given intellectual level do not all have identical levels of adaptive function, epidemiologic data suggest that prevalence of intellectual disability is largely determined by intellectual level and a level of adaptive function, which typically corresponds closely with cognitive ability.

In the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5), various levels of severity of intellectual disability are determined on the basis of adaptive functioning, not on IQ scores. This change in emphasis from prior diagnostic manuals has been adopted by DSM-5 because adaptive functioning determines the level of support that is required. Furthermore, IQ scores are less valid in the lower portions of the IQ range. Making a determination of severity level of intellectual disability, according to DSM-5, includes assessment of functioning in a conceptual domain (e.g., academic skills), a social domain (e.g., relationships), and a practical domain (e.g., personal hygiene).

Societal approaches to children with intellectual disability have shifted significantly over time. Historically, in the mid-1800s many children with intellectual disability were placed in residential educational facilities based on the belief that with sufficient intensive training, these children would be able to return to their families and function in society at a higher level. However, the expectation of educating these children in order to overcome their disabilities was not realized. Gradually, many residential programs increased in size, and eventually the focus began to shift from intensive education to more custodial care. Residential settings for children with intellectual disability received their maximal use in the mid-1900s, until public awareness of the crowded, unsanitary, and, in some cases, abusive conditions sparked the movement toward “deinstitutionalization.” An important force in the deinstitutionalization of children with intellectual disability was the philosophy of “normalization” in living situations, and “inclusion” in educational settings. Since the late 1960s, few children with intellectual disability have been placed in residences, and the concepts of normalization and inclusion remain prominent among advocacy groups and parents.

The passage of Public Law 94–142 (the Education for all Handicapped Children Act) in 1975 mandates that the public school system provide appropriate educational service to all children with disabilities. The Individuals with Disabilities Act in 1990 extended and modified the above legislation. Currently, provision of public education for all children, including those with disabilities, “within the least restrictive environment” is mandated by law.

In addition to the educational system, advocacy groups, including the Council for Exceptional Children (CEC) and the National Association for Retarded Citizens (NARC) are well known parental lobbying organizations for children with intellectual disability and were instrumental in advocating for Public Law 94–142. The American Association on Intellectual and Developmental Disabilities, formerly known as The American Association on Intellectual disability (AAIDD), is the most prominent advocacy organization in this field. It has been very influential in educating the public about, and in supporting research and legislation relating to, intellectual disability.

The AAIDD promotes a view of intellectual disability as a functional interaction between an individual and the environment, rather than a static designation of a person’s limitations. Within this conceptual framework, a child or adolescent with intellectual disability is determined to need intermittent, limited, extensive, or pervasive “environmental support” with respect to a specific set of adaptive function domains. These include communication, self-care, home living, social or interpersonal skills, use of community resources, self-direction, functional academic skills, work, leisure, health, and safety.

The United Nations Convention on the Rights of Persons with Disabilities (2006) has created a forum to promote the full social inclusion of people with intellectual disability. Through its recognition and focus on social barriers, this international forum aims to provide protections for individuals with intellectual disability, and to seek more inclusion of those with intellectual disability in social, civic, and educational activities.

NOMENCLATURE

The accurate definition of intellectual disability has been a challenge for clinicians over the centuries. All current classification systems underscore that intellectual disability is based on more than cognitive deficits, that is, it also includes impaired social adaptive function. According to DSM-5, a diagnosis of intellectual disability should be made only when there are deficits in intellectual functioning and deficits in adaptive functioning (Table 31.3.1). Once intellectual disability is recognized, the level of severity is determined by the level of adaptive functional impairment.

CLASSIFICATION

DSM-5 criteria for intellectual disability include significantly subaverage general intellectual functioning associated with concurrent impairment in adaptive behavior, manifested before the age of 18. The diagnosis is made independent of coexisting physical or mental disorders. Table 31.3.2 presents an overview of developmental levels in communication, academic functioning, and vocational skills expected of persons with various degrees of intellectual disability.

If the clinician chooses to use a standardized test of intelligence—which is still common practice—the term significantly subaverage is defined as an IQ of approximately 70 or below or two standard deviations below the mean for the particular test. Adaptive functioning can be measured by using a standardized scale, such as the Vineland Adaptive Behavior Scale. This scale scores communications, daily living skills, socialization, and motor skills (up to 4 years, 11 months) and generates an adaptive behavior composite that is correlated with the expected skills at a given age.

Approximately 85 percent of individuals who have intellectual disability fall within the DSM-5 mild intellectual
disability category. This is typically defined by a Full Scale IQ between 50 and 70 and an adaptive function severity in the mild range. Adaptive function includes skills such as communication, self-care, social skills, work, leisure, and understanding of safety. Intellectual disability is influenced by genetic, environmental, and psychosocial factors. A host of subtle environmental and developmental factors, including subclinical lead intoxication and prenatal exposure to drugs, alcohol, and other toxins have been implicated as contributors to intellectual disability. Certain genetic syndromes associated with intellectual disability such as fragile X syndrome, Down syndrome, and Prader-Willi syndrome, have characteristic patterns of social, linguistic, and cognitive development and typical behavioral manifestations.

### Table 31.3-1
**DSM-5 Diagnostic Criteria for Intellectual Disability**

<table>
<thead>
<tr>
<th>Level of Intellectual Disability</th>

Note: The diagnostic term intellectual disability is the equivalent term for the ICD-11 diagnosis of intellectual developmental disorder. Although the term intellectual disability is used throughout this manual, both terms are used in the title to clarify relationships with other classification systems. Moreover, a federal statute in the United States (Public Law 111-256, Rosa’s Law) replaces the term mental retardation with intellectual disability, and research journals use the term intellectual disability. Thus, intellectual disability is the term in common use by medical, educational, and other professions and by the lay public and advocacy groups.

Specify current severity:
- 317 (F70) Mild
- 318.0 (F71) Moderate
- 318.1 (F72) Severe
- 318.2 (F73) Profound

DEGREES OF SEVERITY OF INTELLIGENT DISABILITY

The severity levels of intellectual disability are expressed in DSM-5 as mild, moderate, severe, and profound. “Borderline intellectual functioning,” a term previously used to describe individuals with a full scale IQ in the range of 70 to 80, is no longer described as a diagnosis in DSM-5. The term is used in DSM-5 as a condition that may be the focus of clinical attention; however, no criteria are given.

Mild intellectual disability represents approximately 85 percent of persons with intellectual disability. Children with mild intellectual disability often are not identified until the first or second grade, when academic demands increase. By late adolescence, they often acquire academic skills at approximately a sixth-grade level. Specific causes for the intellectual disability are often unidentified in this group. Many adults with mild intellectual disability can live independently with appropriate support and raise their own families. IQ for this level of adaptive function may typically range from 50 to 70.

Moderate intellectual disability represents about 10 percent of persons with intellectual disability. Most children with moderate intellectual disability acquire language and can communicate adequately during early childhood. They are challenged academically and often are not able to achieve above a second to third grade level. During adolescence, socialization difficulties often set these persons apart, and a great deal of social and vocational support is beneficial. As adults, individuals with moderate intellectual disability may be able to perform semiskilled work under appropriate supervision. IQ for this level of adaptive function may typically range from 35 to 50.

Severe intellectual disability represents about 4 percent of individuals with intellectual disability. They may be able to develop communication skills in childhood and often can learn to count as well as recognize words that are critical to functioning. In this group, the cause for the intellectual disability is more likely to be identified than in milder forms of intellectual disability. In adulthood, persons with severe intellectual disability may adapt well to supervised living situations, such as group homes, and may be able to perform work-related tasks under supervision. IQ in individuals with this level of adaptive function may typically range from 20 to 35.

Profound intellectual disability constitutes approximately 1 to 2 percent of individuals with intellectual disability. Most individuals with profound intellectual disability have identifiable causes for their condition. Children with profound intellectual disability may be taught some self-care skills and learn to communicate their needs given the appropriate training. IQ in individuals with this level of adaptive function may typically be less than 20.

The DSM-5 also includes a disorder called “Unspecified Intellectual Disability” (Intellectual Developmental Disorder), reserved for individuals over the age of 5 years who are difficult to evaluate but are strongly suspected of having intellectual disability. Individuals with this diagnosis may have sensory or physical impairments such as blindness or deafness, or concurrent mental disorders, making it difficult to administer typical assessment tools. (e.g., Bayley Scales of Infant Development and Cattell Infant Scale) to aid in determining adaptive functional impairment.

EPIDEMIOLOGY

The majority of population-based prevalence estimates for intellectual disability in developing countries range from 10 to 15 per 1,000 children. The prevalence of intellectual disability at any one time is estimated to range from 1 to 3 percent of the population in Western societies. The incidence of intellectual disability is difficult to accurately calculate because mild disabilities may be unrecognized until middle childhood. In some cases, even when intellectual function is limited, social adaptive skills may not be challenged until late childhood or early adolescence, and the diagnosis is not made until that time. The highest incidence of intellectual disability is reported in school-age children, with the peak at ages 10 to 14 years. Intellectual disability is about 1.5 times more common among males than females.

COMORBIDITY

Prevalence

Epidemiological surveys indicate that up to two thirds of children and adults with intellectual disability have comorbid psychiatric disorders; and this rate is several times higher than that in community samples without intellectual disability. The prevalence of psychopathology appears to be correlated with the severity of intellectual disability; the more severe the intellectual disability, the higher the risk for coexisting psychiatric disorders. An epidemiological study found that 40.7 percent of intellectually disabled children between 4 and 18 years of age met criteria for at least one additional psychiatric disorder. The severity of intellectual disability influenced the risk for particular comorbid psychiatric disorders. Disruptive and conduct-disorder behaviors occurred more frequently in those diagnosed with mild intellectual disability, whereas those with more severe intellectual disability were more likely to meet criteria for autism spectrum disorder and exhibited symptoms such as self-stimulation and self-mutilation. Comorbidity of psychiatric disorders with intellectual disability in children in this study was not correlated with age or gender. Children diagnosed with profound intellectual disability were less likely to exhibit comorbid psychiatric disorders.

Psychiatric disorders among persons with intellectual disability are varied, and include mood disorders, schizophrenia, attention-deficit/hyperactivity disorder (ADHD), and conduct disorder. Children diagnosed with severe intellectual disability have a particularly high rate of comorbid autism spectrum disorder. Approximately 2 to 3 percent of those with intellectual disability meet diagnostic criteria for schizophrenia, which is several times higher than the rate for the general population. Up to 50 percent of children and adults with intellectual disability are found to meet criteria for a mood disorder when instruments such as the Kiddie Schedule for Affective Disorders and Schizophrenia (K-SADS), the Beck Depression Inventory, and the Children’s Depression Inventory were used in studies. However, a limitation of these studies is that these instruments have not been standardized within intellectual disability populations. Frequent psychiatric symptoms that occur in children with intellectual disability, outside the context of a full psychiatric disorder, include hyperactivity and short attention span, self-injurious
behaviors (e.g., head-banging and self-biting), and repetitive stereotypical behaviors (hand-flapping and toe-walking). In children and adults with milder forms of intellectual disability, negative self-image, low self-esteem, poor frustration tolerance, interpersonal dependence, and a rigid problem-solving style are frequent.

Neurological Disorders

Seizure disorders occur more frequently in individuals with intellectual disability than in the general population, and prevalence rates for seizures increase proportionally to severity level of intellectual disability. A review of psychiatric disorders in children and adolescents with intellectual disability and epilepsy, found that approximately one third had comorbid autism spectrum disorder. The combination of intellectual disability, epilepsy, and autism spectrum disorder has been estimated to occur in 0.07 percent of the general population.

Psychosocial Features

A negative self-image and poor self-esteem are common features of mildly and moderately intellectually disabled persons who are aware of their social and academic differences from others. Given their experience of repeated failure and disappointment in being unable to meet their parents' and society's expectations, they may also be faced with falling progressively behind younger siblings. Communication difficulties further increase their vulnerability to feelings of ineptness and frustration. Inappropriate behaviors, such as withdrawal, are common. The perceptual sense of isolation and inadequacy has been linked to feelings of anxiety, anger, dysphoria, and depression.

ETIOLOGY

Etiological factors in intellectual disability can be genetic, developmental, environmental, or a combination. Genetic causes include chromosomal and inherited conditions; developmental and environmental factors include prenatal exposure to infections and toxins; and environmental or acquired factors include prenatal trauma (e.g., prematurity) and sociocultural factors. The severity of intellectual disability may be related to the timing and duration of a given trauma as well as to the degree of exposure to the central nervous system (CNS). In about three fourths of persons diagnosed with severe intellectual disability, the etiology is known, whereas the etiology is apparent in up to half of those diagnosed with mild intellectual disability. A study of 100 consecutive children diagnosed with intellectual disability admitted to a clinical genetics unit of a university pediatric hospital reported that in 41 percent of cases, a causative diagnosis was made. No cause is known for three fourths of persons with IQ ranging from 70 to 80 and variable adaptive functioning. Among chromosomal disorders, Down syndrome and fragile X syndrome are the most common disorders that usually produce at least moderate intellectual disability. A prototype of a metabolic disorder associated with intellectual disability is phenylketonuria (PKU). Deprivation of nutrition, nurturance, and social stimulation can potentially contribute to the development of at least mild forms of intellectual disability. Current knowledge suggests that genetic, environmental, biological, and psychosocial factors work additively in the emergence of intellectual disability.

Genetic Etiological Factors in Intellectual Disability

Single-Gene Causes. One of the most well-known single gene causes of intellectually disability is found in the FMR1 gene whose mutations cause fragile X syndrome. It is the most common and first X-linked gene to be identified as a direct cause of intellectual disability. Abnormalities in autosomal chromosomes are frequently associated with intellectual disability, whereas aberrations in sex chromosomes can result in characteristic physical syndromes that do not include intellectual disability (e.g., Turner's syndrome with XO and Klinefelter's syndrome with XXXY, XXXY, and XXY variations). Some children with Turner's syndrome have normal to superior intelligence. Agreement exists on a few predisposing factors for chromosomal disorders—among them, advanced maternal age, increased age of the father, and X-ray radiation.

Visible and Submicroscopic Chromosomal Causes of Intellectual Disability. Trisomy 21 (Down syndrome) is a prototype of a cytogenetically visible abnormality that accounts for about two-thirds of the 15 percent of intellectual disability attributable to visible abnormal cytogenetics. Other microscopically visible chromosomal abnormalities associated with intellectual disability include deletions, translocations, and supernumerary marker chromosomes. Typically, microscopic chromosome analysis is able to identify abnormalities of 5 to 10 million base pairs or greater. Submicroscopic identification requires the use of microarrays that can identify losses of chromosomal segments too small to be picked up by light microscopy. The altered copy number variants (CNVs) in submicroscopic segments of the chromosome have been identified to be associated with up to 13 to 20 percent of cases of intellectual disability. That is, the genes associated with a particular developmental abnormality have been identified to be located in the critical regions of the pathogenic copy number variants.

Genetic Intellectual Disability and Behavioral Phenotype

Specific and predictable behaviors have been found to be associated with certain genetically based cases of intellectual disability. These behavioral phenotypes are defined as a syndrome of observable behaviors that occur with a significantly greater probability than expected among those individuals with a specific genetic abnormality. Examples of behavioral phenotypes occur in genetically determined syndromes such as fragile X syndrome, Prader-Willi syndrome, and Down syndrome in which specific behavioral manifestations can be expected. Persons with fragile X syndrome have extremely high rates (up to three fourths of those studied) of ADHD. High rates of aberrant interpersonal behavior and language function often meet the criteria for autistic disorder and avoidant personality disorder. Prader-Willi
syndrome is almost always associated with compulsive eating disturbances, hyperphagia, and obesity. Socialization is an area of weakness, especially in coping skills. Externalizing behavior problems—such as temper tantrums, irritability, and arguing—seem to be heightened in adolescence.

Down Syndrome. The etiology of Down syndrome, known to be caused by an extra copy of the entire chromosome 21, makes it one of the more complex disorders. The original description of Down syndrome, first made by the English physician Langdon Down in 1866, was based on physical characteristics associated with subnormal mental functioning. Since then, Down syndrome has been the most investigated, and most discussed, syndrome in intellectual disability. Recent data have suggested that Down syndrome may be more amenable to postnatal interventions to address the cognitive deficits that it produces than was previously thought. Although still in the early stages of animal research, data from experiments with one mouse model, the Ts65Dn, indicates that pharmacologic interventions may influence learning and memory deficits known to occur in Down syndrome.

Phenotypically, children with Down syndrome are observed to have characteristic physical attributes, including slanted eyes, epicanthal folds, and a flat nose.

The etiology of Down syndrome is complicated by the recognition of three types of chromosomal aberrations in Down syndrome:

1. Patients with trisomy 21 (three chromosomes 21, instead of the usual two) represent the overwhelming majority; they have 47 chromosomes, with an extra chromosome 21. The mothers' karyotypes are normal. A nondisjunction during meiosis, occurring for unknown reasons, is held responsible for the disorder.
2. Nondisjunction occurring after fertilization in any cell division results in mosaicism, a condition in which both normal and trisomic cells are found in various tissues.
3. In translocation, a fusion occurs of two chromosomes, usually 21 and 15, resulting in a total of 46 chromosomes, despite the presence of an extra chromosome 21. The disorder, unlike trisomy 21, is usually inherited, and the translocated chromosome may be found in unaffected parents and siblings. The asymptomatic carriers have only 45 chromosomes.

Approximately 6,000 babies are affected with Down syndrome in the United States, which makes the incidence of Down syndrome 1 in every 700 births, or 15 per 10,000 live births. For women older than 32 years of age, the risk of having a child with Down syndrome (trisomy 21) is about 1 in 100 births, but when translocation is present, the risk is about 1 in 3. Most children with Down syndrome are mildly to moderately intellectually disabled, with a minority having an IQ above 50. Cognitive development appears to progress normally from birth to 6 months of age; IQ scores gradually decrease from near normal at 1 year of age to about 30 to 50 as development proceeds. The decline in intellectual function may not be readily apparent. Infant tests may not reveal the full extent of the deficits. According to anecdotal clinical reports, children with Down syndrome are typically placid, cheerful, and cooperative and adapt easily at home. With adolescence, the picture changes: youth with Down syndrome may experience more social and emotional difficulties and behavior disorders, and there is an increased risk for psychotic disorders.

In Down syndrome, language function is a relative weakness, whereas sociability and social skills, such as interpersonal cooperation and conformity with social conventions, are relative strengths. Children with Down syndrome typically manifest deficits in scanning the environment; they are more likely to focus on a single stimulus, leading to difficulty noticing environmental changes. A variety of comorbid psychiatric disorders emerge in persons with Down syndrome; however, the rates appear to be lower than in children with intellectual disability and autism spectrum disorder.

The diagnosis of Down syndrome is made with relative ease in an older child, but it is often difficult in newborn infants. The most important signs in a newborn include general hypotonia; oblique palpebral fissures; abundant neck skin; a small, flattened skull; high cheekbones; and a protruding tongue. The hands are broad and thick, with a single palmar transversal crease, and the little fingers are short and curved inward. Moro reflex is weak or absent. More than 100 signs or stigmata are described in Down syndrome, but rarely are all found in one person. Commonly occurring physical problems in Down syndrome include cardiac defects, thyroid abnormalities, and gastrointestinal problems. Life expectancy was once drastically limited to about the age of 40; however, currently it is vastly increased, although still not as long as those without intellectual disability.

Down syndrome is characterized by deterioration in language, memory, self-care skills, and problem-solving by the third decade of life. Postmortem studies of individuals with Down syndrome older than age 40 have shown a high incidence of senile plaques and neurofibrillary tangles, similar to those seen in Alzheimer's disease. Neurofibrillary tangles are known to occur in a variety of degenerative diseases, whereas senile plaques seem to be found most often in Alzheimer's disease and in Down syndrome.

Fragile X Syndrome. Fragile X syndrome is the second most common single cause of intellectual disability. The syndrome results from a mutation on the X chromosome at what is known as the fragile site (Xq27.3). The fragile site is expressed in only some cells, and it may be absent in asymptomatic males and female carriers. Much variability is present in both genetic and phenotypic expression. Fragile X syndrome is believed to occur in about 1 of every 1,000 males and 1 of every 2,000 females. The typical phenotype includes a large, long head and ears, short stature, hyperextensible joints, and postpubertal macroorchidism. Associated intellectual disability ranges from mild to severe. The behavioral profile of persons with the syndrome includes a high rate of ADHD, learning disorders, and autism spectrum disorder. Deficits in language function include rapid perseverative speech with abnormalities in combining words into phrases and sentences. Persons with fragile X syndrome seem to have relatively strong skills in communication and socialization; their intellectual functions seem to decline in the pubertal period. Female carriers are often less impaired than males with fragile X syndrome, but females can also manifest the typical physical characteristics and may have mild intellectual disability.

Prader-Willi Syndrome. Prader-Willi syndrome is believed to result from a small deletion involving chromosome 15, occurring sporadically. Its prevalence is less than 1 in 10,000. Persons with the syndrome exhibit compulsive eating behavior and often obesity, intellectual disability, hypogonadism, small stature, hypotonia, and small hands and feet.
Cat’s Cry (Cri-du-Chat) Syndrome. Children with cat’s cry syndrome have a deletion in chromosome 5. They are typically severely intellectually disabled and show many signs often associated with chromosomal aberrations, such as microcephaly, low-set ears, oblique palpebral fissures, hypertelorism, and micrognathia. The characteristic cat-like cry that gave the syndrome its name is caused by laryngeal abnormalities that gradually change and disappear with increasing age.

Phenylketonuria. PKU was first described by Ivar Asbjörn Fölling in 1934 as an inborn error of metabolism. PKU is transmitted as a simple recessive autosomal Mendelian trait and occurs in about 1 of every 10,000 to 15,000 live births. For parents who have already had a child with PKU, the chance of having another child with PKU is 20 to 25 percent of successive pregnancies. PKU is reported predominantly in persons of North European origin; a few cases have been described in blacks, Yemenite Jews, and Asians. The basic metabolic defect in PKU is an inability to convert phenylalanine, an essential amino acid, to paratyrosine because of the absence or inactivity of the liver enzyme phenylalanine hydroxylase, which catalyzes the conversion. Therefore, PKU is largely preventable with a screening for it, which, if positive, should be followed with a low phenylalanine diet. Two other types of hyperphenylalaninemia have recently been described. One is caused by a deficiency of the enzyme dihydropteridine reductase, and the other to a deficiency of a cofactor, biopterin. The first defect can be detected in fibroblasts, and biopterin can be measured in body fluids. Both these rare disorders carry a high risk of fatality.

Most patients with PKU are severely intellectually disabled, but some are reported to have borderline or normal intelligence. Eczema, vomiting, and convulsions occur in about one third of all patients. Although the clinical picture varies, typically, children with PKU are reported to be hyperactive and irritable. They frequently exhibit temper tantrums and often display bizarre movements of their bodies and upper extremities, including twisting hand mannerisms. Verbal and nonverbal communication is commonly severely impaired or nonexistent. The children’s coordination is poor, and they have many perceptual difficulties.

Currently, the Guthrie inhibition assay is a widely applied screening test using a bacteriological procedure to detect phenylalanine in the blood. In the United States, newborn infants are routinely screened for PKU. Early diagnosis is important, because a low-phenylalanine diet, in use since 1955, significantly improves both behavior and developmental progress. The best results seem to be obtained with early diagnosis and the start of dietary treatment before the child is 6 months of age. Dietary treatment, however, is not without risk. Phenylalanine is an essential amino acid, and its omission from the diet can lead to such severe complications as anemia, hypoglycemia, or edema. Dietary treatment of PKU should be continued indefinitely. Children who receive a diagnosis before the age of 3 months and are placed on an optimal dietary regimen may have normal intelligence. A low-phenylalanine diet does not reverse intellectual disability in untreated older children and adolescents with PKU, but the diet does decrease irritability and abnormal electroencephalography (EEG) changes and does increase social responsiveness and attention span. The parents of children with PKU and some of the children’s normal siblings are heterozygous carriers.

Rett Syndrome. Rett syndrome, now diagnosed in the DSM-5 as a form of autism spectrum disorder, is believed to be caused by a dominant X-linked gene. It is degenerative and affects only females. In 1966, Andreas Rett reported on 22 girls with a serious progressive neurological disability. Deterioration in communications skills, motor behavior, and social functioning starts at about 1 year of age. Symptoms include ataxia, facial grimacing, teeth-grinding, and loss of speech. Intermittent hyperventilation and a disorganized breathing pattern are characteristic while the child is awake. Stereotypical hand movements, including hand-wringing, are typical. Progressive gait disturbance, scoliosis, and seizures occur. Severe spasticity is usually present by middle childhood. Cerebral atrophy occurs with decreased pigmentation of the substantia nigra, which suggests abnormalities of the dopaminergic nigrostriatal system.

Neurofibromatosis. Also called von Recklinghausen’s, neurofibromatosis is the most common of the neurocutaneous syndromes caused by a single dominant gene, which may be inherited or occur as a new mutation. The disorder occurs in about 1 of 5,000 births and is characterized by café au lait spots on the skin and by neurofibromas, including optic gliomas and acoustic neuromas, caused by abnormal cell migration. Mild intellectual disability occurs in up to one third of those with the disease.

Tuberous Sclerosis. Tuberous sclerosis is the second most common of the neurocutaneous syndromes; a progressive intellectual disability occurs in up to two thirds of all affected persons. It occurs in about 1 of 15,000 persons and is inherited by autosomal dominant transmission. Seizures are present in all those with intellectual disability, and in two thirds of those who are not. Infantile spasms may occur as early as 6 months of age. The phenotypic presentation includes adenoma sebaceum and ash-leaf spots that can be identified with a slit lamp.

Lesch-Nyhan Syndrome. Lesch-Nyhan syndrome is a rare disorder caused by a deficiency of an enzyme involved in purine metabolism. The disorder is X-linked; patients have intellectual disability, microcephaly, seizures, choreoathetosis, and spasticity. The syndrome is also associated with severe compulsive self-mutilation by biting the mouth and fingers. Lesch-Nyhan syndrome is another example of a genetically determined syndrome with a specific, predictable behavioral pattern.

Adrenoleukodystrophy
The most common of several disorders of sudanophilic cerebral sclerosis, adrenoleukodystrophy is characterized by diffuse demyelination of the cerebral white matter resulting in visual and intellectual impairment, seizures, spasticity, and progression to death. The cerebral degeneration in adrenoleukodystrophy is accompanied by adrenocortical insufficiency. The disorder is transmitted by a sex-linked gene located on the distal end of the long arm of the X chromosome. The clinical onset is generally between 5 and 8 years of age, with early
seizures, disturbances in gait, and mild intellectual impairment. Abnormal pigmentation reflecting adrenal insufficiency sometimes precedes the neurological symptoms, and attacks of crying are common. Spastic contractures, ataxia, and swallowing disturbances are also frequent. Although the course is often rapidly progressive, some patients may have a relapsing and remitting course.

Maple Syrup Urine Disease. The clinical symptoms of maple syrup urine disease appear during the first week of life. The infant deteriorates rapidly and has decerebrate rigidity, seizures, respiratory irregularity, and hypoglycemia. If untreated, maple syrup urine disease is usually fatal in the first months of life, and the survivors have severe intellectual disability. Some variants have been reported with transient ataxia and only mild intellectual disability. Treatment follows the general principles established for PKU and consists of a diet very low in the three involved amino acids—leucine, isoleucine, and valine.

Other Enzyme Deficiency Disorders. Several enzyme deficiency disorders associated with intellectual disability have been identified, and still more diseases are being added as new discoveries are made, including Hartnup disease, galactosemia, and glycogen-storage disease. Table 31.3-3 lists 30 important disorders with inborn errors of metabolism, hereditary transmission patterns, defective enzymes, clinical signs, and relation to intellectual disability.

### Acquired and Developmental Factors

#### Prenatal Period

Important prerequisites for the overall development of the fetus include the mother's physical, psychological, and nutritional health during pregnancy. Maternal chronic illnesses and conditions affecting the normal development of the fetus's CNS include uncontrolled diabetes, anemia, emphysema, hypertension, and long-term use of alcohol and narcotic substances. Maternal infections during pregnancy, especially viral infections, have been known to cause fetal damage and intellectual disability. The extent of fetal damage depends on such variables as the type of viral infection, the gestational age of the fetus, and the severity of the illness. Although numerous infectious diseases have been reported to affect the fetus's CNS, the following maternal illnesses have been identified to increase risk of intellectual disability in the newborn.

**Rubella (German measles).** Rubella has replaced syphilis as the major cause of congenital malformations and intellectual disability caused by maternal infection. The children of affected mothers may show several abnormalities, including congenital heart disease, intellectual disability, cataracts, deafness, microcephaly, and microphthalmia. Timing is crucial, because the extent and frequency of the complications are inversely related to the duration of the pregnancy at the time of maternal infection. When mothers are infected in the first trimester of pregnancy, 10 to 15 percent of the children are affected, but the incidence rises to almost 50 percent when the infection occurs in the first month of pregnancy. The situation is often complicated by subclinical
forms of maternal infection that go undetected. Maternal rubella can be prevented by immunization.

**Cytomegalic Inclusion Disease.** In many cases, cytomegalic inclusion disease remains dormant in the mother. Some children are stillborn, and others have jaundice, microcephaly, hepatosplenomegaly, and radiographic findings of intracerebral calcification. Children with intellectual disability from the disease frequently have cerebral calcification, microcephaly, or hydrocephalus. The diagnosis is confirmed by positive findings of the virus in throat and urine cultures and the recovery of inclusion-bearing cells in the urine.

**Syphilis.** Syphilis in pregnant women was once the main cause of various neuropathological changes in their offspring, including intellectual disability. Today, the incidence of syphilitic complications of pregnancy fluctuates with the incidence of syphilis in the general population. Some recent alarming statistics from several major cities in the United States indicate that there is still no room for complacency.

**Toxoplasmosis.** Toxoplasmosis can be transmitted by the mother to the fetus. It causes mild or severe intellectual disability and, in severe cases, hydrocephalus, seizures, microcephaly, and chorioretinitis.

**Herpes Simplex.** The herpes simplex virus can be transmitted transplacentally, although the most common mode of infection is during birth. Microcephaly, intellectual disability, intracranial calcification, and ocular abnormalities may result.

**Human Immunodeficiency Virus (HIV).** Cognitive impairments are well known to be associated with transmission of HIV from mothers to their babies. HIV may have both direct and indirect influences on the developing brain. A subset of infants born infected with HIV may develop progressive encephalopathy, intellectual disabilities, and seizures within the first year of life. Fortunately, over the last two decades, there has been a dramatic decrease in perinatal HIV transmission due to a combination of antiviral agents provided to mothers during pregnancy and delivery, obstetric interventions that reduce risk, and administration of zidovudine (ZDV) as a prophylaxis for six weeks to newborns exposed to HIV. In the United States, the highest rate of reported pediatric acquired immunodeficiency disease (AIDS) occurred in 1992, with 1,700 cases reported compared to less than 50 cases reported annually now. In the United States, fewer than 300 cases of HIV transmission from mother to child were reported in 2005. However, vertical transmission of HIV from mother to child around the world, especially in Africa, is considerable. Most babies born to HIV-infected mothers in the United States are not infected with the virus.

**Fetal Alcohol Syndrome.** Fetal alcohol syndrome (FAS) results from prenatal alcohol exposure and can lead to a wide range of problems in the newborn. According to the Centers for Disease Control and Prevention, FAS in the United States occurs at a rate ranging from 0.2 to 1.5 per 1,000 live births. FAS is one of the leading preventable causes of intellectual disability and physical disabilities. The typical phenotypic picture of a child with FAS includes facial dysmorphism comprising hypertelorism, microcephaly, short palpebral fissures, inner epicantal folds, and a short, turned-up nose. Often, the affected children have learning disorders and ADHD, and in some cases intellectual disability. Cardiac defects are also frequent. The entire syndrome occurs in up to 15 percent of babies born to women who regularly ingest large amounts of alcohol. Babies born to women who consume alcohol regularly during pregnancy have a high incidence of ADHD, learning disorders, and intellectual disability without the facial dysmorphism.

**Prenatal Drug Exposure.** Prenatal exposure to opioids, such as heroin, often results in infants who are small for their gestational age, with a head circumference below the tenth percentile and withdrawal symptoms that appear within the first 2 days of life. The withdrawal symptoms of infants include irritability, hypertonia, tremor, vomiting, a high-pitched cry, and an abnormal sleep pattern. Seizures are unusual, but the withdrawal syndrome can be life-threatening to infants if it is untreated. Diazepam (Valium), phenobarbital (Luminal), chlorpromazine (Thorazine), and paregoric have been used to treat neonatal opioid withdrawal. The long-term sequelae of prenatal opioid exposure are not fully known; the children's developmental milestones and intellectual functions may be within the normal range, but they have an increased risk for impulsivity and behavioral problems. Infants prenatally exposed to cocaine are at high risk for low birth weight and premature delivery. In the early neonatal period, they may have transient neurological and behavioral abnormalities, including abnormal results on EEG studies, tachycardia, poor feeding patterns, irritability, and excessive drowsiness. Rather than a withdrawal reaction, the physiological and behavioral abnormalities are a response to the cocaine, which may be excreted for up to a week postnatally.

**Complications of Pregnancy.** Toxemia of pregnancy and uncontrolled maternal diabetes present hazards to the fetus and can potentially result in intellectual disability. Maternal malnutrition during pregnancy often results in prematurity and other obstetrical complications. Vaginal hemorrhage, placenta previa, premature separation of the placenta, and prolapse of the cord can damage the fetal brain by causing anoxia. The use of lithium during pregnancy was recently implicated in some congenital malformations, especially of the cardiovascular system (e.g., Ebstein's anomaly).

**Perinatal Period.** Some evidence indicates that premature infants and infants with low birth weight are at high risk for neurological and subtle intellectual impairments that may not be apparent until their school years. Infants who sustain intracranial hemorrhages or show evidence of cerebral ischemia are especially vulnerable to cognitive abnormalities. The degree of neurodevelopmental impairment generally correlates with the severity of the intracranial hemorrhage. Recent studies have documented that, among children with very low birth weight (less than 1,000 g), 20 percent had significant disabilities, including cerebral palsy, intellectual disability, autism, and low intelligence with severe learning problems. Very premature children and those who had intrauterine growth retardation were
found to be at high risk for developing both social problems and academic difficulties. Socioeconomic deprivation can also affect the adaptive function of these vulnerable infants. Early intervention may improve their cognitive, language, and perceptual abilities.

**Acquired Childhood Disorders**

**Infection.** The most serious infections affecting cerebral integrity are encephalitis and meningitis. Measles encephalitis has been virtually eliminated by the universal use of measles vaccine, and the incidence of other bacterial infections of the CNS has been markedly reduced with antibacterial agents. Most episodes of encephalitis are caused by viruses. Sometimes a clinician must retrospectively consider a probable encephalitic component in a previous obscure illness with high fever. Meningitis that was diagnosed late, even when followed by antibiotic treatment, can seriously affect a child's cognitive development. Thrombotic and purulent intracranial phenomena secondary to septicemia are rarely seen today except in small infants.

**Head Trauma.** The best-known causes of head injury in children that produces developmental handicaps, including seizures, are motor vehicle accidents, but more head injuries are caused by household accidents, such as falls from tables, open windows, and on stairways. Child maltreatment is not infrequently implicated in head traumas or intracranial trauma such as bleeding due “shaken baby” syndrome.

**Asphyxia.** Brain damage due to asphyxia associated with near drowning is not an uncommon cause of intellectual disability.

**Long-term Exposures.** Long-term exposure to lead is a well-established cause of compromised intelligence and learning skills. Intracranial tumors of various types and origins, surgery, and chemotherapy can also adversely affect brain function.

**Environmental and Sociocultural Factors**

Mild intellectual disability has been associated with significant deprivation of nutrition and nurture. Children who have endured these conditions are at risk for a host of psychiatric disorders including mood disorders, posttraumatic stress disorder, and attentional and anxiety disorders. Prenatal environment compromised by poor medical care and poor maternal nutrition may be contributing factors in the development of mild intellectual disability. Teenage pregnancies are at risk for mild intellectual disability in the baby due to the increased risk of obstetrical complications, prematurity, and low birth weight. Poor postnatal medical care, malnutrition, exposure to toxic substances such as lead, and potential physical trauma are additional risk factors for mild intellectual disabilities. Child neglect and inadequate caretaking may deprive an infant of both physical and emotional nurturances, leading to failure to thrive syndromes.

**DIAGNOSIS**

The diagnosis of intellectual disability can be made after the history is obtained, using information from a standardized intellectual assessment, and a standardized measure of adaptive function indicating that a child is significantly below the expected level in both areas. The severity of the intellectual disability will be determined on the basis of the level of adaptive function. A history and psychiatric interview are useful in obtaining a longitudinal picture of the child's development and functioning. Examination of physical signs, neurological abnormalities, and in some cases, laboratory tests can be used to ascertain the cause and prognosis.

**History**

The clinician taking the history, which may elucidate pathways to intellectual disability, should pay particular attention to the mother's pregnancy, labor, and delivery; the presence of a family history of intellectual disability; consanguinity of the parents; and known familial hereditary disorders.

**Psychiatric Interview**

A psychiatric interview of a child or adolescent with intellectual disability requires a high level of sensitivity in order to elicit information at the appropriate intellectual level while remaining respectful of the patient's age and emotional development. The patient's verbal abilities, including receptive and expressive language, can be initially screened by observing the communication between the caretakers and patient. If the patient communicates largely through gestures or sign language, the parents may serve as interpreters. Patients with milder forms of intellectual disability are often well aware of their differences from others and their failures, and may be anxious and ashamed during the interview. Approaching patients with a clear, supportive, concrete explanation of the diagnostic process, particularly patients with sufficiently receptive language ability, may allay anxiety and fears. Providing support and praise in language appropriate to the patient's age and understanding is beneficial. Subtle direction, structure, and reinforcement may be necessary to keep patients focused on the task or topic.

In general, the psychiatric examination of an intellectually disabled child or adolescent should reveal how the patient has coped with stages of development. Frustration tolerance, impulse control, and over-aggressive motor and sexual behavior are important areas of attention in the interview. It is equally important to elicit the patient's self-image, areas of self-confidence, and an assessment of tenacity, persistence, curiosity, and willingness to explore the environment.

**Structured Instruments, Rating Scales and Psychological Assessment**

In children and adolescents who have acquired language, one of several standardized instruments that include numerous domains of cognitive function are used. For children ages 6 to 16 years, the Wechsler Intelligence Test for Children is typically administered, and for children ages 3 to 6 years, the Wechsler Preschool and Primary Scale of Intelligence-Revised is commonly used. The Stanford-Binet Intelligence Scale, Fourth Edition, has the advantage that it can be administered to children even younger, starting at age 2 years. The Kaufman Assessment Battery for Children can be used in children ages 2½ to 12½ years,
whereas the Kaufman Adolescent and Adult Intelligence Test is applicable to a wide range of ages, from 11 to 85 years. All of the above standardized instruments evaluate cognitive abilities across multiple domains including verbal, performance, memory, and problem solving. Standardized instruments measuring adaptive function (functions of “everyday” life) are based on the construct that adaptive skills increase with age, and that adaptation may vary across different settings such as school, peer relationships, and family life. The Vineland Adaptive Behavior Scales can be used in infants through youth 18 years of age and includes four basic domains including Communication (Receptive, Expressive, and Written); Daily Living Skills (Personal, Domestic, and Community); Socialization (Interpersonal Relations, Play and Leisure, and Coping Skills); Motor Skills (Fine and Gross).

Several behavioral rating scales have been developed for the population with intellectual disability. General behavioral ratings scales include the Aberrant Behavior Checklist (ABC) and the Developmental Behavior Checklist (DBC). The Behavior Problem Inventory (BPI) is a good screening instrument for self-injurious, aggressive, and stereotyped behaviors. The Psychopathology Inventory for Mentally Retarded Adults (PIMRA) is utilized to identify the presence of comorbid psychiatric symptoms and disorders.

Examining clinicians can use several screening instruments for developmental and intellectual delay or disability in infants and toddlers. However, controversy over the predictive value of infant psychological tests is heated. Some report the correlation of abnormalities during infancy with later abnormal functioning as very low, and others report it to be very high. The correlation rises in direct proportion to the age of the child at the time of the developmental examination. Some exercises such as copying geometric figures, the Goodenough Draw-a-Person Test, the Kohs Block Test, and geometric puzzles all may be used as quick screening tests of visual-motor coordination. The Gesell and Bayley scales and the Cattell Infant Intelligence Scale are most commonly used with infants.

The Peabody Vocabulary Test is the most widely used vocabulary test solely based on pictures. Other tests often found useful in detecting intellectual disability are the Bender Gestalt Test and the Benton Visual Retention Test. The psychological evaluation should assess perceptual, motor, linguistic, and cognitive abilities.

Physical Examination

Various parts of the body may demonstrate identifying characteristics of specific perinatal and prenatal events or conditions associated with intellectual disabilities. For example, the configuration and the size of the head may offer clues to a variety of conditions, such as microcephaly, hydrocephalus, or Down syndrome. A patient’s facial characteristics, for example, hypertelorism, a flat nasal bridge, prominent eyebrows, epicanthal folds may provide clues to a recognizable syndrome such as FAS. Additional facial characteristics including corneal opacities, retinal changes, low-set and small or misshapen ears, a protruding tongue, and disturbance in dentition may be stigmata of a variety of known syndromes. Facial expression, color and texture of the skin and hair, a high-arched palate, the size of the thyroid gland, and the proportions of a child’s trunk and extremities may offer clues for particular syndromes. The circumference of the head should be measured as part of the clinical investigation. Dermatoglyphics may offer another diagnostic tool, because uncommon ridge patterns and flexion creases on the hand are often found in persons who are intellectually disabled. Abnormal dermatoglyphics occur in chromosomal disorders and in persons who were prenatally infected with rubella. Table 31.3-4 lists syndromes with intellectual disability and their behavioral phenotypes.

Neurological Examination

Sensory impairments occur frequently among persons with intellectual disabilities. For example, hearing impairment occurs in 10 percent of persons with intellectual disability, a rate that is four times that of the general population. Visual disturbances can range from blindness to disturbances of spatial concepts, design recognition, and concepts of body image. Seizure disorders occur in about 10 percent of intellectually disabled populations and in one third of those with severe intellectual disability. Neurological abnormalities increase in incidence and severity in direct proportion to the degree of intellectual disability. Disturbances in motor areas are manifested in abnormalities of muscle tone (spasticity or hypotonia), reflexes (hypertreflexia), and involuntary movements (choreathetosis). Less disability may also be associated with clumsiness and poor coordination.

CLINICAL FEATURES

Mild intellectual disability may not be recognized or diagnosed in a child until school challenges the child’s social and communicative skills. Cognitive deficits include poor ability to abstract and egocentric thinking, both of which become more easily evident as a child reaches middle childhood. Children with milder intellectual disabilities may function academically at the high elementary level and may acquire vocational skills sufficient to support themselves in some cases; however, social assimilation may be problematic. Communication deficits, poor self-esteem, and dependence may further contribute to a relative lack of social spontaneity.

Moderate levels of intellectual disability are significantly more likely to be observed at a younger age, since communication skills develop more slowly and social isolation may ensue in the elementary school years. Academic achievement is usually limited to the middle-elementary level. Children with moderate intellectual deficits benefit from individual attention focused on the development of self-help skills. However, these children are aware of their deficits and often feel alienated from their peers and frustrated by their limitations. They continue to require a relatively high level of supervision but can become competent at occupational tasks in supportive settings.

Severe intellectual disability is typically obvious in the preschool years; affected children have minimal speech and impaired motor development. Some language development may occur in the school-age years. By adolescence, if language has not improved significantly, poor, nonverbal forms of communication may have evolved. Behavioral approaches are useful means to promote some self-care, although those with severe intellectual disability generally need extensive supervision.
### Table 31.3-4
Syndromes with Intellectual Disability and Behavioral Phenotypes

<table>
<thead>
<tr>
<th>Disorder</th>
<th>Pathophysiology</th>
<th>Clinical Features and Behavioral Phenotype</th>
</tr>
</thead>
<tbody>
<tr>
<td>Down syndrome</td>
<td>Trisomy 21, 95% nondisjunction, approx. 4% translocation; 1/1,000 live births; 1:2,500 in women less than 30 years old, 1:80 over 40 years old; possible overproduction of β-amyloid due to defect at 21q21.1</td>
<td>Hypotonia, upward-slanted palpebral fissures, midface depression, flat wide nasal bridge, simian crease, short stature, increased incidence of thyroid abnormalities and congenital heart disease. Possible, affable, hyperactivity in childhood, stubborn; verbal &gt; auditory processing, increased risk of depression, and dementia of the Alzheimer type in adulthood.</td>
</tr>
<tr>
<td>Fragile X syndrome</td>
<td>Inactivation of FMR-1 gene at Xq27.3 due to CGG base repeats, methylation; recessive; 1:1,000 male births, 1:3,000 female; accounts for 10–12% of intellectual disability in males</td>
<td>Long face, large ears, midface hypoplasia, high arched palate, short stature, macroorchidism, mitral valve prolapse, joint laxity, strabismus. Hyperactivity, inattention, anxiety, stereotypies, speech and language delays, IQ decline, gaze aversion, social avoidance, shyness, irritability, learning disorder in some females; mild intellectual disability in affected females, moderate to severe in males; verbal IQ &gt; performance IQ.</td>
</tr>
<tr>
<td>Prader-Willi syndrome</td>
<td>Deletion in 15q12 (15q11–15q13) of paternal origin; some cases of maternal uniparental disomy; dominant 1/10,000 live births; 90% sporadic; candidate gene: small nuclear ribonucleoprotein polypeptide (SNRPN)</td>
<td>Hypotonia, failure to thrive in infancy, obesity, small hands and feet microorchidism, cryptorchidism, short stature, almond-shaped eyes, fair hair and light skin, flat face, scoliosis, orthopedic problems, prominent forehead and bitemporal narrowing.</td>
</tr>
<tr>
<td>Angelman syndrome</td>
<td>Deletion in 15q12 (15q11–15q13) of maternal origin; dominant; frequent deletion of γ-amino butyric acid (GABA) B-3 receptor subunit, prevalence unknown but rare, estimated 1/20,000–1/30,000</td>
<td>Fair hair and blue eyes (66%); dysmorphic faces including wide smiling mouth, thin upper lip, and pointed chin; epilepsy (90%) with characteristic EEG; ataxia; small head circumference, 25% microcephalic.</td>
</tr>
<tr>
<td>Cornelia de Lange syndrome</td>
<td>Lack of pregnancy associated plasma protein A (PAPP) linked to chromosome 9q33; similar phenotype associated with trisomy 5p, ring chromosome 3; rare (1/40,000–1/100,000 live births); possible association with 3q26.3</td>
<td>Continuous eyebrows, thin downturned upper lip, microcephaly, short stature, small hands and feet, small upturned nose, antverted nostrils, malformed upper limbs, failure to thrive. Self-injury, limited speech in severe cases, language delays, avoidance of being held, stereotypic movements, twirling, severe to profound intellectual disability.</td>
</tr>
<tr>
<td>Williams syndrome</td>
<td>1/20,000 births; hemizygous deletion that includes elastin locus chromosome 7q11–23; autosomal dominant</td>
<td>Short stature, unusual facial features including broad forehead, depressed nasal bridge, stellate pattern of the iris, widely spaced teeth, and full lips; elfinlike facies; renal and cardiovascular abnormalities; thyroid abnormalities; hypercalcaemia.</td>
</tr>
<tr>
<td>Cri-du-chat syndrome</td>
<td>Partial deletion 5p; 1/50,000; region may be 5p15.2</td>
<td>Anxiety, hyperactivity, fears, outgoing, sociable, verbal skills &gt; visual spatial skills.</td>
</tr>
<tr>
<td>Smith-Magenis syndrome</td>
<td>Incidence unknown, estimated 1/25,000 live births; complete or partial deletion of 17p11.2</td>
<td>Short stature, unusual facial features including broad forehead, depressed nasal bridge, stellate pattern of the iris, widely spaced teeth, and full lips; elfinlike facies; renal and cardiovascular abnormalities; thyroid abnormalities; hypercalcaemia.</td>
</tr>
<tr>
<td>Rubinstein-Taybi syndrome</td>
<td>1/250,000, approx. male = female; sporadic; likely autosomal dominant; documented microdeletions in some cases at 16p13.3</td>
<td>Short stature and microcephaly; broad thumb and big toes, prominent nose, broad nasal bridge, hypertelorism, ptosis, frequent fractures, feeding difficulties in infancy, congenital heart disease, EEG abnormalities, seizures. Poor concentration, distractible, expressive language difficulties, performance IQ &gt; verbal IQ; anecdotally happy, loving, sociable, responsive to music, self-stimulating behavior; older patients have mood lability and temper tantrums.</td>
</tr>

Children with profound intellectual disability require constant supervision and are severely limited in both communication and motor skills. By adulthood, some speech development may be present, and simple self-help skills may be acquired. Clinical features frequently observed in populations with intellectual disability either in isolation or as part of a mental disorder, include hyperactivity, low frustration tolerance, aggression, affective instability, repetitive and stereotypic motor behaviors, and self-injurious behaviors. Self-injurious behaviors occur more frequently and with greater intensity in more severe intellectual disability.

---

Dylan was a full-term infant, the second child born to his 42-year-old mother, a medical technician, and 48-year-old father, a high school basketball coach. The pregnancy was unremarkable, and Dylan’s sister, who was two years older, was healthy and developing normally. The family lived in a rural town in the Midwest. Dylan was an extremely fussy, active newborn with extended periods of crying that the pediatrician labeled classic colic. As a newborn, it was noticed that Dylan seemed to have large ears and strabismus, which the pediatrician said would probably resolve spontaneously. At
positive responses to treatments for his attentional and anxiety symptoms and were pleased with Dylan's recent increased interest in sharing activities with classmates and peers.

**LABORATORY EXAMINATION**

Laboratory tests that may elucidate the causes of intellectual disability include chromosomal analysis, urine and blood testing for metabolic disorders, and neuroimaging. Chromosomal abnormalities are the single most known common cause of intellectual disability.

**Chromosome Studies**

Chromosome analysis is commonly obtained when multiple physical anomalies, developmental delays, and intellectual disability present together. Current techniques are able to chromosomal regions with specific fluorescent in situ hybridization (FISH) markers, leading to microscopic deletions being identified in up to 7% of persons with moderate to severe intellectual disability. A history of growth retardation, the presence of microcephaly, a family history of intellectual disability, short stature, hypertelorism, and other facial abnormalities increase the risk for finding subtelomeric defects.

Amniocentesis, in which a small amount of amniotic fluid is removed from the amniotic cavity transabdominally at about the 15 weeks of gestation, has been useful in diagnosing prenatal chromosomal abnormalities. Its use is considered when an increased fetal risk exists, such as with increased maternal age. Amniotic fluid cells, mostly fetal in origin, are cultured for cytogenetic and biochemical studies.

Chronic villi sampling (CVS) is a screening technique to determine fetal chromosomal abnormalities. It is done at 8 to 10 weeks of gestation, 6 weeks earlier than amniocentesis is done. The results are available in a short time (hours or days) and, if the result is abnormal, the decision to terminate the pregnancy can be made within the first trimester. The procedure has a miscarriage risk between 2 and 5 percent; the risk in amniocentesis is lower (1 in 200). A non-invasive blood test called maternIT21 is a proprietary prenatal test that detects abnormalities of chromosomes 21, 18, 13, X and Y. It is highly specific for Down syndrome (Figure 31.3-1). There is no risk of miscarriage.

**Urine and Blood Analysis**

Lesch-Nyhan syndrome, galactosemia, PKU, Hurler's syndrome (Figure 31.3-2), and Hunter's syndrome (Figure 31.3-3) are examples of disorders characterized by intellectual disability that can be identified through assays of the appropriate enzyme or organic or amino acids. Enzymatic abnormalities in chromosomal disorders, particularly Down syndrome, promise to become useful diagnostic tools.

**Electroencephalography**

Electroencephalography is indicated whenever a seizure disorder is considered. "Nonspecific" EEG changes, characterized by slow frequencies with bursts of spikes and sharp or blunt wave complexes are found with greater frequency among populations
with intellectual disability than in the general population; however, these findings do not elucidate specific diagnoses.

**Neuroimaging**

Neuroimaging studies with populations of intellectually disabled patients using either computerized tomography (CT) or magnetic resonance imaging (MRI) have found high rates of abnormalities in those patients with microcephaly, significant delay, cerebral palsy, and profound disability. Among patients with intellectual disability, neuroimaging is indicated, accompanying findings that suggest seizures, microcephaly or macrocephaly, loss of previously acquired skills, or neurologic signs such as dystonia, spasticity, or altered reflexes.

Although clinically not diagnostic, neuroimaging studies are currently also utilized to gather data that may eventually uncover biological mechanisms contributing to intellectual disability. Structural MRI, functional MRI (fMRI), and diffusion tensor imaging (DTI) are utilized in current research. For example, current data suggest that individuals with fragile X syndrome...
and concurrent attentional deficits are also more likely to show aberrant frontal-striatal pathways on MRI than those patients without attentional problems. MRI is also useful to elucidate myelination patterns. MRI studies can also provide a baseline for comparison of a later, potentially degenerative process in the brain.

Hearing and Speech Evaluations

Hearing and speech should be evaluated routinely. Speech development may be the most reliable criterion in investigating intellectual disability. Various hearing impairments often occur in persons who are intellectually disabled, but in some instances hearing impairments can simulate intellectual disability. The commonly used methods of hearing and speech evaluation, however, require the patient's cooperation and, thus, are often unreliable in severely disabled persons.

COURSE AND PROGNOSIS

Although the underlying intellectual impairment does not improve, in most cases of intellectual disability, level of adaptation increases with age and can be influenced positively by an enriched and supportive environment. In general, persons with mild and moderate mental intellectual disabilities have the most flexibility in adapting to various environmental conditions. Comorbid psychiatric disorders negatively impact overall prognosis. When psychiatric disorders are superimposed on intellectual disability, standard treatments for the comorbid mental disorders are often beneficial; however, less robust responses and increased vulnerability to side effects of psychopharmacologic agents are often the case.

DIFFERENTIAL DIAGNOSIS

By definition, intellectual disability must begin before the age of 18. In some cases, severe child maltreatment in the form of neglect or abuse may contribute to delays in development, which can appear to be intellectual disability. However these damages are partially reversible when a corrective, enriched, and stimulating environment is provided in early childhood. Sensory disabilities, especially deafness and blindness, can be mistaken for intellectual disability when a lack of awareness of the sensory deficit leads to inappropriate testing. Expressive and receptive speech disorders may give the impression of intellectual disability in a child of average intelligence, and cerebral palsy may be mistaken for intellectual disability. Chronic, debilitating medical diseases may depress and delay a child's functioning and achievement, despite normal intelligence. Seizure disorders, especially those that are poorly controlled, may contribute to persisting intellectual disability. Specific organic syndromes leading to isolated handicaps such as failure to read (alexia), failure to write (agraphia), or failure to communicate (aphasia), may occur in a child of normal and superior intelligence. Children with learning disorders (which can coexist with intellectual disability) experience a delay or failure of development in a specific area, such as reading or mathematics, but they develop normally in other areas. In contrast, children with intellectual disability show general delays in most areas of development.

Intellectual disability and autism spectrum disorder (ASD) often coexist; 70 to 75 percent of those with ASD have an IQ below 70. In addition, epidemiologic data indicate that ASD occurs in approximately 19.8% of persons with intellectual disability. Children with ASD have relatively more severe impairment in social relatedness and language than other children with the same level of intellectual disability.

A child younger than the age of 18 years with significant adaptive functional impairment, with an IQ less than 70, who also meets diagnostic criteria for dementia, will receive both a diagnosis of dementia and intellectual disability. However, a child whose IQ drops below 70 after the age of 18 years with newly acquired cognitive impairment will receive only the diagnosis of dementia.

TREATMENT

Interventions for children and adolescents with intellectual disability are based on an assessment of social, educational, psychiatric, and environmental needs. Intellectual disability is associated with a variety of comorbid psychiatric disorders that often require specific treatment, in addition to psychosocial support. Of course, when preventive measures are available, the optimal approach includes primary, secondary, and tertiary interventions.

Primary Prevention

Primary prevention comprises actions taken to eliminate or reduce the conditions that lead to development of intellectual disability, as well as associated disorders. For example, screening babies for PKU, and administrating a low phenylalanine diet when PKU is present, significantly alters the emergence of intellectual disability in those affected children. Additional primary prevention steps include education of the general public about strategies to prevent intellectual disability, such as abstinence from alcohol during pregnancy; continuing efforts of health professionals to ensure and upgrade public health policies; and legislation to provide optimal maternal and child health care. Family and genetic counseling helps reduce the incidence of intellectual disability in a family with a history of a genetic disorder.

Secondary and Tertiary Prevention

Prompt attention to medical and psychiatric complications of intellectual disability can diminish their course (secondary prevention) and minimize the sequelae or consequent disabilities (tertiary prevention). Hereditary metabolic and endocrine disorders, such as PKU and hypothyroidism, can be treated effectively in an early stage by dietary control or hormone replacement therapy.

Educational Interventions. Educational settings for children with intellectual disability should include a comprehensive program that addresses academics and training in adaptive skills, social skills, and vocational skills. Particular attention should focus on communication and efforts to improve the quality of life.
Behavioral and Cognitive-Behavioral Interventions. The difficulties in adaptation among the intellectual disability populations are widespread and so varied that several interventions alone or in combination may be beneficial. Behavior therapy has been used for many years to shape and enhance social behaviors and to control and minimize aggressive and destructive behaviors. Positive reinforcement for desired behaviors and benign punishment (e.g., loss of privileges) for objectionable behaviors has been helpful. Cognitive therapy, such as dispelling false beliefs and relaxation exercises with self-instruction, has also been recommended for intellectually disabled persons who can follow the instructions. Psychodynamic therapy has been used with patients and their families to decrease conflicts about expectations that result in persistent anxiety, rage, and depression. Psychiatric treatment modalities require modifications that take into consideration the patient's level of intelligence.

Family Education. One of the most important areas that a clinician can address is educating the family of a child or adolescent with intellectual disability about ways to enhance competence and self-esteem while maintaining realistic expectations for the patient. The family often finds it difficult to balance the fostering of independence and the providing of a nurturing and supportive environment for an intellectually disabled child, who is likely to experience some rejection and failure outside the family context. The parents may benefit from continuous counseling or family therapy and should be allowed opportunities to express their feelings of guilt, despair, anguish, recurring denial, and anger about their child's disorder and future. The psychiatrist should be prepared to give the parents all the basic and current medical information regarding causes, treatment, and other pertinent areas (e.g., special training and the correction of sensory defects).

Social Intervention. One of the most prevalent problems among persons with intellectual disability is a sense of social isolation and social skills deficits. Thus, improving the quantity and quality of social competence is a critical part of their care. Special Olympics International is the largest recreational sports program geared for this population. In addition to providing a forum to develop physical fitness, Special Olympics also enhances social interactions, friendships, and (it is hoped) general self-esteem. A recent study confirmed positive effects of the Special Olympics on the social competence of the intellectually disabled adults who participated.

Psychopharmacologic Interventions. Pharmacological approaches to the treatment of behavioral and psychological symptoms in children with intellectual disability follow the paradigms of the evidence-based literature on treatment for all children with psychiatric disorders. However, given the paucity of randomized trials in the childhood intellectual disability population, an empirical approach must also be taken.

Common Comorbid Psychiatric Symptoms and Disorders

Aggression, Irritability, and Self-Injurious Behavior. Risperidone has been well documented as an efficacious treatment for irritability (aggression, self-injury, and severe tantrums) in children with ASD by the Research Units on Pediatric Psychopharmacology (RUPP, Autism Network 2002). Risperidone is helpful in treating disruptive behaviors in children with below-average intelligence, and has a good overall safety and tolerability profile. Cognitive testing has demonstrated small but significant improvement in cognitive ability with risperidone use. Children and adolescents with intellectual disability appear to be at higher risk for the development of tardive dyskinesia after use of antipsychotic medications; however, the atypical antipsychotics, including risperidone and clozapine (Clozaril), may provide some relief with a decreased risk of tardive dyskinesia.

There is evidence to support the use of antipsychotic agents in the management of self-injurious behavior (SIB). Although data exist on the efficacy of thioridazine in improving SIB, a “black box” warning regarding QT prolongation with thioridazine has drastically diminished use of this drug, and atypical antipsychotic agents are currently preferred.

Attention-Deficit/Hyperactivity Disorder. Estimates of attention deficit/hyperactivity (ADHD) and ADHD-like symptoms among children with sub average intelligence, genetic disorders, and developmental delay is estimated to be significantly higher than rates in the community. Randomized clinical trials of several psychopharmacologic agents have been done in children with sub-average intelligence. These include trials with methylphenidate, clonidine, and risperidone. The existing data for the treatment of ADHD and ADHD-like symptoms in youth with sub-average intelligence and developmental disorders suggest that agents, particularly stimulants used to treat ADHD in typically developing children, provide some degree of benefit to children with intellectual disability and ADHD. However, the occurrence of side effects within this population appears to be greater than in children with ADHD in the community. Thus, recommendations regarding treatment of ADHD in children and adolescents with comorbid ADHD include close monitoring for side effects. Studies of methylphenidate (Ritalin) treatment in those mildly intellectually disabled with ADHD have shown significant improvement in the ability to maintain attention, and to focus on tasks. Methylphenidate treatment studies have not shown evidence of long-term improvement in social skills or learning. Risperidone also has been found to be beneficial in reducing symptoms of ADHD in this population; however, it may produce an increase in serum prolactin level. It is prudent to begin with a trial of a stimulant medication before the use of antipsychotic agents for the treatment of ADHD symptoms in intellectual disorder. A new extended release methylphenidate oral suspension (Quillivant XR, 2013) is currently available in 25 mg/5 mL preparation, and is taken once daily for the treatment of ADHD in children 6 to 12 years of age.

Amphetamine-based preparations have been shown to be efficacious in treating ADHD in typically developing children; however, it does not appear that these stimulant preparations have been specifically studied in children with intellectual disability. Clonidine has been used clinically in this population, especially to ameliorate hyperactivity and impulsivity. Although there are scant data, clinical ratings by parents and clinicians suggest its efficacy.
Atomoxetine has been shown to be efficacious in children diagnosed with ASD and prominent ADHD features, and it is used clinically in the intellectually disabled population.

**Depressive Disorders.** The identification of depressive disorders among individuals with intellectual disability requires careful evaluation, since it may be inadvertently overlooked when behavioral problems are prominent. There have been anecdotal reports of disinhibition in response to SSRIs (e.g., fluoxetine [Prozac], paroxetine [Paxil], and sertraline [Zoloft]) in intellectually disabled individuals with ASD. Given the relative safety of SSRI antidepressants, a trial is indicated when a depressive disorder is diagnosed in a child or adolescent with intellectual disability.

**Stereotypical Motor Movements.** Antipsychotic medications—historically, haloperidol (Haldol) and chlorpromazine, and currently, the atypical antipsychotics—are used in the treatment of repetitive self-stimulatory behaviors in children with intellectual disability when these behaviors are either harmful to the child or disruptive. Anecdotal reports indicate that these agents may diminish self-stimulatory behaviors; however, there is no improvement seen in adaptive behavior. Obsessive-compulsive symptoms often overlap with the repetitive stereotypical behaviors seen in children and adolescents with intellectual disability, particularly in those with comorbid ASD. SSRIs such as fluoxetine, fluvoxamine (Luvox), paroxetine, and sertraline have been shown to have efficacy in treating obsessive-compulsive symptoms in children and adolescents and may have some efficacy for stereotyped motor movements.

**Explosive Rage Behavior.** Antipsychotic medications, particularly risperidone, have been shown to be efficacious for the treatment of explosive rage. Systematic controlled studies are indicated to confirm the efficacy of these drugs in the treatment of rage outbursts. β-Adrenergic receptor antagonists (beta-blockers), such as propranolol (Inderal), have been reportedly anecdotally to result in fewer explosive rages in some children with intellectual disability and ASD.

**SERVICES AND SUPPORT FOR CHILDREN WITH INTELLECTUAL DISABILITY**

**Early Intervention**

Early intervention programs serve individuals for the first 3 years of life. Such services are generally provided by the state and begin with a specialist visiting the home for several hours per week. Since the passage of Public Law 94–447, the Education of the Handicapped Amendments of 1986, early intervention services for the entire family are emphasized. Agencies are required to develop an Individualized Family Service Plan (IFSP) for each family, which identifies specific interventions to best help the family and child.

**School**

From ages 3 to 21 years, school is responsible by law to provide appropriate educational services to children and adolescents with intellectual disability in the United States. These mandates were created by the passage of Public Law 94–142, the Education for all Handicapped Children Act of 1975, and expanded with the addition of the Individuals with Disabilities Act (IDEA) of 1990. Through these laws, public schools must develop and provide an individualized educational program for each student with intellectual disability, determined at a meeting designated as the Individualized Education Plan (IEP) with school personnel and the family. The education must be provided for the child in the “least restrictive environment” that will allow the child to learn.

**Supports**

A wide variety of organized groups and services are available for children with intellectual disability and their families. These include short-term respite care, which allow families a break and is generally set up by state agencies. Other programs include the Special Olympics, which allows children with intellectual disability to participate in team sports and in sports competitions. Many organizations also exist for families who wish to connect with others who have children with intellectual disability.

31.4 Communication Disorders

Communication disorders range from mild delays in acquiring language to expressive or mixed receptive–expressive disorders, phonological disorders, and stuttering, which may remit spontaneously or persist into adolescence or even adulthood. Language delay is one of the most common very early childhood developmental delays, affecting up to approximately 7 percent of 5-year-olds. The rates of language disorders are understandably higher in preschoolers than in school-age children; rates were reported to be close to 20 percent of 4-year-olds in the Early Language in Victoria Study (ELVS). To communicate effectively, children must have a mastery of multiple aspects of language—that is, the ability to understand and express ideas—using words and speech, and express themselves in vernacular language. In the Fifth Edition of the American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders (DSM-5), Language Disorder includes both expressive and mixed receptive–expressive problems. DSM-5 speech disorders include Speech Sound Disorder (formerly known as Phonological Disorder) and Childhood-Onset Fluency Disorder (Stuttering). Children with expressive language deficits have difficulties expressing their thoughts with words and sentences at a level of sophistication expected for their age and developmental level in other areas. These children may struggle with limited vocabularies, speak in sentences that are short or ungrammatical, and often present descriptions of situations that are disorganized, confusing, and infantile. They may be delayed in developing an understanding and a memory of words compared with others their age. Children with language disorder are at higher risk for developing reading difficulties. Current expert consensus considers reading comprehension impairment a form of language impairment, distinct from other reading deficits such as dyslexia.

Language and speech are pragmatically intertwined, despite the distinct categories of language disorders and speech disorders in DSM-5. Language competence spans four domains: phonology, grammar, semantics, and pragmatics. Phonology refers to the ability to produce sounds that constitute words in a given language and the skills to discriminate the various phonemes (sounds that are made by a letter or group of letters in a language). To imitate words, a child must be able to produce the sounds of a word. Grammar designates the organization of words and the rules for placing words in an order that makes sense in that language. Semantics refers to the organization of concepts and the acquisition of words themselves. A child draws from a mental list of words to produce sentences. Children with language impairments exhibit a wide range of difficulties with semantics that include acquiring new words, storage and organization of known words, and word retrieval. Speech and language evaluations that are sufficiently broad to test all of the preceding skill levels will be more accurate in evaluating a child’s remedial needs. Pragmatics has to do with skill in the actual use of language and the “rules” of conversation, such as pausing so that a listener can answer a question and knowing when to change the topic when a break occurs in a conversation. By age 2 years, toddlers without speech or language delay may know a few words or up to 200 words, and by age 3 years, most children understand the basic rules of language and can converse effectively. Table 31.4a-1 provides an overview of typical milestones in language and nonverbal development.

Over the last decade there have been an increasing number of investigative studies of speech and language interventions with positive outcomes identified in numerous areas of language. These include improvements in expressive vocabulary, syntax usage, and overall phonologic development. Most interventions are targeted strategies for the child’s particular deficit, and delivered by speech and language therapists.

31.4a Language Disorder

Language disorder consists of difficulties in the acquisition and use of language across many modalities, including spoken and written, due to deficits in comprehension or production based on both expressive and receptive skills. These deficits include reduced vocabulary, limited abilities in forming sentences using the rules of grammar, and impairments in conversing based on difficulties using vocabulary to connect sentences in descriptive ways.

EXPRESSIONAL LANGUAGE DEFICITS

Expressive language deficits are present when a child demonstrates a selective deficit in expressive language development relative to receptive language skills and nonverbal intellectual function. Infants and young children with typically developing expressive language will laugh and coo by about 6 months of age, babble and verbalize syllables such as dadada or mamama by about 9 months, and by one year, babies imitate vocalizations and can often speak at least one word. Expressive speech and language generally continue to develop in a stepwise fashion, so that at a year and a half, children typically can say a handful of words, and by 2 years, children generally are combining words into simple sentences. By the age of 2½ years, children can name an action in a picture, and are able to make themselves understood through their verbalizations about half of the time. By 3 years, most children can speak understandably, and are able to name a color and describe what they see with several adjectives. At 4 years, children typically can name at least 4 colors, and can converse understandably. In the early years, prior to entering preschool, the development of proficiency in vocabulary and language usage is highly variable, and influenced by the amount and quality of verbal interactions with family members, and after beginning school, a child’s language skills are significantly influenced by the level of verbal engagement in school. A child with expressive language deficits may be identified using the Wechsler Intelligence Scale for Children III (WISC-III), in that verbal intellectual level may appear to be depressed compared with the child’s overall intelligence quotient (IQ). A child with expressive language problems is likely to function below the expected levels of acquired vocabulary, correct tense usage, complex sentence constructions, and word recall. Children with expressive language deficits often present verbally as younger than their age. Language disability can be

</table>

acquired during childhood (e.g., secondary to a trauma or a neurological disorder), although less frequently, or it can be developmental; it is usually congenital, without an obvious cause. Most childhood language disorders fall into the developmental category. In either case, deficits in receptive skills (language comprehension) or expressive skills (ability to use language) can occur. Expressive language disturbance often appears in the absence of comprehension difficulties, whereas receptive dysfunction generally diminishes proficiency in the expression of language. Children with expressive language disturbance...
alone have better prognoses, and less interference with learning, than children with mixed receptive-expressive language disturbances.

Although language use depends on both expressive and receptive skills, the degree of deficits in a given individual may be severe in one area, and hardly impaired at all in the other. Thus, language disorder can be diagnosed in children with expressive language disturbance in the absence of receptive language problems, or when both receptive and expressive language syndromes are present. In general, when receptive skills are sufficiently impaired to warrant a diagnosis, expressive skills are also impaired. In DSM-5 language disorder is not limited to developmental language disabilities; acquired forms of language disturbances are included. To meet the DSM-5 criteria for language disorder, patients must have scores on standardized measures of expressive or receptive language markedly below those of standardized nonverbal IQ subtests and standardized tests.

Epidemiology

The prevalence of expressive language disturbance decreases with a child’s increasing age, and overall it is estimated to be as high as 6 percent in children between the ages of 5 and 11 years of age. Surveys have indicated rates of expressive language as high as 20 percent in children younger than 4 years of age. In school-age children over the age of 11 years, the estimates are lower, ranging from 3 percent to 5 percent. The disorder is two to three times more common in boys than in girls and is most prevalent among children whose relatives have a family history of phonologic disorder or other communication disorders.

Comorbidity

Children with language disorder have above-average rates of comorbid psychiatric disorders. In one large study of children with speech and language disorders, the most common comorbid disorders were attention-deficit/hyperactivity disorder (ADHD; 19 percent), anxiety disorders (10 percent), oppositional defiant disorder, and conduct disorder (7 percent combined). Children with expressive language disorder are also at higher risk for a speech disorder, receptive difficulties, and other learning disorders. Many disorders—such as reading disorder, developmental coordination disorder, and other communication disorders—are associated with expressive language disturbance. Children with expressive language disturbance often have some receptive impairment, although not always sufficiently significant for the diagnosis of language disorder on this basis. Speech sound disorder, formerly known as phonologic disorder, is commonly found in young children with language disorder, and neurologic abnormalities have been reported in a number of children, including soft neurologic signs, depressed vestibular responses, and electroencephalography (EEG) abnormalities.

Etiology

The specific causes of the expressive components of language disorder are likely to be multifactorial. Scant data are available on the specific brain structure of children with language disorder, but limited magnetic resonance imaging (MRI) studies suggest that language disorders are associated with diminished left–right brain asymmetry in the perisylvian and planum temporale regions. Results of one small MRI study suggested possible inversion of brain asymmetry (right > left). Left-handedness or ambilaterality appears to be associated with expressive language problems with more frequency than right-handedness. Evidence shows that language disorders occur more frequently within some families, and several studies of twins show significant concordance for monozygotic twins with respect to language disorders. Environmental and educational factors are also postulated to contribute to developmental language disorders.

Diagnosis

Language disorder of the expressive disturbance type is diagnosed when a child has a selective deficit in language skills and is functioning well in nonverbal areas. Markedly below-average level verbal or sign language, accompanied by a low score on standardized expressive verbal tests, is diagnostic of expressive deficits in language disorder. Although expressive language deficits are frequently exhibited in children with autism spectrum disorders, these disturbances also occur frequently in the absence of autism spectrum disorder and are characterized by the following features: limited vocabulary, simple grammar, and variable articulation. “Inner language” or the appropriate use of toys and household objects is present. One assessment tool, the Carter Neurocognitive Assessment, itemizes and quantifies skills in areas of social awareness, visual attention, auditory comprehension, and vocal communication even when there are compromised expressive language and motor skills in very young children—up to 2 years of age. To confirm the diagnosis, a child is given standardized expressive language and nonverbal intelligence tests. Observations of children's verbal and sign language patterns in various settings (e.g., school yard, classroom, home, and playground) and during interactions with other children help ascertain the severity and specific areas of a child's impairment and aid in early detection of behavioral and emotional complications. Family history should include the presence or absence of expressive language disorder among relatives.

Clinical Features

Children with expressive language deficits are vague when telling a story and use many filler words such as “stuff” and “things” instead of naming specific objects.

The essential feature of expressive deficits in language disorder is marked impairment in the development of age-appropriate expressive language, which results in the use of verbal or sign language markedly below the expected level in view of a child’s nonverbal intellectual capacity. Language understanding (decoding) skills remain relatively intact. When severe, the disorder becomes recognizable by about the age of 18 months, when a child fails to utter spontaneously or even echo single words or sounds. Even simple words, such as “Mama” and “Dada,” are absent from the child's active vocabulary, and the child points or uses gestures to indicate desires. The child seems to want to communicate, maintains eye contact, relates well to the mother, and enjoys games such as pat-a-cake and peek-a-boo. The child's vocabulary is severely limited. At 18 months,
the child may be limited to pointing to common objects when they are named. When a child with expressive language deficits begins to speak, the language impairment gradually becomes apparent. Articulation is often immature; numerous articulation errors occur but are inconsistent, particularly with such sounds as th, r, s, z, y, and l, which are either omitted or are substituted for other sounds.

By the age of 4 years, most children with expressive language disturbance can speak in short phrases, but may have difficulty retaining new words. After beginning to speak, they acquire language more slowly than do most children. Their use of various grammatical structures is also markedly below the age-expected level, and their developmental milestones may be slightly delayed. Emotional problems involving poor self-image, frustration, and depression may develop in school-age children.

Jessica was a sociable, active 5-year-old, who was diagnosed with language disorder. She was well liked in kindergarten despite her language deficits and played with many of her classmates. During an activity in which each student recounted the story of Little Red Riding Hood to her doll, Jessica’s classmate’s story began: “Little Red Riding Hood was taking a basket of food to her grandmother who was sick. A bad wolf stopped Red Riding Hood in the forest. He tried to get the basket away from her but she wouldn’t give it to him.”

When it was Jessica’s turn, she tried to avoid being picked, but when she could not avoid her turn, Jessica’s story sounded quite different: Jessica struggled and came up with: “Riding Hood going to grandma house. Her taking food. Bad wolf in a bed. Riding Hood say, what big ears, and grandma? Hear you, dear. What big eyes, grandma? See you, dear. What big mouth, grandma? Eat you all up!”

Ramon was a quiet, sullen 8-year-old boy whose expressive language problems had improved over time and were no longer obvious in play with peers. His speech now rarely contained the incomplete sentences and grammatical errors that were so evident when he was younger. Ramon’s expressive problems, however, were still impairing him in tasks involving abstract use of language, and he was struggling in his third-grade academic work. An example was Ramon’s explanation of a recent science experiment: “The teacher had stuff in some jars. He poured it, and it got pink. The other thing made it white.” Although each sentence was grammatical, his explanation was difficult to follow, because key ideas and details were vaguely explained. Ramon also showed problems in word finding, and he relied on vague and nonspecific terms, such as thing, stuff, and got.

In the first and second grades, Ramon had struggled to keep up with his classmates in reading, writing, and other academic skills. By third grade, however, the increasing demands for written work were beyond his abilities. Ramon’s written work was characterized by poor organization and lack of specificity. In addition, classmates began to tease him about his difficulties, and he was ashamed of his disability and reacted quite aggressively, often leading to physical fighting. Nonetheless, Ramon continued to show relatively good comprehension of spoken language, including classroom teaching concerning abstract concepts. He also comprehended sentences that were grammatically and conceptually complex (e.g., “The car the truck hit had hubcaps that were stolen. Had it been possible, she wouldn’t give it to him.”)

Differential Diagnosis

Language disorders are associated with various psychiatric disorders including other learning disorders and ADHD, and in some cases, the language disorder is difficult to separate from another dysfunction. In mixed receptive–expressive language disorder, language comprehension (decoding) is markedly below the expected age-appropriate level, whereas in expressive language disorder, language comprehension remains within normal limits.

In autism spectrum disorders, children often have impaired language, symbolic and imagery play, appropriate use of gesture, or capacity to form typical social relationships. In contrast, children with expressive language disorder become very frustrated with their disorder, and are usually highly motivated to make friends despite their disability.
Children with acquired aphasia or dysphasia have a history of early normal language development; the disordered language had its onset after a head trauma or other neurologic disorder (e.g., a seizure disorder). Children with selective mutism have normal language development. Often these children will speak only in front of family members (e.g., mother, father, and siblings). Children affected by selective mutism are socially anxious and withdrawn outside the family.

Pathology and Laboratory Examination
Children with speech and language disorders should have an audiogram to rule out hearing loss.

Course and Prognosis
The prognosis for expressive language disturbance worsens the longer it persists in a child; prognosis is also dependent on the severity of the disorder. Studies of infants and toddlers who are "late talkers" concur that 50 to 80 percent of these children master language skills that are within the expected level during the preschool years. Most children who are delayed in acquiring language catch up during preschool years. Outcome of expressive language deficits is influenced by other comorbid disorders. If children do not develop mood disorders or disruptive behavior problems, the prognosis is better. The rapidity and extent of recovery depends on the severity of the disorder, the child's motivation to participate in speech and language therapy, and the timely initiation of therapeutic interventions. The presence or absence of hearing loss, or intellectual disability, impedes remediation and leads to a worse prognosis. Up to 50 percent of children with mild expressive language disorder recover spontaneously without any sign of language impairment, but those children with severe expressive speech disorder may persist in exhibiting some symptoms into middle childhood or later.

Current literature shows that children who demonstrate poor comprehension, poor articulation, or poor academic performance tend to continue to have problems in these areas at follow-up 7 years later. An association is also seen between particular language impairment profiles and persistent mood and behavior problems. Children with poor comprehension associated with expressive difficulties seem to be more socially isolated and impaired with respect to peer relationships.

Treatment
The primary goals for early childhood speech and language treatment are to guide children and their parents toward greater production of meaningful language. There are more data to support improvements through speech and language interventions for expressive language deficit in young school-aged children with primary deficits than in preschool children. A recent study investigating Parent-Child Interaction Therapy (PCIT) for school-aged children with expressive language impairment found that PCIT was particularly efficacious in improving a child's verbal initiation, mean length of utterances, and the proportion of child-to-parent utterances. A large-scale randomized trial of a yearlong intervention targeting preschoolers with language delay in Australia found that a community-based program did not affect language acquisition in 2- and 3-year-olds. Given the high rate of spontaneous remission of language deficits in preschoolers, and less than robust effects of interventions for children that young, treatment for expressive language disorder is generally not initiated unless it persists after the preschool years. Various techniques have been used to help a child improve use of such parts of speech as pronouns, correct tenses, and question forms. Direct interventions use a speech and language pathologist who works directly with the child. Mediated interventions, in which a speech and language professional teaches a child's teacher or parent how to promote therapeutic language techniques, have also been efficacious. Language therapy is often aimed at using words to improve communication strategies and social interactions as well. Such therapy consists of behaviorally reinforced exercises and practice with phonemes (sound units), vocabulary, and sentence construction. The goal is to increase the number of phrases by using block-building methods and conventional speech therapies.

MIXED RECEPTIVE AND EXPRESSIVE DEFICITS
Children with both receptive and expressive language impairment may have impaired ability in sound discrimination, deficits in auditory processing, or poor memory for sound sequences. Children with mixed receptive–expressive disturbance exhibit impaired skills in the expression and reception (understanding and comprehension) of spoken language. The expressive difficulties in these children may be similar to those of children with only expressive language disturbance, which is characterized by limited vocabulary, use of simplistic sentences, and short sentence usage. Children with receptive language difficulties may be experiencing additional deficits in basic auditory processing skills, such as discriminating between sounds, rapid sound changes, association of sounds and symbols, and the memory of sound sequences. These deficits may lead to a whole host of communication barriers for a child, including a lack of understanding of questions or directives from others, or inability to follow the conversations of peers or family members. Recognition of mixed expressive–receptive language disturbance may be delayed because of early misattribution of their communication by teachers and parents as a behavioral problem rather than a deficit in understanding.

The essential features of mixed receptive–expressive language disturbance are shown on scores on standardized tests; both receptive (comprehension) and expressive language development scores fall substantially below those obtained from standardized measures of nonverbal intellectual capacity. Language difficulties must be sufficiently severe to impair academic achievement or daily social communication.

Epidemiology
Mixed receptive–expressive language deficits occur less frequently than expressive deficits; however, epidemiologic data are scant regarding specific prevalence rates. Mixed receptive–expressive language disturbance is believed to occur in about 5 percent of preschoolers and to persist in approximately 3 percent of school-age children. It is known to be less common than expressive language disturbance. Mixed receptive–expressive language disorder is believed to be at least twice as prevalent in boys as in girls.
Comorbidity

Children with mixed receptive–expressive deficits are at high risk for additional speech and language disorders, learning disorders, and additional psychiatric disorders. About half of children with these deficits also have pronunciation difficulties leading to speech sound disorder, and about half also have reading disorder. These rates are significantly higher than the comorbidity found in children with only expressive language problems. ADHD is present in at least one third of children with mixed receptive–expressive language disturbances.

Etiology

Language disorders most likely have multiple determinants, including genetic factors, developmental brain abnormalities, environmental influences, neurodevelopmental immaturity, and auditory processing features in the brain. As with expressive language disturbance alone, evidence is found of familial aggregation of mixed receptive–expressive language deficits. Genetic contribution to this disorder is implicated by twin studies, but no mode of genetic transmission has been proved. Some studies of children with various speech and language disorders have also shown cognitive deficits, particularly slower processing of tasks involving naming objects, as well as fine motor tasks. Slower myelination of neural pathways has been hypothesized to account for the slow processing found in children with developmental language disorders. Several studies suggest an underlying impairment of auditory discrimination, because most children with the disorder are more responsive to environmental sounds than to speech sounds.

Diagnosis

Children with mixed receptive–expressive language deficits develop language more slowly than their peers and have trouble understanding conversations that peers can follow. In mixed receptive–expressive language disorder, receptive dysfunction coexists with expressive dysfunction. Therefore, standardized tests for both receptive and expressive language abilities must be given to anyone suspected of having language disorder with mixed receptive–expressive disturbance.

A markedly below-expected level of comprehension of verbal or sign language with intact age-appropriate nonverbal intellectual capacity, confirmation of language difficulties by standardized receptive language tests, and the absence of autism spectrum disorder, confirm the diagnosis of mixed receptive–expressive language deficits; however, in DSM-5, these deficits are included in the diagnosis of language disorder.

Clinical Features

The essential clinical feature of this language disturbance is significant impairment in both language comprehension and language expression. In the mixed type, expressive impairments are similar to those of expressive language disturbance, but can be more severe. The clinical features of the receptive component of the disorder typically appear before the age of 4 years. Severe forms are apparent by the age of 2 years; mild forms may not become evident until age 7 (second grade) or older, when language becomes complex. Children with language disorder characterized by mixed receptive–expressive disturbance show markedly delayed and below-normal ability to comprehend (decode) verbal or sign language, although they have age-appropriate nonverbal intellectual capacity. In most cases of receptive dysfunction, verbal or sign expression (encoding) of language is also impaired. The clinical features of mixed receptive–expressive language disturbance in children between the ages of 18 and 24 months result from a child’s failure to utter a single phoneme spontaneously or to mimic another person’s words.

Many children with mixed receptive–expressive language deficits have auditory sensory difficulties and compromised ability to process visual symbols, such as explaining the meaning of a picture. They have deficits in integrating both auditory and visual symbols—for example, recognizing the basic common attributes of a toy truck and a toy passenger car. Whereas at 18 months, a child with expressive language deficits only comprehends simple commands and can point to familiar household objects when told to do so, a child of the same age with mixed receptive–expressive language disturbance typically cannot either point to common objects or obey simple commands. A child with mixed receptive–expressive language deficits may appear to be deaf. He or she responds normally to sounds from the environment, but not to spoken language. If the child later starts to speak, the speech contains numerous articulation errors, such as omissions, distortions, and substitutions of phonemes. Language acquisition is much slower for children with mixed receptive–expressive language disturbance than for other children of the same age.

Children with mixed receptive–expressive language disturbance have difficulty recalling early visual and auditory memories and recognizing and reproducing symbols in proper sequence. Some children with mixed receptive–expressive language deficits have a partial hearing defect for true tones, an increased threshold of auditory arousal, and an inability to localize sound sources. Seizure disorders and reading disorder are more common among the relatives of children with mixed receptive–expressive problems than in the general population.

Pathology and Laboratory Examination

An audiogram is indicated for all children thought to have mixed receptive–expressive language disturbance to rule out or confirm the presence of deafness or auditory deficits. A history of the child and family and observation of the child in various settings help to clarify the diagnosis.

Jenna was a pleasant 2-year-old, who did not yet use any spoken words, and did not respond to simple commands without gestures. She made her needs known with vocalizations and simple gestures (e.g., showing or pointing) such as those typically used by younger children. She seemed to understand the names for only a few familiar people and objects (e.g., mommy, daddy, cat, bottle, and cookie). Compared with other children her age, she had a small comprehension vocabulary and showed limited understanding of simple verbal directions (e.g., “Get your doll.” “Close your eyes.”). Nonetheless, her hearing was normal, and her motor and play skills were developing as expected for her age. She showed interest in her environment and in the activities of the other children at her day care.
Lena was a shy, reserved 5-year-old who grew up in a bilingual home. Lena's parents and older siblings spoke English and Cantonese proficiently. Her grandparents, who lived in the same home, spoke only Cantonese. Lena began to understand and speak both languages much later than her older siblings had. Throughout her preschool years, Lena continued to develop slowly in comprehension and production. At the start of kindergarten, Lena understood fewer English words for objects, actions, and relations than her classmates did. Lena was unable to follow complex classroom instructions, particularly those that involved words for concepts of time (e.g., tomorrow, before, or day) and space (e.g., behind, next to, or under). It was also hard for Lena to match one of several pictures to a syntactically complex sentence that she had heard (e.g., "It was not the train she was waiting for.” "Because he had already completed his work, he was not kept after school.”). Lena played with other children but only rarely tried to speak with them, which led to her being ostracized by her classmates. Lena's attempts at conversations usually broke down, because she misinterpreted what others said or could not express her own thoughts clearly. Consequently, her classmates generally ignored her, preferring instead to play with more verbally competent peers. Lena's infrequent interactions further limited her opportunities to learn and to practice her already weak language skills. Lena also showed limited receptive and expressive skills in Cantonese, as revealed by an assessment conducted with the assistance of a Cantonese interpreter. Nonetheless, her nonverbal cognitive and motor skills were within the normal range for her age. Lena was quite proficient in solving spatial and numerical problems, provided they were presented on paper and were not word problems.

Mark received a diagnosis of Language Disorder, based on mixed receptive-expressive deficits when he was a preschooler. By 7 years of age, he had also received the comorbid diagnoses of reading disorder and ADHD. This combination of language, reading, and attention problems made it virtually impossible for Mark to succeed in school, although he was able to engage his peers during free play. His comprehension and attention difficulties limited his ability to understand and to learn important information, or to follow classroom instructions or discussions. Mark fell further and further behind his classmates. He was also disadvantaged because he could read only a few familiar words. This meant that he was neither motivated nor able to learn academic information outside of the classroom by reading. Mark received tutoring and speech and language interventions, and despite some improvements, he continued to lag behind his classmates academically. Despite his academic problems, however, Mark made friends during sports activities in which he excelled, and continued to show nonverbal intellectual skills within the average range.

### Differential Diagnosis

Children with language disorder characterized by mixed receptive-expressive deficits have a deficit in language comprehension as well as in language production. The receptive deficit may be overlooked at first, because the expressive language deficit may be more obvious. In expressive language disturbance alone, comprehension of spoken language (decoding) remains within age norms. Children with speech sound disorder and child-onset fluency disorder (stuttering) have normal expressive and receptive language competence, despite the speech impairments.

Most children with mixed receptive-expressive language disturbance have a history of variable and inconsistent responses to sounds; they respond more often to environmental sounds than to speech sounds (Table 31.4a-2). Intellectual disability,
selective mutism, acquired aphasia, and autism spectrum disorder should also be ruled out.

Course and Prognosis

The overall prognosis for language disorder with mixed receptive–expressive disturbance is less favorable than that for expressive language disturbance alone. When the mixed disorder is identified in a young child, it is usually severe, and the short-term prognosis is poor. Language develops at a rapid rate in early childhood, and young children with the disorder may appear to be falling behind. In view of the likelihood of comorbid learning disorders and other mental disorders, the prognosis is guarded. Young children with severe mixed receptive-expressive language deficits are likely to have learning disorders in the future. In children with mild versions, mixed disorder may not be identified for several years, and the disruption in everyday life may be less overwhelming than that in severe forms of the disorder. Over the long run, some children with mixed receptive–expressive language disturbance achieve close to normal language functions. The prognosis for children who have mixed receptive–expressive language disturbances varies widely and depends on the nature and severity of the damage.

Treatment

A comprehensive speech and language evaluation is recommended for children with mixed receptive–expressive language disturbance, given the complexities of having both deficits. Some controversy exists as to whether remediation of receptive deficits before expressive language provides more efficacy overall. A review of the literature indicates that it is not more beneficial to address receptive deficits before expressive, and in fact, in some cases, remediation of expressive language may reduce or eliminate the need for receptive language remediation. Thus, current recommendations are either to address both simultaneously, or to provide interventions for the expressive component first, and then address the receptive language. Preschoolers with mixed receptive–expressive language problems optimally receive interventions designed to promote social communication and literacy as well as oral language. For children at the kindergarten level, optimal intervention includes direct teaching of key pre-reading skills as well as social skills training. An important early goal of interventions for young children with mixed receptive–expressive language disturbance is the achievement of rudimentary reading skills, in that these skills are protective against the academic and psychosocial ramifications of falling behind early on in reading. Some language therapists favor a low-stimuli setting, in which children are given individual linguistic instruction. Others recommend that speech and language instruction be integrated into a varied setting with several children who are taught several language structures simultaneously. Often, a child with receptive and expressive language deficits will benefit from a small, special-educational setting that allows more individualized learning.

Psychotherapy may be helpful for children with mixed language disorder who have associated emotional and behavioral problems. Particular attention should be paid to evaluating the child’s self-image and social skills. Family counseling in which parents and children can develop more effective, less frustrating means of communicating may be beneficial.

31.4b Speech Sound Disorder

Children with speech sound disorder have difficulty pronouncing speech sounds correctly due to omissions of sounds, distortions of sounds, or atypical pronunciation. Formerly called phonological disorder, typical speech disturbances in speech sound disorder include omitting the last sounds of the word (e.g., saying mou for mouse or drin for drink), or substituting one sound for another (saying bwu instead of blue or tup for cup). Distortions in sounds can occur when children allow too much air to escape from the side of their mouths while saying sounds like sh or producing sounds like s or z with their tongue protruded. Speech sound errors can also occur in patterns because a child has an interrupted airflow instead of a steady airflow preventing their words to be pronounced (e.g., pat for pass or vacuum for vacuum). Children with a speech sound disorder can be mistaken for younger children because of their difficulties in producing speech sounds correctly. The diagnosis of a speech sound disorder is made by comparing the skills of a given child with the expected skill level of others of the same age. The disorder results in errors in whole words because of incorrect pronunciation of consonants, substitution of one sound for another, omission of entire phonemes, and, in some cases, dysarthria (slurred speech because of incoordination of speech muscles) or dyspraxia (difficulty planning and executing speech). Speech sound development is believed to be based on both linguistic and motor development that must be integrated to produce sounds.

Speech sound disturbances such as dysarthria and dyspraxia are not diagnosed as speech sound disorder if they are known to have a neurological basis, according to DSM-5. Thus, speech sound abnormalities accounted for by cerebral palsy, cleft palate, deafness or hearing loss, traumatic brain injury, or neurological conditions are not diagnosed as speech sound disorder. Articulation difficulties not associated with a neurological condition are the most common components of speech sound disorder in children. Articulation deficits are characterized by poor articulation, sound substitution, and speech sound omission, and give the impression of “baby talk.” Typically, these deficits are not caused by anatomical, structural, physiological, auditory, or neurological abnormalities. They vary from mild to severe and result in speech that ranges from completely intelligible to unintelligible.

Epidemiology

Epidemiologic studies suggest that the prevalence of speech sound disorder is at least 3 percent in preschoolers, 2 percent in children 6 to 7 years of age, and 0.5 percent in 17-year-old adolescents. Approximately 7 to 8 percent of 5-year-old children in one large community sample had speech sound production problems of developmental, structural, or neurological origins. Another study found that up to 7.5 percent of children between the ages of 7 and 11 years had speech sound disorders. Of those, 2.5 percent had speech delay (deletion and substitution errors past the age of 4 years) and 5 percent had residual articulation errors beyond the age of 8 years. Speech
sound disorders occur much more frequently than disorders with known structural or neurological origin. Speech sound disorder is approximately two to three times more common in boys than in girls. It is also more common among first-degree relatives of patients with the disorder than in the general population. Although speech sound mistakes are quite common in children younger than 3 years of age, these mistakes are usually self-corrected by age 7 years. Misarticulating after the age of 7 years is likely to represent a speech sound disorder. The prevalence of speech sound disorders reportedly falls to 0.5 percent by mid to late adolescence.

**COMORBIDITY**

More than half of children with speech sound disorder have some difficulty with language. Disorders most commonly present with speech sound disorders are language disorder, reading disorder, and developmental coordination disorder. Enuresis may also accompany the disorder. A delay in reaching speech milestones (e.g., first word and first sentence) has been reported in some children with speech sound, but most children with the disorder begin speaking at the appropriate age. Children with both speech sound and language disorders are at greatest risk for attentional problems and specific learning disorders. Children with speech sound disorder in the absence of language disorder have lower risk of comorbid psychiatric disorders and behavioral problems.

**ETIOLOGY**

Contributing factors leading to speech disturbance may include perinatal problems, genetic factors, and auditory processing problems. Given the high rates of spontaneous remission in very young children, a maturational delay in the developmental brain process underlying speech has been postulated in some cases. The likelihood of neuronal cause is supported by the observation that children with speech sound disorder are also more likely to manifest “soft neurological signs” as well as language disorder and a higher-than-expected rate of reading disorder. Genetic factors are implicated by data from twin studies that show concordance rates for monozygotic twins that are higher than chance.

Articulation disorders caused by structural or mechanical problems are rare. Articulation problems that are not diagnosed as speech sound disorder may be caused by neurological impairment and can be divided into dysarthria and apraxia or dyspraxia. Dysarthria results from an impairment in the neural mechanisms regulating the muscular control of speech. This can occur in congenital conditions, such as cerebral palsy, muscular dystrophy, or head injury, or because of infectious processes. Apraxia or dyspraxia is characterized by difficulty in the execution of speech, even when no obvious paralysis or weakness of the muscles used in speech exists.

Environmental factors may play a role in speech sound disorder, but constitutional factors seem to make the most significant contribution. The high proportion of speech sound disorder in certain families implies a genetic component in the development of this disorder. Developmental coordination disorder and coordination in the mouth such as in chewing and blowing the nose may be associated.

**DIAGNOSIS**

The essential feature of speech sound disorder is a child’s delay or failure to produce developmentally expected speech sounds, especially consonants, resulting in sound omissions, substitutions, and distortions of phonemes. A rough guideline for clinical assessment of children's articulation is that normal 3-year-olds correctly articulate m, n, ng, b, p, h, t, k, q, and d; normal 4-year-olds correctly articulate f, y, ch, sh, and z; and normal 5-year-olds correctly articulate th, s, and r.

Speech sound disorder cannot be accounted for by structural or neurological abnormalities, and typically, it is accompanied by normal language development.

**CLINICAL FEATURES**

Children with speech sound disorder are delayed in, or incapable of, producing accurate speech sounds that are expected for their age, intelligence, and dialect. The sounds are often substitutions—for example, the use of /r/ instead of /k/—and omissions, such as leaving off the final consonants of words. Speech sound disorder can be recognized in early childhood. In severe cases, the disorder is first recognized at between 2 and 3 years of age. In less severe cases, the disorder may not be apparent until the age of 6 years. A child’s articulation is judged disordered when it is significantly behind that of most children at the same age level, intellectual level, and educational level.

In very mild cases, a single speech sound (i.e., phoneme) may be affected. When a single phoneme is affected, it is usually one that is acquired late in normal language acquisition. The speech sounds most frequently misarticulated are also those acquired late in the developmental sequence, including /r/, /sh/, /th/, /f/, /z/, /l/, and /ch/. In severe cases and in young children, sounds such as /b/, /m/, /t/, /d/, /n/, and /h/ may be mispronounced. One or many speech sounds may be affected, but vowel sounds are not among them.

Children with speech sound disorder cannot articulate certain phonemes correctly and may distort, substitute, or even omit the affected phonemes. With omissions, the phonemes are absent entirely—for example, /bu/ for /blue/, /ca/ for /car/, or what? For what’s that? With substitutions, difficult phonemes are replaced with incorrect ones—for example, /wabbit/ for /rabbit/, /fum/ for /thumb/, or /whath dat/? For what’s that? With distortions, the correct phoneme is approximated but is articulated incorrectly. Rarely, additions (usually of the vowel uh) occur—for example, /puhretty/ for /pretty/, what’s uh that uh? For what’s that?

Omissions are thought to be the most serious type of misarticulating, with substitutions the next most serious, and distortions the least serious type. Omissions, which are most frequent in the speech of young children, usually occur at the ends of words or in clusters of consonants (ka for car, sciss for scissors). Distortions, which are found mainly in the speech of older children, result in a sound that is not part of the speaker’s dialect. Distortions may be the last type of misarticulating remaining in the speech of children whose articulation problems have mostly remitted. The most common types of distortions are the lateral slip—in which a child pronounces /s/ sounds with the airstream going across the tongue, producing a whistling effect—and the palatal or lip—in which the /s/ sound, formed with the tongue too close to the palate, produces a /sh/ sound effect.
The misarticulating of children with speech sound disorder is often inconsistent and random. A phoneme may be pronounced correctly one time and incorrectly another time. Misarticulating is most common at the ends of words, in long and syntactically complex sentences, and during rapid speech.

Omissions, distortions, and substitutions also occur normally in the speech of young children learning to talk. But, whereas young, normally speaking children soon replace their misarticulations, children with speech sound disorder do not. Even as children with articulation problems grow and finally acquire the correct phoneme, they may use it only in newly acquired words and may not correct the words learned earlier that they have been mispronouncing for some time.

Most children eventually outgrow speech sound disorder, usually by the third grade. After the fourth grade, however, spontaneous recovery is unlikely, and so it is important to try to remediate the disorder before the development of complications. Often, beginning kindergarten or school precipitates the improvement when recovery from speech sound disorder is spontaneous. Speech therapy is clearly indicated for children who have not shown spontaneous improvement by the third or fourth grade. Speech therapy should be initiated at an early age for children whose articulation is significantly unintelligible and who are clearly troubled by their inability to speak clearly.

Children with speech sound disorder may have various concomitant social, emotional, and behavioral problems, particularly when comorbid expressive language problems are present. Children with chronic expressive language deficits and severe articulation impairment are the ones most likely to suffer from psychiatric problems.

Martin was a talkative, likeable 3-year-old with virtually unintelligible speech, despite excellent receptive language skills and normal hearing. Martin’s level of expressive language development was difficult to quantify due to his very poor pronunciation. The rhythm and melody of his speech, however, suggested that he was trying to produce multivowel utterances, as would be expected at his age. Martin produced only a few vowels (/e/, /a/, and /o/u), some early developing consonants (/m/, /n/, /d/, /t/, /p/, /b/, /n/, and /w/), and limited syllables. This reduced sound repertoire made many of his spoken words indistinguishable from one another (e.g., he said bahbah for bottle, baby, and bubble, and he used nee for knee, need, and Anita [his sister]). Moreover, he consistently omitted consonant sounds at the end of words and in consonant cluster sequences (e.g., /tr-/ /st-/ /m/, and /mp/). Understandably, on occasion Martin reacted with frustration and tantrums to his difficulties in making his needs understood.

Brad was a pleasant, cooperative 5-year-old, who was recognized as early as preschool to have articulation problems, and these persisted into kindergarten. His language comprehension skills, and hearing were within normal limits. He showed some mild expressive language problems, however, in the use of certain grammatical features (e.g., pronouns, auxiliary verbs, and past-tense word endings) and in the formulation of complex sentences. He correctly produced all vowel sounds and most of the early developing consonants, but he was inconsistent in his attempts to produce later-developing consonants (e.g., /r/, /l/, /s/, /z/, /sh/, /th/, and /ch/).

Sometimes, he omitted them; sometimes, he substituted other sounds for them (e.g., /w/ for /r/ or /f/ for /th/); occasionally, he even produced them correctly. Brad had particular problems in correctly producing consonant cluster sequences and multisyllabic words. Cluster sequences had omitted or incorrect sounds (e.g., blue might be produced as bu or bwe, and hearts might be said as kots or hars). Multisyllabic words had syllables omitted (e.g., efant for elephant and getti for spaghetti) and sounds mispronounced or even transposed (e.g., animal for animal and lemon for melon). Strangers were unable to understand approximately 80 percent of Brad’s speech. Brad often spoke more slowly and clearly than usual, however, when he was asked to repeat something, as he often was.

Jane was a hyperactive 8-year-old, with a history of significant speech delay. During her preschool and early school years, she had overcome many of her earlier speech errors. A few late-developing sounds (/r/, /l/, and /th/), however, continued to pose a challenge for her. Jane often substituted /f/ or /d/ for /th/ and produced /w/ for /r/ and /l/. Overall, her speech was easily understood, despite these minor errors. Nonetheless, she became somewhat aggressive with her peers because of the teasing she received from her classmates about her speech.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of speech sound disorder includes a careful determination of symptoms, severity, and possible medical conditions that might be producing the symptoms. First, the clinician must determine that the misarticulating is sufficiently severe to be considered impairing, rather than a normative developmental process of learning to speak. Second, the clinician must determine that no physical abnormalities account for the articulation errors and must rule out neurological disorders that may cause dysarthria, hearing impairment, mental retardation, and pervasive developmental disorders. Third, the clinician must obtain an evaluation of receptive and expressive language to determine that the speech difficulty is not solely attributable to the above mentioned disorders.

Neurological, oral structural, and audiometric examinations may be necessary to rule out physical factors that cause certain types of articulation abnormalities. Children with dysarthria, a disorder caused by structural or neurological abnormalities, differ from children with speech sound disorder in that dysarthria is less likely to remit spontaneously and may be more difficult to remediate. Drooling, slow, or uncoordinated motor behavior; abnormal chewing or swallowing; and awkward or slow protrusion and retraction of the tongue indicate dysarthria. A slow rate of speech also indicates dysarthria (Table 31.4b-1).

 COURSE AND PROGNOSIS

Spontaneous remission of symptoms is common in children whose misarticulating involves only a few phonemes. Children who persist in exhibiting articulation problems after the age of 5 years may be experiencing a myriad of other speech and language impairments, so that a comprehensive evaluation may be indicated at that time. Children older than age 5 with
artificial problems are at higher risk for auditory perceptual problems. Spontaneous recovery is rare after the age of 8 years. Some debate exists regarding the relationship between articulation problems and reading disorder, or dyslexia. A recent study comparing children with phonological problems only, with children who had dyslexia only, and those with both phonological difficulties and dyslexia concluded that children with both disorders have somewhat distinct profiles and are comorbid disorders rather than one mixed disorder.

**TREATMENT**

Two main approaches have been used successfully to improve speech sound difficulties. The first one, the phonological approach, is usually chosen for children with extensive patterns of multiple speech sound errors that may include final consonant deletion, or consonant cluster reduction. Exercises in this approach to treatment focus on guided practice of specific sounds, such as final consonants, and when that skill is mastered, practice is extended to use in meaningful words and sentences. The other approach, the traditional approach is utilized for children who produce substitution or distortion errors in just a few sounds. In this approach, the child practices the production of the problem sound while the clinician provides immediate feedback and cues concerning the correct placement of the tongue and mouth for improved articulation. Children who have errors in articulation because of abnormal swallowing resulting in tongue thrust and lips are treated with exercises that improve swallowing patterns and, in turn, improve speech. Speech therapy is typically provided by a speech-language pathologist, yet parents can be taught to provide adjunctive help by practicing techniques used in the treatment. Early intervention can be helpful, because for many children with mild articulation difficulties, even several months of intervention may be helpful in early elementary school. In general, when a child’s articulation and intelligibility is noticeably different than peers by 8 years of age, speech deficits often lead to problems with peers, learning, and self-image, especially when the disorder is so severe that many consonants are misarticulated, and when errors involve omissions and substitutions of phonemes, rather than distortions.

Children with persistent articulation problems are likely to be teased or ostracized by peers and may become isolated and demoralized. Therefore, it is important to give support to children with phonological disorders and, whenever possible, to support prosocial activities and social interactions with peers. Parental counseling and monitoring of child-peer relationships and school behavior can help minimize social impairment in children with speech sound and language disorder.

### 31.4c Child-Onset Fluency Disorder (Stuttering)

Child-onset fluency disorder (stuttering) usually begins during the first years of life and is characterized by disruptions in the normal flow of speech by involuntary speech motor events. Stuttering can include a variety of specific disruptions of fluency, including sound or syllable repetitions, sound prolongations, dysrhythmic phonations, and complete blocking or unusual pauses between sounds and syllables of words. In severe cases, the stuttering may be accompanied by accessory or secondary attempts to compensate such as respiratory, abnormal voice phonations, or tongue clicks. Associated behaviors, such as eye
blinks, facial grimacing, head jerks, and abnormal body movements, may be observed before or during the disrupted speech. Early intervention is important because children who receive early intervention have been found to be more than 7 times more likely to have full resolution of their stuttering. In severe and some untreated cases, stuttering can become an entrenched pattern that is more challenging to remediate later in life and is associated with significant psychological and social distress. When stuttering becomes chronic, persisting into adulthood, the rates of concurrent social anxiety disorder are reported to be between 40 and 60 percent.

**Epidemiology**

An epidemiologic survey of 3- to 17-year-olds derived from the United States National Health Interview Surveys reports that the prevalence of stuttering is approximately 1.6 percent. Stuttering tends to be most common in young children and has often resolved spontaneously by the time the child is older. The typical age of onset is 2 to 7 years of age, with 90 percent of children exhibiting symptoms by age 7 years. Approximately 65 to 80 percent of young children who stutter are likely to have a spontaneous remission over time. According to the DSM-5, the rate dips to 0.8 percent by adolescence. Stuttering affects about three to four males for every one female. The disorder is significantly more common among family members of affected children than in the general population. Reports suggest that for male persons who stutter, 20 percent of their male children and 10 percent of their female children will also stutter.

**Comorbidity**

Very young children who stutter typically show some delay in the development of language and articulation without additional disorders of speech and language. Preschoolers and school-age children who stutter exhibit an increased incidence of social anxiety, school refusal, and other anxiety symptoms. Older children who stutter also do not necessarily have comorbid speech and language disorders, but often manifest anxiety symptoms and disorders. When stuttering persists into adolescence, social isolation occurs at higher rates than in the general adolescent population. Stuttering is also associated with a variety of abnormal motor movements, upper body tics, and facial grimaces. Other disorders that coexist with stuttering include phonological disorder, expressive language disorder, mixed receptive-expressive language disorder, and ADHD.

**Etiology**

Converging evidence indicates that cause of stuttering is multifactorial, including genetic, neurophysiological, and psychological factors that predispose a child to have poor speech fluency. Although research evidence does not indicate that anxiety or conflicts cause stuttering or that persons who stutter have more psychiatric disturbances than those with other forms of speech and language disorders, stuttering can be exacerbated by certain stressful situations.

Other theories about the cause of stuttering include organic models and learning models. Organic models include those that focus on incomplete lateralization or abnormal cerebral dominance. Several studies using EEG found that stuttering males had right hemispheric alpha suppression across stimulus words and tasks; nonstutterers had left hemispheric suppression. Some studies of stutters have noted an overrepresentation of left-handedness and ambidexterity. Twin studies and striking gender differences in stuttering indicate that stuttering has some genetic basis.

Learning theories about the cause of stuttering include the semantogenic theory, in which stuttering is basically a learned response to normative early childhood disfluencies. Another learning model focuses on classic conditioning, in which the stuttering becomes conditioned to environmental factors. In the cybernetic model, speech is viewed as a process that depends on appropriate feedback for regulation; stuttering is hypothesized to occur because of a breakdown in the feedback loop. The observations that stuttering is reduced by white noise and that delayed auditory feedback produces stuttering in normal speakers lend support to the feedback theory.

The motor functioning of some children who stutter appears to be delayed or slightly abnormal. The observation of difficulties in speech planning exhibited by some children who stutter suggests that higher-level cognitive dysfunction may contribute to stuttering. Although children who stutter do not routinely exhibit other speech and language disorders, family members of these children often exhibit an increased incidence of a variety of speech and language disorders. Stuttering is most likely to be caused by a set of interacting variables that include both genetic and environmental factors.

**Diagnosis**

The diagnosis of childhood-onset fluency disorder (stuttering) is not difficult when the clinical features are apparent and well developed and each of the following four phases (described in the next section) are readily recognized. Diagnostic difficulties can arise when evaluating for stuttering in young children, because some preschool children experience transient dysfluency. It may not be clear whether the nonfluential pattern is part of normal speech and language development or whether it represents the initial stage in the development of stuttering. If incipient stuttering is suspected, referral to a speech pathologist is indicated.

**Clinical Features**

Stuttering usually appears between the ages of 18 months and 9 years, with two sharp peaks of onset between the ages of 2 to 3.5 years and 5 to 7 years. Some, but not all, stutters have other speech and language problems, such as phonological disorder and expressive language disorder. Stuttering does not begin suddenly; it typically develops over weeks or months with a repetition of initial consonants, whole words that are usually the first words of a phrase, or long words. As the disorder progresses, the repetitions become more frequent, with consistent stuttering on the most important words or phrases. Even after it develops, stuttering may be absent during oral readings, singing, and talking to pets or inanimate objects.

Four gradually evolving phases in the development of stuttering have been identified:

- **Phase 1** occurs during the preschool period. Initially, the difficulty tends to be episodic and appears for weeks or months between long interludes of normal speech. A high percentage of recovery from these periods of stuttering occurs.
During this phase, children stutter most often when excited or upset, when they seem to have a great deal to say, and under other conditions of communicative pressure.

- **Phase 2** usually occurs in the elementary school years. The disorder is chronic, with few if any intervals of normal speech. Affected children become aware of their speech difficulties and regard themselves as stutterers. In phase 2, the stuttering occurs mainly with the major parts of speech—nouns, verbs, adjectives, and adverbs.

- **Phase 3** usually appears after the age of 8 years and up to adulthood, most often in late childhood and early adolescence. During phase 3, stuttering comes and goes largely in response to specific situations, such as reciting in class, speaking to strangers, making purchases in stores, and using the telephone. Some words and sounds are regarded as more difficult than others.

- **Phase 4** typically appears in late adolescence and adulthood.

Stutterers show a vivid, fearful anticipation of stuttering. They fear words, sounds, and situations. Word substitutions and circumlocutions are common. Stutterers avoid situations requiring speech and show other evidence of fear and embarrassment.

Stutterers may have associated clinical features: vivid, fearful anticipation of stuttering, with avoidance of particular words, sounds, or situations in which stuttering is anticipated; and eye blinks, tics, and tremors of the lips or jaw. Frustration, anxiety, and depression are common among those with chronic stuttering.

**DIFFERENTIAL DIAGNOSIS**

Normal speech dysfluency in preschool years is difficult to differentiate from incipient stuttering. In stuttering occurs more nonfluencies, part-word repetitions, sound prolongations, and disruptions in voice airflow through the vocal track. Children who stutter appear to be tense and uncomfortable with their speech pattern, in contrast to young children who are nonfluent in their speech but seem to be at ease. Spastic dysphonia is a stuttering-like speech disorder distinguished from stuttering by the presence of an abnormal breathing pattern.

Cluttering is a speech disorder characterized by erratic and dysrhythmic speech patterns of rapid and jerky spurts of words and phrases. In cluttering, those affected are usually unaware of the disturbance, whereas, after the initial phase of the disorder, stutterers are aware of their speech difficulties. Cluttering is often an associated feature of expressive language disturbance.

**COURSE AND PROGNOSIS**

The course of stuttering is often long term, with periods of partial remission lasting for weeks or months and exacerbations occurring most frequently when a child is under pressure to communicate. In children with mild cases, 50 to 80 percent recover spontaneously. School-age children who stutter chronically may have impaired peer relationships as a result of teasing and social rejection. These children may face academic difficulties, especially if they persistently avoid speaking in class. Stuttering is associated with anxiety disorders in chronic cases, and approximately half of individuals with persistent stuttering have social anxiety disorder.

**TREATMENT**

Evidence-based treatments for stuttering are emerging in the literature. One such treatment is the Lidcombe Program, which is based on an operant conditioning model in which parents use praise for periods of time in which the child does not stutter, and intervene when the child does stutter to request the child to self-correct the stuttered word. This treatment program is largely administered at home by parents, under the supervision of a speech and language therapist. A second treatment program being investigated in clinical trials is a family-based, parent-child interaction therapy that identifies stressors possibly associated with increased stuttering and aims to diminish these stressors. A third treatment currently under investigation in clinical trials is based on the knowledge that speaking each syllable in time to a particular rhythm has led to diminished stuttering in adults. This treatment program appears to be promising when administered early on, to preschoolers.

Distinct forms of interventions have historically been used in the treatment of stuttering. The first approach, direct speech therapy, targets modification of the stuttering response to fluent-sounding speech by systematic steps and rules of speech mechanics that the person can practice. The other form of therapy for stuttering targets diminishing tension and anxiety during speech. These treatments may utilize breathing exercises and relaxation techniques, to help children slow the rate of speaking and modulate speech volume. Relaxation techniques are based on the premise that it is nearly impossible to be relaxed and stutter in the usual manner at the same time. Current interventions for stuttering use individualized combinations of behavioral distraction, relaxation techniques, and directed speech modification.

Stutterers who have poor self-image, comorbid anxiety disorders or depressive disorders are likely to require additional treatments with cognitive-behavioral therapy (CBT) and/or pharmacologic agents such as one of the selective serotonin reuptake inhibitor (SSRI) antidepressants.

An approach to stuttering proposed by the Speech Foundation of America is labeled self-therapy, based on the premise that stuttering is not a symptom, but a behavior that can be modified. Stutterers are told that they can learn to control their difficulty partly by modifying their feelings about stuttering and attitudes toward it and partly by modifying the deviant behaviors associated with their stuttering blocks. The approach includes desensitizing; reducing the emotional reaction to, and fears of, stuttering; and substituting positive action to control the moment of stuttering.

**31.4d Social (Pragmatic) Communication Disorder**

Social (pragmatic) communication disorder is a newly added diagnosis to DSM-5 characterized by persistent deficits in using verbal and nonverbal communication for social purposes in the absence of restricted and repetitive interests and behaviors. Deficits may be exhibited by difficulty in understanding and
following social rules of language, gesture, and social context. This may limit a child's ability to communicate effectively with peers, in academic settings, and in family activities. To successfully achieve social and pragmatic communication, a child or adolescent would be expected to integrate gestures, language, and social context of a given interaction to correctly infer its meaning. Thus, the child or adolescent would be able to understand another speaker's "intention" of the communication with verbal and nonverbal cues as well as through an understanding of the environmental and social context of the interaction. One of the reasons that social (pragmatic) communication disorder was introduced into the DSM-5 was to include those children with social communication impairment who do not exhibit restrictive and repetitive interests and behaviors, and therefore do not fulfill the criteria for autism spectrum disorders. Pragmatic communication encompasses the ability to infer meaning in a given communication by not only understanding the words used, but also integrating the phrases into their prior understanding of the social environment. Social (pragmatic) communication disorder is a new disorder; however, the concept of children with social communication deficits without repetitive and restrictive interests and behaviors has been identified for many years, and is often associated with delayed language acquisition and language disorder.

**EPIDEMIOLOGY**

It is difficult to estimate the prevalence of social (pragmatic) communication disorder. Nevertheless, a body of literature has documented a profile of children who present with these persistent difficulties in pragmatic language, who do not meet criteria for autism spectrum disorder.

**COMORBIDITY**

Social (pragmatic) communication disorder is commonly associated with language disorder, consisting of diminished vocabulary for expected age, deficits in receptive skills, as well as impaired ability to use expressive language. Attention-deficit/hyperactivity disorder (ADHD) is often concurrent with social (pragmatic) communication disorder. Specific learning disorders with impairments in reading and writing are also commonly comorbid disorders with social (pragmatic) communication disorder. Although some symptoms of social anxiety disorder may overlap with social (pragmatic) communication disorder, the full disorder of social anxiety disorder may emerge comorbidly with social (pragmatic) communication disorder.

**ETIOLOGY**

A family history of communication disorders, autism spectrum disorder, or specific learning disorder all appear to increase the risk for social (pragmatic) communication disorder. This suggests that genetic influences are contributing factors in the development of this disorder. The etiology of social (pragmatic) communication disorder, however, is likely to be multifactorial, and given its frequent comorbidity with both language disorder and ADHD, developmental and environmental influences are likely to also play a role.

**DIAGNOSIS**

The diagnosis of social (pragmatic) communication disorder can be difficult to distinguish from mild variants of autism spectrum disorder in which repetitive and restricted interests and behaviors are minimal. There have been largely discrepant data regarding how many children previously diagnosed with autism would be excluded from the DSM-5 criteria, which now focus on only two symptom domains: social communication deficits and restricted repetitive interests and behaviors. In one study, only 60.6 percent of children who had previously met the criteria for autistic spectrum disorder in the previous edition of the DSM met DSM-5 criteria for autistic spectrum disorder. However, in another study, up to 91 percent patients with of autism continued to meet the same DSM-5 criteria.

The essential features of social (pragmatic) communication disorder are persistently impaired social pragmatic communication resulting in limited effective communication, compromised social relationships, and difficulties with academic or occupational achievement.

**CLINICAL FEATURES**

Social (pragmatic) communication disorder is characterized by impaired ability to effectively use verbal and nonverbal communication for social purposes and occurs in the absence of restricted and repetitive interests and behaviors. According to the DSM-5, all of the following features must be present in order to meet diagnostic criteria: (1) Deficits in using appropriate communication such as greeting, or sharing information in a social situation or context. (2) Impaired ability to modulate the tone, level, or vocabulary used in social communication to match the listener and the situation, such as inability to simplify communication when speaking to a young child. (3) Impaired ability in following the rules for conversations such as taking turns or rephrasing a statement for clarification and failure to recognize and respond socially appropriately to verbal and nonverbal feedback. (4) Difficulty understanding things that are not explicitly stated, impaired ability to make inferences, understand humor, or interpret socially ambiguous stimuli. Although the preceding deficits begin in the early developmental period, the diagnosis is rarely made in a child younger than 4 years of age. In milder cases, the difficulties may not become apparent until adolescence when the demands for language and social understanding are increased. The deficits in social communication lead to impairment in function in social situations, in developing relationships, and in family and academic settings.

**DIFFERENTIAL DIAGNOSIS**

The primary diagnostic consideration in social (pragmatic) communication disorder is autism spectrum disorder. The two disorders are most easily distinguished when the prominence of restricted and repetitive interests and behaviors characteristic of autistic spectrum disorder is present. However, in many cases of autism, the restrictive interests and repetitive behaviors manifest more prominently in the early developmental period and are not obvious in older childhood. However, even when these features are not observable, if they are obtained by history, social (pragmatic) communication disorder is not diagnosed, rather
autism is the diagnosis. Social (pragmatic) communication disorder is considered only when the restricted interests and repetitive behaviors have never been present. ADHD may overlap with social (pragmatic) communication disorder in social communication disturbance; however, the core features of ADHD are not likely to be confused with autism spectrum disorder. In some cases, however, the two disorders may coexist. Another childhood disorder with socially impairing symptoms that may overlap with social (pragmatic) communication disorder is social anxiety disorder. In social anxiety disorder, however, social communication skills are present, but not manifested in feared social situations. In social (pragmatic) communication disorder, appropriate social communication skills are not present in any setting. Both social anxiety disorder and social (pragmatic) communication disorder may occur comorbidly, however, and children with social (pragmatic) communication disorder may be at higher risk for social anxiety disorder. Finally, intellectual disability may be confused with social (pragmatic) communication disorder, in that social communication skills may be deficits in children with intellectual disability. A diagnosis of social (pragmatic) communication disorder is made only when social communication skills are clearly more severe than the intellectual disability.

COURSE AND PROGNOSIS

The course and outcome of social (pragmatic) communication disorder is highly variable and dependent on both the severity of the disorder and potential interventions administered. By age 5 years, most children demonstrate enough speech and language to be able to discern the presence of deficits in social communication. However, in the milder forms of the disorder, social communication deficits may not be identified until adolescence, when language and social interactions are sufficiently complex that deficits stand out. Many children have significant improvement over time; however, even so, some early pragmatic deficits may cause lasting impairment in social relationships and in academic progress. There is a newly growing body of investigations on therapeutic interventions that may affect future outcome and prognosis of social (pragmatic) communication disorder.

TREATMENT

There are few data to date to inform an evidence-based treatment for social (pragmatic) communication disorder, or to fully distinguish it from other disorders with overlapping symptoms such as autism spectrum disorder, ADHD, and social anxiety disorder. A randomized controlled trial of a social communication intervention directed specifically at children with social (pragmatic) communication disorder aimed at three areas of communication: (1) social understanding and social interaction; (2) verbal and nonverbal pragmatic skills, including conversational and language processing, involving making inferences, and learning new words. Although the primary outcome measure in this study did not show significant differences for the intervention group versus the “treatment as usual” group, there were several ratings by parents and teachers that demonstrate potential improvements in social communication skills after a 20-session intensive intervention for social (pragmatic) communication disorder. It is clear that continued investigation is necessary to both validate the preceding results and to promote evidence-based treatments for children with social (pragmatic) communication disorder.

Disorders that do not meet the diagnostic criteria for any specific communication disorder fall into the category of unspecified communication disorder. An example is voice disorder, in which the patient has an abnormality in pitch, loudness, quality, tone, or resonance. To be coded as a disorder, the voice abnormality must be sufficiently severe to impair academic achievement or social communication. Operationally, speech production can be broken down into five interacting subsystems, including respiration (airflow from the lungs), phonation (sound generation in the larynx), resonance (shaping of the sound quality in the pharynx and nasal cavity), articulation (modulation of the sound stream into consonant and vowel sounds with the tongue, jaw, and lips), and suprasegmental (speech rhythm, loudness, and intonation). These systems work together to convey information, and voice quality conveys information about the speaker’s emotional, psychological, and physical status. Thus, voice abnormalities can cover a broad area of communication as well as indicate many different types of abnormalities.

Cluttering is not listed as a disorder in the DSM-5, but it is an associated speech abnormality in which the disturbed rate and rhythm of speech impair intelligibility. Speech is erratic and dysrhythmic and consists of rapid, jerky spurts that are inconsistent with normal phrasing patterns. The disorder usually occurs in children between 2 and 8 years of age; in two thirds of cases, the patient recovers spontaneously by early adolescence. Cluttering is associated with learning disorders and other communication disorders.

REFERENCES

Autism spectrum disorder, previously known as the pervasive developmental disorders, is a phenotypically heterogeneous group of neurodevelopmental syndromes, with polygenic heritability, characterized by a wide range of impairments in social communication and restricted and repetitive behaviors. Prior to the development of the Fifth Edition of the American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders (DSM-5), autism spectrum disorder was conceptualized as five discrete disorders, including: autistic disorder, Asperger’s disorder, childhood disintegrative disorder, Rett syndrome, and pervasive developmental disorder not otherwise specified. Autistic disorder was characterized by impairments in three domains: social communication, restricted and repetitive behaviors, and aberrant language development and usage. A less extensive form of autism spectrum disorder, Asperger’s disorder, did not include language impairment as a diagnostic criterion. Recent clinical consensus has shifted the conceptualization of autism spectrum disorder toward a continuum model in which heterogeneity of symptoms is recognized as inherent in the disorder, and core diagnostic impairments are collapsed into two domains: deficits in social communication, and restricted and repetitive behaviors. Aberrant language development and usage is no longer considered a core feature of autism spectrum disorder. This diagnostic change, is based, in part, on recent studies in siblings with diagnoses of autistic disorder, suggesting that symptom domains may be transmitted separately, and that aberrant language development and usage is not a defining feature, but an associated feature in some individuals with autism spectrum disorder. Autism spectrum disorder is typically evident during the second year of life, and in severe cases, a lack of developmentally appropriate interest in social interactions may be noted even in the first year. Some studies suggest that a decline in social interaction may ensue between the first and second years of life. However, in milder cases, core impairments in autism spectrum disorder may not be identified for several more years. Although language impairment is not a core diagnostic criterion in autism spectrum disorder, clinicians and parents share concerns about a child who by 12 to 18 months has not developed any language, and delayed language accompanied by diminished social behavior are frequently the heralding symptoms in autism spectrum disorder. In up to 25 percent of cases of autism spectrum disorder, some language develops and is subsequently lost. Autism spectrum disorder in children with normal intellectual function and mild impairment in language function may not be identified until middle childhood when both academic and social demands are increased. Children with autism spectrum disorder often exhibit idiosyncratic intense interest in a narrow range of activities, resist change, and typically, do not respond to their social environment in accordance with their peers.

According to the DSM-5, diagnostic criteria for autism spectrum disorder include deficits in social communication and restricted interests, which present in the early developmental period, however, when subtle, may not be identified until several years later. Approximately one third of children meeting the
current DSM-5 diagnosis of autism spectrum disorder, exhibit intellectual disability (ID).

Of interest, is that according to DSM-IV-TR, Rett syndrome or disorder appeared to occur exclusively in females and is characterized by normal development for at least 6 months, followed by stereotyped hand movements, a loss of purposeful motions, diminishing social engagement, poor coordination, and decreasing language use. In the formerly labeled childhood disintegrative disorder, development progresses normally for approximately 2 years, after which the child shows a loss of previously acquired skills in two or more of the following areas: language use, social responsiveness, play, motor skills, and bladder or bowel control. The former Asperger’s disorder is characterized by impairment in social relatedness and repetitive and stereotyped patterns of behavior without a delay or marked aberrant in language development and usage. In Asperger’s disorder, cognitive abilities and major adaptive skills are age appropriate, although social communication is impaired. A survey of children undertaken with the former autism spectrum disorders, revealed that the average age of diagnosis was 3.1 years for children with autistic disorder, 3.9 years for children diagnosed with pervasive developmental disorder not otherwise specified, and 7.2 years for those youth with Asperger’s disorder. Children with autism spectrum disorder who exhibited severe language deficits received an autism spectrum disorder diagnosis, on average, a year earlier than children without impairment in language. Children with autism spectrum disorder who exhibited repetitive behaviors such as hand-flapping, toe-walking, and odd play were also identified with autism spectrum disorder disorders at a younger age than those who did not exhibit such behaviors. The current DSM-5 autism spectrum disorder criteria provide specifications for severity of the main domains of impairment and also specifications for the presence or absence of language impairment and intellectual impairment.

HISTORY OF AUTISTIC DISORDER

“Early infantile autism” was described by Leo Kanner in 1943; however, even as early as 1867, the psychiatrist Henry Maudsley had observed a group of very young children with severe mental disorders characterized by marked deviation, delay, and distortion in development. In that era, most serious developmental disturbance in young children was believed to fall within the category of psychoses. Kanner’s classic paper “Autistic Disturbances of Affective Contact,” coined the term infantile autism and provided a clear, comprehensive account of the early childhood syndrome. Kanner described children who exhibited extreme “autistic aloneness”; failure to assume an anticipatory posture; delayed or deviant language development with echolalia and often with pronominal reversal (using you for I); monotonous repetitions of noises or verbal utterances; excellent rote memory; limited range of spontaneous activities, stereotypes, and mannerisms; and anxiously obsessive desire for the maintenance of sameness and dread of change. Socially, Kanner’s sample was described as having poor eye contact; awkward relationships; and a preference for pictures and inanimate objects. Kanner suspected that the syndrome was more frequent than it seemed, and suggested that some children with infantile autism may have been misclassified as “mentally retarded” or schizophrenic. Before 1980, children with symptoms of autism spectrum disorder were generally diagnosed with childhood schizophrenia. Over time, it became evident that autism spectrum disorder and schizophrenia were two distinct psychiatric entities. In some cases, however, a child with autism spectrum disorder may develop comorbid schizophrenic disorder later in childhood.

EPIDEMIOLOGY

Prevalence
Autism spectrum disorders have been increasingly diagnosed over the last two decades, with the current prevalence estimated at approximately 1 percent in the United States. Autistic disorder, based on DSM-IV-TR criteria, is believed to occur at a rate of about 8 cases per 10,000 children (0.08 percent). By definition, the onset of autism spectrum disorder is in the early developmental period; however, some cases are not recognized until the child is much older. Because of this delay between onset and diagnosis, the prevalence rates increase with age in young children.

Sex Distribution
Autism spectrum disorder is diagnosed four times more often in boys than in girls. In clinical samples, girls with autism spectrum disorder more often exhibit intellectual disability than boys. One potential explanation for this is that girls with autism spectrum disorder without intellectual disability may be less likely to be identified, referred clinically, and diagnosed.

ETIOLOGY AND PATHOGENESIS

Genetic Factors
Family and twin studies suggest that autism spectrum disorder has a significant heritable contribution; however, it does not appear to be fully penetrant. Although up to 15 percent of cases of autism spectrum disorder appear to be associated with a known genetic mutation, in most cases, its expression is dependent on multiple genes. Family studies have demonstrated increased rates of autism spectrum disorder in siblings of an index child, as high as 50 percent in some families with two or more children with autism spectrum disorder. Siblings of a child with autism spectrum disorder are also at increased risk for a variety of developmental impairments in communication and social skills, even when they do not meet criteria for autism spectrum disorder.

The concordance rate of autistic disorder in two large twin studies was 36 percent in monozygotic pairs versus 0 percent in dizygotic pairs in one study and about 96 percent in monozygotic pairs versus about 27 percent in dizygotic pairs in the second study. High rates of cognitive impairments, in the nonautistic twin in monozygotic twins with perinatal complications, suggest that contributions of perinatal environmental factors interact with genetic vulnerability differentially in autism spectrum disorder.

The heterogeneity in expression of symptoms in families with autism spectrum disorder suggests that there are multiple patterns of genetic transmission. Studies indicate that both an increase and decrease in certain genetic patterns may be risk factors for autism spectrum disorder. In addition to specific genetic factors, gender plays a strong role in the expression of autism spectrum disorder. Genetic studies have identified two biological systems that are influenced in autism spectrum disorder: the consistent finding of elevated platelet serotonin (5-HT), and the mTOR, that is, mammalian target of rapamycin–linked synaptic plasticity mechanisms, which appear to be disrupted.
in autism spectrum disorder. These will be discussed further in the next section.

A number of known genetically caused syndromes include autism spectrum disorder as part of a broader phenotype. The most common of these inherited disorders is fragile X syndrome, an X-linked recessive disorder that is present in 2 to 3 percent of individuals with autism spectrum disorder. Fragile X syndrome exhibits a nucleotide repeat in the 5' untranslated region of the *FMNRI* gene, resulting in symptoms of autism spectrum disorder. Children with fragile X syndrome characteristically exhibit intellectual disability, gross and fine motor impairments, an unusual facies, macroorchidism, and significantly diminished expressive language ability. Tuberous sclerosis, another genetic disorder characterized by multiple benign tumors, inherited by autosomal dominant transmission, is found with greater frequency among children with autism spectrum disorder. Up to 2 percent of children with autism spectrum disorder also have tuberous sclerosis.

Researchers who screened the DNA of more than 150 pairs of siblings with autism spectrum disorder found evidence of two regions on chromosomes 2 and 7 containing genes that may contribute to autism spectrum disorder. Additional genes hypothesized to be involved in autism spectrum disorder were found on chromosomes 16 and 17.

**Biomarkers in Autism Spectrum Disorder**

Autism spectrum disorder is associated with several biomarkers, potentially resulting from interactions of genes and environmental factors, which then influence neuronal function, dendrite development, and contribute to altered neuronal information processing. Several biomarkers of abnormal signaling in the 5-HT system, the mTOR-linked synaptic plasticity mechanisms, and alterations of the γ-aminobutyric acid (GABA) inhibitory system.

The first biomarker identified in autism spectrum disorder was elevated serotonin in whole blood, almost exclusively in the platelets. Platelets acquire 5-HT through the process of SERT (serotonin transporter), known to be hereditary, as they pass through the intestinal circulation. The genes that mediate SERT (*SLC6A4*), and the 5-HT receptor 5-HT 2A gene (*HTR2A*) are known to be more heritable than autism spectrum disorder, and encode the same protein in the platelets and in the brain. Because 5-HT is known to be involved in brain development, it is possible that the changes in 5-HT regulation may lead to alterations in neuronal migration and growth in the brain.

Both structural and functional neuroimaging studies have suggested specific biomarkers associated with autism spectrum disorder. Several studies found increased total brain volume in children younger than 4 years of age with autism spectrum disorder, whose neonatal head circumferences were within normal limits or slightly below. By about age 5 years, however, 15 to 20 percent of children with autism spectrum disorder developed macrocephaly. Additional studies found confirmatory data in samples of infants who were later diagnosed with autism spectrum disorder, who exhibited normal head circumferences at birth; by 4 years, 90 percent had larger brain volumes than controls, with 37 percent of the autism spectrum disorder group meeting criteria for macrocephaly. In contrast, structural magnetic resonance imaging (sMRI) studies of children with autism spectrum disorder ranging from 5 to 16 years did not find mean values of total brain volume increased. One study followed the size of the amygdala in youth with autism spectrum disorder in the first few years of life, and similarly, found an increased size in the first few years of life, followed by a decrease in size over time. The size of the striatum has also been found in several studies to be enlarged in young children with autism spectrum disorder, with a positive correlation of striatal size with frequency of repetitive behaviors. The dynamic process of the atypical and changing total brain volume observed in children with autism spectrum disorder lends support for the overarching hypothesis that there are sensitive periods or “critical periods” within the brain’s plasticity that may be disrupted in ways that may contribute to the emergence of autism spectrum disorder.

Functional MRI (fMRI) studies have focused on identifying biomarkers, that is, the functional brain correlates of various observed core symptoms in autism spectrum disorder. fMRI studies of children, adolescents, and adults with autism spectrum disorder have employed tasks including face perception, neutral face tasks, “theory of mind” deficits, language and communication impairments, working memory and repetitive behaviors. fMRI studies have provided evidence that individuals with autism spectrum disorder have a tendency to scan faces differently than controls, in that they focus more on the mouth region of the face rather than on the eye region and rather than scan the entire face multiple times, individuals with autism spectrum disorder focus more on individual features of the face. In response to socially relevant stimuli, researchers have come to the conclusion that individuals with autism spectrum disorder have greater amygdala hyperarousal. In terms of “theory of mind,” that is, the ability to attribute emotional states to others, and to oneself, fMRI studies find differences in activation in brain regions such as the right temporal lobe and other areas of the brain known to become activated in controls during tasks involving theory of mind. This difference has been hypothesized by some researchers to represent dysfunction of the mirror neuron system (MNS). Atypical patterns of frontal lobe activation have been found in multiple studies of autism spectrum disorder during face processing tasks, suggesting that this area of the brain may be critical in social perception and emotional reasoning. Decreased activation in individuals with autism spectrum disorder in the left frontal regions of the brain during memory and language-based tasks led researchers to hypothesize that individuals with autism spectrum disorder utilized more visual strategies during language processing than controls did.

Both sMRI and fMRI research has contributed to demonstrating brain correlates of core impairments observed in individuals with autism spectrum disorder.

**Immunological Factors**

Several reports have suggested that immunological incompatibility (i.e., maternal antibodies directed at the fetus) may contribute to autistic disorder. The lymphocytes of some autistic children react with maternal antibodies, which raises the possibility that embryonic neural tissues may be damaged during gestation. These reports usually reflect single cases rather than controlled studies, and this hypothesis is still under investigation.
Prenatal and Perinatal Factors

A higher-than-expected incidence of prenatal and perinatal complications seems to occur in infants who are later diagnosed with autism spectrum disorder. The most significant prenatal factors associated with autism spectrum disorder in the offspring are advanced maternal and paternal age at birth, maternal gestational bleeding, gestational diabetes, and first-born baby. Perinatal risk factors for autism spectrum disorder include umbilical cord complications, birth trauma, fetal distress, small for gestational age, low birth weight, low 5-minute Apgar score, congenital malformation, ABO blood group system or Rh factor incompatibility and hyperbilirubinemia. Many of the obstetrical complications that are associated with risk for autism spectrum disorder are also risk factors for hypoxia, which may be an underlying risk factor itself. There is not sufficient evidence to implicate any one single perinatal or prenatal factor in autism spectrum disorder etiology, and a genetic predisposition to autism spectrum disorder may be interacting with perinatal factors.

Comorbid Neurological Disorders

Electroencephalography (EEG) abnormalities and seizure disorders occur with greater than expected frequency in individuals with autism spectrum disorder. Four percent to 32 percent of individuals with autism spectrum disorder have grand mal seizures at some time, and about 20 to 25 percent show ventricular enlargement on computed tomography (CT) scans. Various EEG abnormalities are found in 10 to 83 percent of children with the previously defined autistic disorder, and although no EEG finding specific to autistic disorder, there is some indication of failed cerebral lateralization. The current consensus is that autism spectrum disorder is a set of behavioral syndromes caused by a multitude of factors acting on the central nervous system.

Psychosocial Theories

Studies comparing parents of children with autism spectrum disorder with parents of normal children have shown no significant differences in child-rearing skills. Kanner's early speculations that parental emotional factors might be implicated as contributing to the development of autism spectrum disorder have been clearly refuted.

DIAGNOSIS AND CLINICAL FEATURES

The DSM-5 diagnostic criteria for autism spectrum disorder are shown in Table 31.5-1.

Core Symptoms of Autism Spectrum Disorder

Persistent Deficits In Social Communication and Interaction. Children with autism spectrum disorder characteristically do not conform to the expected level of reciprocal social skills and spontaneous nonverbal social interactions. Infants with autism spectrum disorder may not develop a social smile, and as older babies may lack the anticipatory posture for being picked up by a caretaker. Less frequent and poor eye contact is common during childhood and adolescence compared to other children. The social development of children with autism spectrum disorder is characterized by atypical, but not absent, attachment behavior. Children with autism spectrum disorder may not explicitly acknowledge or differentiate the most important persons in their lives—parents, siblings, and teachers—and on the other hand, may not react as strongly to being left with a stranger compared to others their age. Children with autism spectrum disorder often feel and display extreme anxiety when their usual routine is disrupted. By the time children with autism spectrum disorder reach school age, their social skills may have increased, and social withdrawal may be less obvious, particularly in higher-functioning children. An observable deficit, however, often remains in spontaneous play with peers and in subtle social abilities that promote developing friendships. The social behavior of children with autism spectrum disorder is often awkward and may be inappropriate. In older school-aged children, social impairments may be manifested in a lack of conventional back and forth conversation, fewer shared interests, and fewer body and facial gestures during conversations. Cognitively, children with autism spectrum disorder are frequently more skilled in visual-spatial tasks than in tasks requiring skill in verbal reasoning.

One observation of the cognitive style of children with autism spectrum disorder is an impaired ability to infer the feelings or emotional state of others around them. That is, individuals with autism spectrum disorder have difficulty with making attributions about the motivation or intentions of others (also termed “theory of mind”) and thus have difficulty developing empathy. The lack of a “theory of mind” produces difficulties interpreting the social behavior of others and leads to a lack of social reciprocation.

Individuals with autism spectrum disorder generally desire friendships, and higher functioning children may be aware that their lack of spontaneity and poor skills in responding to the emotions and feelings of their peers are major obstacles in developing friendships. Children with autism spectrum disorder are often avoided or shunned by peers who expect them to conform to their mainstream activities, and experience their behavior as awkward and alienating. Adolescents and adults with autism spectrum disorder often desire romantic relationships, and for some, their increase in social competence and skills over time enables them to develop long-term relationships.

Restricted, Repetitive Patterns of Behavior, Interests, and Activities. From the first years of life, in a child with autism spectrum disorder, developmentally expected exploratory play is restricted and muted. Toys and objects may not be used typically, instead, are often manipulated in a ritualistic manner, with fewer symbolic features. Children with autism spectrum disorder generally do not show the level of imitative play or abstract pantomime that other children of their age exhibit spontaneously. The activities and play of children with autism spectrum disorder may appear more rigid, repetitive, and monotonous than their peers. Ritualistic and compulsive behaviors are common in early and middle childhood. Children with autism spectrum disorder often seem to enjoy spinning, banging, and watching water flowing. Frank compulsive behaviors are not uncommon among children with autism spectrum disorder, such as lining up objects, and not infrequently a child with autism spectrum disorder may exhibit a strong attachment to a particular
Table 31.5-1

DSM-5 Diagnostic Criteria for Autism Spectrum Disorder

A. Persistent deficits in social communication and social interaction across multiple contexts, as manifested by the following, currently or by history (examples are illustrative, not exhaustive; see text):
   1. Deficits in social-emotional reciprocity, ranging, for example, from abnormal social approach and failure of normal back-and-forth conversation; to reduced sharing of interests, emotions, or affect; to failure to initiate or respond to social interactions.
   2. Deficits in nonverbal communicative behaviors used for social interaction, ranging, for example, from poorly integrated verbal and nonverbal communication; to abnormalities in eye contact and body language or deficits in understanding and use of gestures; to a total lack of facial expressions and nonverbal communication.
   3. Deficits in developing, maintaining, and understanding relationships, ranging, for example, from difficulties adjusting behavior to suit various social contexts; to difficulties in sharing imaginative play or in making friends; to absence of interest in peers.

Specify current severity:

Severity is based on social communication impairments and restricted, repetitive patterns of behavior.

B. Restricted, repetitive patterns of behavior, interests, or activities, as manifested by at least two of the following, currently or by history (examples are illustrative, not exhaustive; see text):
   1. Stereotyped or repetitive motor movements, use of objects, or speech (e.g., simple motor stereotypes, lining up toys or flipping objects, echolalia, idiosyncratic phrases).
   2. Insistence on sameness, inflexible adherence to routines, or ritualized patterns of verbal or nonverbal behavior (e.g., extreme distress at small changes, difficulties with transitions, rigid thinking patterns, greeting rituals, need to take same route or eat same food every day).
   3. Highly restricted, fixated interests that are abnormal in intensity or focus (e.g., strong attachment to or preoccupation with unusual objects, excessively circumscribed or perseverative interests).
   4. Hyper- or hyporeactivity to sensory input or unusual interest in sensory aspects of the environment (e.g., apparent indifference to pain/temperature, adverse response to specific sounds or textures, excessive smelling or touching of objects, visual fascination with lights or movement).

Specify current severity:

Severity is based on social communication impairments and restricted, repetitive patterns of behavior.

C. Symptoms must be present in the early developmental period (but may not become fully manifest until social demands exceed limited capacities, or may be masked by learned strategies in later life).

D. Symptoms cause clinically significant impairment in social, occupational, or other important areas of current functioning.

E. These disturbances are not better explained by intellectual disability (intellectual developmental disorder) or global developmental delay. Intellectual disability and autism spectrum disorder frequently co-occur; to make comorbid diagnoses of autism spectrum disorder and intellectual disability, social communications should be below that expected for general developmental level.

Note: Individuals with a well-established DSM-IV diagnosis of autistic disorder, Asperger's disorder, or pervasive developmental disorder not otherwise specified should be given the diagnosis of autism spectrum disorder. Individuals who have marked deficits in social communication, but whose symptoms do not otherwise meet criteria for autism spectrum disorder, should be evaluated for social (pragmatic) communication disorder.

Specify if:

With or without accompanying intellectual impairment

With or without accompanying language impairment

Associated with a known medical or genetic condition or environmental factor (Coding note: Use additional code to identify the associated medical or genetic condition.)

Associated with another neurodevelopmental, mental, or behavioral disorder (Coding note: Use additional code[s] to identify the associated neurodevelopmental, mental, or behavioral disorder[s].)

With catatonia (refer to the criteria for catatonia associated with another mental disorder for definition) (Coding note: Use additional code 293.89 [F06.1] catatonia associated with autism spectrum disorder to indicate the presence of the comorbid catatonia.)

(Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (Copyright ©2013). American Psychiatric Association. All Rights Reserved.)

inanimate object. Children with autism spectrum disorder who are severely intellectually disabled have increased rates of self-stimulatory and self-injurious behaviors. Stereotypies, mannerisms, and grimacing emerge most frequently when a child with autism spectrum disorder is in a less-structured situation. Children with autism spectrum disorder often find transitions and changes intimidating. Moving to a new house, rearranging furniture in a room, or even a change such as eating a meal before a bath when the reverse was the routine, may evoke panic, fear, or temper tantrums in a child with autism spectrum disorder.

Associated Physical Characteristics. At first glance, children with autism spectrum disorder do not show any physical signs indicating the disorder. Children with autism spectrum disorder, overall, do exhibit higher rates of minor physical anomalies, such as ear malformations, and others that may reflect abnormalities in fetal development of those organs along with parts of the brain.

A greater than expected number of children with autism spectrum disorder do not show early handedness and lateralization, and remain ambidextrous at an age when cerebral dominance is established in most children. Children with autism spectrum disorder have been observed to have a higher incidence of abnormal dermatoglyphics (e.g., fingerprints) than those in the general population. This finding may suggest a disturbance in neuroectodermal development.
Associated Behavioral Symptoms that May Occur in Autism Spectrum Disorder

Disturbances In Language Development and Usage. Deficits in language development and difficulty using language to communicate ideas are not among the core criteria for diagnosing autism spectrum disorder; however, they occur in a subset of those individuals with autism spectrum disorder. Some children with autism spectrum disorder are not simply reluctant to speak, and their speech abnormalities do not result from lack of motivation. Language deviance, as much as language delay, is characteristic of more severe subtypes of autism spectrum disorder. Children with severe autism spectrum disorder have significant difficulty putting meaningful sentences together, even when they have large vocabularies. When children with autism spectrum disorder whose language was delayed do learn to converse fluently, their conversations may impart information without typical prosody or inflection.

In the first year of life, a typical pattern of babbling may be minimal or absent. Some children with autism spectrum disorder vocalize noises—clicks, screeches, or nonsense syllables—in a stereotyped fashion, without a seeming intent of communication. Unlike most young children who generally have better receptive language skills than expressive ones, children with autism spectrum disorder may express more than they understand. Words and even entire sentences may drop in and out of a child's vocabulary. It is not atypical for a child with autism spectrum disorder to use a word once and then not use it again for a week, a month, or years. Children with autism spectrum disorder may exhibit speech that contains echolalia, both immediate and delayed, or stereotyped phrases that seem out of context. These language patterns are frequently associated with pronoun reversals. A child with autistic disorder might say, "You want the toy" when she means that she wants it. Difficulties in articulation are also common. Many children with autistic disorder use peculiar voice quality and rhythm. About 50 percent of autistic children never develop useful speech. Some of the brightest children show a particular fascination with letters and numbers. Children with autism spectrum disorder sometimes excel in certain tasks or have special abilities; for example, a child may learn to read fluently at preschool age (hyperlexia), often astonishingly well. Very young children with autism spectrum disorder who can read many words, however, have little comprehension of the words read.

Intellectual Disability. About 30 percent of children with autism spectrum disorder function in the intellectually disabled range of intellectual function. Of those, about 30 percent of children function in the mild to moderate range, and about 45 to 50 percent are severely to profoundly intellectually disabled. The intelligent quotient (IQ) scores of autism spectrum disorder children with intellectual impairments tend to reflect most severe problems with verbal sequencing and abstraction skills, with relative strengths in visuospatial or rote memory skills. This finding suggests the importance of defects in language-related functions.

Irritability. Broadly defined, irritability includes aggression, self-injurious behaviors, and severe temper tantrums. These phenomena are commonly encountered in children and adolescents with autism spectrum disorder. Severe temper tantrums may be difficult to subdue, and self-injurious behaviors are often problematic to control. These symptoms are often produced by everyday situations in which these youth are expected to transition from one activity to another, sit in a classroom setting, or remain still when they desire to run around. In children with autism spectrum disorder who are lower functioning and have intellectual deficits, aggression may emerge unexpectedly without an obvious trigger or purpose, and self-injurious behaviors such as head banging, skin picking, and biting oneself may also be noted.

Instability of Mood and Affect. Some children with autism spectrum disorder exhibit sudden mood changes, with bursts of laughing or crying without an obvious reason. It is difficult to learn more about these episodes if the child cannot express the thoughts related to the affect.

Response to Sensory Stimuli. Children with autism spectrum disorder have been observed to overrespond to some stimuli and underrespond to other sensory stimuli (e.g., to sound and pain). It is not uncommon for a child with autism spectrum disorder to appear deaf, at times showing little response to a normal speaking voice; on the other hand, the same child may show intent interest in the sound of a wristwatch. Some children have a heightened pain threshold or an altered response to pain. Indeed, some children with autism spectrum disorder do not respond to an injury by crying or seeking comfort. Some youth with autism spectrum disorder perseverate on a sensory experience; for example, they frequently hum a tune or sing a song or commercial jingle before saying words or using speech. Some particularly enjoy vestibular stimulation—spinning, swinging, and up-and-down movements.

Hyperactivity and Inattention. Hyperactivity and inattention are both common behaviors in young children with autism spectrum disorder. Lower than average activity level is less frequent; when present, it often alternates with hyperactivity. Short attention span, poor ability to focus on a task, may also interfere with daily functioning.

Precocious Skills. Some individuals with autism spectrum disorder have precocious or splinter skills of great proficiency, such as prodigious rote memories or calculating abilities, usually beyond the capabilities of their normal peers. Other potential precocious abilities in some children with autism spectrum disorder include hyperlexia, an early ability to read well (even though they cannot understand what they read), memorizing and reciting, and musical abilities (singing or playing tunes or recognizing musical pieces).

Insomnia. Insomnia is a frequent sleep problem among children and adolescents with autism spectrum disorder, estimated to occur in 44 to 83 percent of school-aged children. Both behavioral and pharmacologic interventions have been applied as interventions. Behavioral interventions include modification of parental behavior before and at bedtime, and providing routines that remove reinforcers for remaining awake. Medication interventions have included melatonin, which appears to be a promising agent in doses ranging
from 1 mg fast-release to 4 mg controlled-release in the few controlled studies for insomnia in youth with autism spectrum disorder.

**Minor Infections and Gastrointestinal Symptoms.** Young children with autism spectrum disorder have been reported to have a higher-than-expected incidence of upper respiratory infections and other minor infections. Gastrointestinal symptoms commonly found among children with autism spectrum disorder include excessive burping, constipation, and loose bowel movements. Also seen is an increased incidence of febrile seizures in children with autism spectrum disorder. Some children do not show temperature elevations with minor infectious illnesses and may not show the typical malaise of illness. In other children, behavior problems and relatedness seem to improve noticeably during a minor illness, and in some, such changes are a clue to physical illness.

**Assessment Tools**

A standardized instrument that can be very helpful in eliciting comprehensive information regarding autism spectrum disorder is the *Autism Diagnostic Observation Schedule-Generic* (ADOS-G).

Brett was the first of two children born to middle-class parents both in their early 40s after difficult pregnancy, with an induced labor at 36 weeks due to fetal distress. As an infant, Brett was undemanding and relatively placid; he did not have colic, and motor development proceeded appropriately, but language development was delayed. Brett's parents first became concerned about his development when he was 18 months of age and still not speaking; however, upon questioning, they noted that, in comparison to other toddlers in his play group, Brett had seemed less interested in social interaction and the social games with toddlers and adults. Stranger anxiety became marked at 18 months, much later compared to the other toddlers in his day care program. Brett would become extremely upset if his usual day care worker was not present and would tantrum until his mother took him home. Brett's pediatrician initially reassured his parents that he was a "late talker"; however, when Brett was 24 months old he was referred for developmental evaluation. At 24 months, motor skills were age appropriate. His language and social development, however, was severely delayed, and he was noted to be resistant to changes in routine and unusually sensitive to aspects of the inanimate environment. Brett's play skills were quite limited, and he played with toys in repetitive and idiosyncratic ways. His younger sister, now 12 months, was beginning to say a few words, and the family history was negative for language and developmental disorders. A comprehensive medical evaluation revealed a normal EEG and CT scan; genetic screening and chromosome analysis were normal as well.

Brett was diagnosed with autism spectrum disorder, and he was enrolled in a special education program in which he gradually began to speak. His speech was extremely literal and characterized by a monotonic voice quality and an occasional pronoun reversal. Brett often spoke and was able to make his needs known; however, his language was odd and the other toddlers did not play with him. Brett pursued mainly solo activities and remained quite isolated. By age 5 years, Brett was quite attached to his mother and often became separation anxious and upset when she went out, exhibiting severe tantrums. Brett also had developed a number of self-stimulatory behaviors in which he engaged, such as waving his fingers in front of his eyes. His extreme sensitivity to change continued over the next few years. Intelligence testing revealed a full-scale IQ in the average range with relative weakness in the verbal subtests compared to the performance subtests. In the 4th grade, Brett began to have serious behavioral problems at school and at home. Brett was unable to complete his class work, would wander around the classroom, and would begin to tantrum when the teacher insisted that he sit in his seat. He would sometimes begin screaming so loudly that he had to be asked to leave the classroom. He would then become upset and throw all of his books off his desk in a rage, sometimes inadvertently hitting other students. It took him up to 2 hours to calm down. At home, Brett would fly into a tantrum if anyone touched his things, and he would become stubborn and belligerent when asked to do anything that he was not expecting. Brett's tantrum behavior continued into middle school, and by the 8th grade, when he was 13 years old, these behaviors became so severe that the school warned his parents that he was becoming unmanageable. Brett was evaluated by a child and adolescent psychiatrist who recommended a social skills group for him and prescribed risperidone, starting with 0.5 mg p.o. b.i.d. and titrating up to 1.5 mg p.o. bid. At that dose, Brett's tantrums were less frequent and less severe. Brett seemed calmer in general, and did not become physically out of control during tantrums. Brett continued in middle school in a combination of special education classes and regular classes. Brett's social skills group was helpful in terms of teaching him how to approach peers in ways that would lead to less rejection. Brett had made some acquaintances, and by the time he started high school, he had acquired two friends who would come to his home and play video games with him. Brett knew that he was different than the other students, but he had trouble articulating what was different about him. Brett continued in high school with a combination of special and regular education and had plans to attend a community college and live at home for the first year.

(Adapted from a case by Fred Volkmar, M.D.)

**DIFFERENTIAL DIAGNOSIS**

Disorders to consider in the differential diagnosis of autism spectrum disorder include social (pragmatic) communication disorder, the newly described DSM-5 communication disorder; schizophrenia with childhood onset; congenital deafness or severe hearing disorder; and psychosocial deprivation. It is also difficult to make the diagnosis of autism spectrum disorder because of its potentially overlapping symptoms with childhood schizophrenia, intellectual disability syndromes with behavioral symptoms, and language disorders. In view of the many concurrent problems often encountered in autism spectrum disorder, Michael Rutter and Lionel Hersov suggested a stepwise approach to the differential diagnosis.

**Social (Pragmatic) communication disorder**

This disorder is characterized by difficulty in conforming to typical storytelling, understanding the rules of social communication through language, exemplified by a lack of conventional greeting others, taking turns in a conversation, and

Responding to verbal and nonverbal cues of a listener. Other forms of language impairment may accompany social communication disorders such as delay in learning language or expressive and receptive difficulties. Social communication disorder is found with greater frequency in relatives of individuals with autism spectrum disorder, which increases the difficulty in discriminating this disorder from autism spectrum disorder. Although relationships may be negatively affected by social communication disorder, this disorder does not include restricted or repetitive behaviors and interests, as autistic spectrum disorder does.

**Childhood Onset Schizophrenia**

Schizophrenia is rare in children younger than 12 years and almost nonexistent before the age of 5 years. Characterized by hallucinations or delusions, childhood onset schizophrenia has a lower incidence of seizures and intellectual disability and poor social skills. Table 31.5-2 compares autism spectrum disorder and schizophrenia with childhood onset.

Intellectual Disability with Behavioral Symptoms

Children with intellectual disability may exhibit behavioral symptoms that overlap with some autism spectrum disorder features. The main differentiating features between autism spectrum disorder and intellectual disability are that children with intellectual disability syndromes generally display global impairments in both verbal and nonverbal areas, whereas children with autism spectrum disorder are relatively weak in social interactions compared to other areas of performance. Children with intellectual disability generally relate verbally and socially to adults and peers in accordance with their mental age, and they exhibit a relatively even profile of limitations.

Language Disorder

Some children with language disorders also have autism spectrum disorder features, which may present a diagnostic challenge. Table 31.5-3 summarizes the major differences between autism spectrum disorder and language disorders.
**Congenital Deafness or Hearing Impairment**

Because children with autism spectrum disorder may appear mute or lack language development, congenital deafness and hearing impairment must be considered and ruled out. Differentiating factors include the following: infants with autism spectrum disorder may babble only infrequently, whereas deaf infants often have a history of relatively normal babbling that then gradually tapers off and may stop at 6 months to 1 year of age. Deaf children generally respond only to loud sounds, whereas children with autism spectrum disorder may ignore loud or normal sounds and respond to soft or low sounds. Most importantly, audiogram or auditory-evoked potentials indicate significant hearing loss in deaf children. Deaf children usually seek out nonverbal social communication with regularity and seek social interactions with peers and family members more consistently than children with autism spectrum disorder.

**Psychosocial Deprivation**

Severe neglect, maltreatment, and lack of parental care can lead children to appear apathetic, withdrawn, and alienated. Language and motor skills may be delayed. Children with these signs generally improve when placed in a favorable and enriched psychosocial environment, but such improvement is not the case with children with autism spectrum disorder.

**COURSE AND PROGNOSIS**

Autism spectrum disorder is typically a lifelong, albeit heterogeneous, disorder with a highly variable severity and prognosis. Children with autism spectrum disorder and IQs above 70 with average adaptive skills, who develop communicative language by ages 5 to 7 years, have the best prognoses. A longitudinal study comparing symptoms in children with high-IQ autism spectrum disorder at the age of 5 years, with their symptoms at age 13 through young adulthood, found that a small proportion no longer met criteria for autism spectrum disorder. Most of these youth demonstrated positive changes in communication and social domains over time. Early intensive behavioral interventions have been found to provide a profound positive impact on many children with autism spectrum disorder, and in some cases lead to recovery and function in the average range.

The autism spectrum disorder symptom areas that do not seem to improve substantively over time with early behavioral interventions are related to ritualistic and repetitive behaviors. However, currently, evidence-based behavioral interventions specifically targeting repetitive behaviors may ameliorate them. The prognosis of a given child with autism spectrum disorder is generally improved if the home environment is supportive.

**TREATMENT**

The goals of treatment for children with autism spectrum disorder are to target core behaviors to improve social interactions, communication, broaden strategies to integrate into schools, develop meaningful peer relationships, and increase long-term skills in independent living. Psychosocial treatment interventions aim to help children with autism spectrum disorder to develop skills in social conventions, increase socially accept-
acquisition, and for parents, may be administered at a lower intensity such as weekly; however, once parents are trained, the interventions occur throughout the day with the child. Another example of a parent training approach is the Hanen More Than Words Program.

Social Skills Approaches

1. Social Skills Training. Typically provided by therapeutic leaders to children of various ages in a group setting with peers; children are given guided practice in initiating social conversation, greetings, initiating games, and joint attention. Emotion identification and regulation are often included in practice with recognizing and learning how to label emotions in given social situations, learning to attribute appropriate emotional reactions in others, and social problem-solving techniques. The goals are that with practice in the group setting, the child will be able to use the techniques in less-structured settings and internalize strategies to interact positively with peers.

Behavioral Interventions (BI) and Cognitive-Behavioral Therapy (CBT) for Repetitive Behaviors and Associated Symptoms

1. Behavioral Therapy. Applied behavioral analysis has been found to be somewhat effective in reducing some repetitive behaviors in children and adolescents with autism spectrum disorder. Early intervention is recommended for repetitive behaviors that are self-injurious; behavioral interventions may need to be combined with pharmacologic treatments to adequately manage the symptoms.

2. Cognitive-Behavioral Therapy. There is a significant evidence base from RCTs for the efficacy of CBT for symptoms of anxiety, depression, and obsessive-compulsive disorders in children. There are fewer controlled trials of this treatment in children with autism spectrum disorder, although there are at least two published studies in which CBT was used to treat repetitive behavior in individuals with autism spectrum disorder.

Interventions for comorbid symptoms in autism spectrum disorder

1. Neurofeedback. This modality has been administered in an attempt to influence symptoms of attention-deficit/hyperactivity disorder (ADHD), anxiety, and increased social interaction by providing computer games or other games in which the desired behavior is reinforced, while the child wears electrodes that monitor electrical activity in the brain. The aim is to influence brainwave activity to prolong or produce electrical activity present during the desired behaviors. This modality is still under investigation in the treatment of symptoms in autism spectrum disorder.

2. Management of insomnia in autism spectrum disorder. Insomnia is a prevalent concern among children and adolescents with autism spectrum disorder, and both behavioral and pharmacologic interventions may be administered to improve this condition. The most common behavioral intervention for insomnia in autism spectrum disorder is based on changing the parents behavior first toward the child at bedtime and throughout the night, such that there is a removal of reinforcement and attention for being awake, leading to a gradual extinction of the "staying awake" behavior. Several studies using massage therapy before bedtime in children with autism spectrum disorder between the ages of 2 years and 13 years provided an improvement in falling asleep and a sense of relaxation.

Educational interventions for children with autism spectrum disorder

1. Treatment and Education of Autistic and Communication-related Handicapped children (TEACCH). Originally developed at the University of North Carolina at Chapel Hill in the 1970s, TEACCH involves structured teaching based on the notion that children with autism spectrum disorder have difficulty with perception, and so this teaching method incorporates many visual supports and a picture schedule to aid in teaching academic subjects as well as socially appropriate responses. The physical environment is arranged to support visual learning, and the day is structured to promote autonomy and social relatedness.

2. Broad-based approaches. These educational plans include a blend of teaching strategies that use behavioral analysis and also focus on language remediation. Behavioral reinforcement is provided for socially acceptable behaviors while academic subjects are being taught. TEACCH may also be incorporated into a broader special educational program for autism spectrum disorder.

3. Computer-based approaches and virtual reality. Computer-based approaches and virtual reality teaching are centered on using computer-based programs, games, and interactive programs to teach language acquisition and reading skills. This provides the child with a sense of mastery and delivers a behaviorally based instruction in a modality that is appealing for the child. The Let's Face It! program is a computerized game that helps to teach children with autism spectrum disorder to recognize faces. It consists of seven interactive computer games that target changes in facial expression, attention to the eye region of the face, holistic face recognition, and identifying emotional expression. A randomized controlled trial of use of this program with children with autism spectrum disorder provided evidence that after 20 hours of face training with Let's Face It!, compared to the control group, the trained children demonstrated improvement in their ability to focus on the eye region of a face and improved their analytic and holistic face-processing skills. Several studies using virtual reality environments to teach children with autism spectrum disorder social skills and interaction have provided evidence of their value. In one study, a virtual café for children with autism spectrum disorder allowed the children to practice ordering and paying for drinks and food by navigation with the use of a computer mouse.

Psychopharmacological Interventions

Psychopharmacological interventions in autism spectrum disorder are mainly directed at ameliorating impairing associated behavioral symptoms rather than core features of autism spectrum disorder. Target symptoms include irritability, broadly
Irritability. Two second-generation antipsychotics, risperidone and aripiprazole, have been approved by the Food and Drug Administration (FDA) in the United States for treatment of irritability in individuals with autism spectrum disorder. Risperidone, a high-potency antipsychotic with combined dopamine (D₃) and serotonin (5-HT₂) receptor antagonist properties, has been shown to subdue aggressive or self-injurious behaviors in children with and without autism spectrum disorder. Starting with the National Institutes of Health supported Research Units on Pediatric Psychopharmacology randomized controlled trial of risperidone for treating irritability in autism spectrum disorder in 2002, there have been seven randomized controlled trials, three reanalysis studies, and two add-on studies, which have converged to confirm risperidone as an efficacious pharmacological treatment for irritability in children and adolescents with autism spectrum disorder in doses ranging from 0.5 mg to 1.5 mg. Some of the preschoolers in this study were also receiving intensive behavioral treatments. Risperidone is considered the first-line of medication treatment for children and adolescents with autism spectrum disorder who exhibit severe irritability. Despite its efficacy, risperidone's main side effects of weight gain and increased appetite; metabolic side effects such as hyperglycemia, prolactin elevation, and dyslipidemia; along with other common adverse effects such as fatigue, drowsiness, dizziness, and drooling have limited its use in some individuals. Risperidone should be used with caution in individuals with underlying cardiac abnormalities or hypotension, since risperidone may contribute to orthostatic hypotension. In further continuation studies of risperidone in the treatment of irritability in autism spectrum disorder, persistent efficacy and tolerability were found over a 6-month period, with a rapid return of symptoms in good responders when the risperidone was discontinued. Other drugs studied in the treatment of irritability in autism spectrum disorder include aripiprazole and olanzapine.

Two large studies utilizing aripiprazole in the treatment of tantrums, aggression, and self-injury in children and adolescents with autism spectrum disorder found that aripiprazole was both efficacious and safe. Doses ranged from 5 mg to 15 mg per day. Main side effects included sedation, dizziness, insomnia, akathisia, nausea, and vomiting. Although weight gain was not as pronounced as with risperidone, it was still considered a moderate adverse event, with approximately 1.3 to 1.5 kg gained during an 8-week study period. The weight gain was similar at the lower and higher doses. Olanzapine, which specifically blocks 5-HT₂A and D₂ receptors and also blocks muscarinic receptors, has been studied in children and adolescents with autism spectrum disorder for the treatment of irritability with a trend toward a positive response; however, significant weight gain of approximately 3.5 kg occurred. The main side effect was sedation.

Hyperactivity, Impulsivity, and Inattention. Several randomized placebo-controlled trials of methylphenidate have been conducted for the treatment of hyperactivity, impulsivity, and inattention in children and adolescents with autism spectrum disorder. The Research Units of Pediatric Psychopharmacology found methylphenidate to be at least moderately efficacious at doses of 0.25 to 0.5 mg/kg for youth with autism spectrum disorder and ADHD symptoms. Efficacy of methylphenidate in this population was less effective than in children with ADHD without autism spectrum disorder, and children with autism spectrum disorder developed more frequent side effects, including increased irritability, compared to ADHD children. A study of methylphenidate in the treatment of hyperactivity and inattention in preschoolers with autism spectrum disorder found the stimulant safe and relatively efficacious; half of the preschoolers developed side effects including increased stereotypes, gastrointestinal upset, sleep problems, and emotional lability. Among nonstimulants, one double-blind placebo-controlled study of hyperactivity, impulsivity, and inattention using atomoxetine in children with autism spectrum disorder found that it was significantly more effective than placebo. Side effects included sedation, irritability, constipation, and nausea. Clonidine, an α-agonist has also been studied in children with autism spectrum disorder for the treatment of hyperactivity with mixed results. Guanfacine was also found to be of use in some cases.

Repetitive and Stereotypic Behavior. These core symptoms of autism spectrum disorder have been studied using selective serotonin reuptake inhibitor (SSRI) antidepressants, second-generation antipsychotics (SGAs), and mood-stabilizing agents such as valproate. One study with fluoxetine found the medication group only slightly better and not significantly better than the placebo group regarding the target symptoms, and another trial with escitalopram found no difference between groups. Risperidone, however, was found to be effective in targeting irritability, and restrictive and repetitive behaviors were improved. One recent study using valproate in a 12-week trial with 55 children with a mean age of 9½ years with autism spectrum disorder, found that those who were considered responders with respect to irritability were also found to be spending less time engaging in repetitive behaviors.

Agents Administered For Behavioral Impairment In Autism Spectrum Disorder Based On Open Trials. Quetiapine is an antipsychotic with more potent 5-H₂ than D₂ receptor blocking properties. Although only open-label trials have been done with this agent, it is sometimes tried when risperidone and olanzapine are not efficacious or well tolerated. It has been used in clinical practice at doses ranging from 50 to 200 mg per day. Adverse effects include drowsiness, tachycardia, agitation, and weight gain.

Ziprasidone has receptor-blocking properties at the 5-HT₂A and D₂ receptor sites and carries little risk of extrapyramidal and antihistaminic effects. No guidelines exist for its use in autistic children with aggressive and self-injurious behaviors, but it has been used clinically to treat the latter behaviors in children
who are treatment resistant. In studies of its use in adults with schizophrenia, dose ranges of 40 to 160 mg were found to be effective. Adverse effects include sedation, dizziness, and light-headedness. An electrocardiography (ECG) recording is generally obtained before use of this medication.

Lithium (Eskalith) has been shown to be efficacious in children with aggression without autism spectrum disorder, and it is used clinically in the treatment of aggressive or self-injurious behaviors when antipsychotic medications are not effective.

**Agents Used For Behavioral Impairment In Autism Spectrum Disorder Without Efficacy Of Efficacy**

A double-blind study investigated the efficacy of amantadine (Symmetrel), which blocks N-methyl-d-aspartate (NMDA) receptors, in the treatment of behavioral disturbance, such as irritability, aggression, and hyperactivity, in children with autism. Some researchers have suggested that abnormalities of the glutamatergic system may contribute to the emergence of autism spectrum disorders. High glutamate levels have been found in children with the formerly labeled Rett syndrome. In the amantadine study, 47 percent of children on amantadine were rated “improved” by their parents, and 37 percent of children on placebo were rated “improved” by parents in irritability and hyperactivity, although this difference was not statistically significant. Investigators rated the children on amantadine “significantly improved” with respect to hyperactivity. A double-blind, placebo-controlled study of the efficacy of the anticonvulsant lamotrigine (Lamictal) on hyperactivity in children with autism showed high rates of placebo improvement in ratings of hyperactivity, which were similar to response to the medication.

Clomipramine (Anafranil) has been used in autism spectrum disorder, without RCTs to provide evidence of positive results. Fenfluramine (Pondimin), which reduces blood serotonin levels, has also been used unsuccessfully in the treatment of autism. Improvement does not seem to be associated with a reduction in blood serotonin level. Naltrexone (ReVia), an opioid receptor antagonist, has been investigated without much success, based on the notion that blocking endogenous opioids would reduce autistic symptoms.

Tetrahydrobiopterin, a coenzyme that enhances the action of enzymes was used in a double-blind placebo-controlled crossover study of 12 children with autistic disorder and low concentrations of spinal tetrahydrobiopterin. The children received a daily dose of 3 mg tetrahydrobiopterin per kilogram during a 6-month period alternating with placebo. Results indicated small, nonsignificant changes in the total scores on the Childhood Autism Rating Scale after 3- and 6-month treatment. Post hoc analysis of the three core symptoms of autism—social interaction, communication, and stereotyped behaviors—revealed a significant improvement in social interaction score after 6 months of active treatment. A positive correlation was noted between social response and IQ. These results suggest that there is a possible effect of tetrahydrobiopterin on the social functioning of children with autism.

A recent case report suggested that low-dose venlafaxine (Effexor) was efficacious in three adolescents and young adults with autistic disorder with self-injurious behavior and hyperactivity. Dose of venlafaxine used was 18.75 mg per day, and efficacy was reported to be sustained over a 6-month period.

**Complementary and Alternative Medicine (CAM) Approaches to Autism Spectrum Disorder**

Complementary and alternative medicine (CAM) is a group of nontraditional treatments that are generally used in conjunction with conventional treatments. Safe interventions that have been applied to target both core and associated behavioral features of autism spectrum disorder with unknown efficacy include the following: music therapy, to promote communication and expression; and yoga, to promote attention and decrease activity level. A biologically based practice that is deemed safe and shown to be efficacious is melatonin, which is effective in reducing sleep-onset latency in children. Other biological practices that are recognized as safe but with unknown efficacy include vitamin C, multivitamins, essential fatty acids, and the amino acids carnosine and creatine. Secretin has been shown to be ineffective in RCTs in the treatment of autism spectrum disorder.

**DISORDERS INCLUDED IN AUTISTIC SPECTRUM DISORDER**

The autistic spectrum covers a range of behaviors which, prior to the change in the DSM-5 were listed separately, and which are now no longer diagnosed as separate entities in the diagnostic manual. Nevertheless, the descriptive value of these entities remains important, and it may be some time before the disorders described herein disappear from the psychiatric lexicon. In addition, they remain in use in Europe and around the world as useful diagnostic entities and are still coded as separate disorders in ICD-10 as discussed.

**International Classification of Diseases, Tenth Edition (ICD-10)**

The classification system used in International Classification of Diseases, Tenth Revision (ICD-10) is not congruent with the revisions made in DSM-5 about autistic disorders. ICD-10 still includes separate designations for Rett syndrome, Childhood Disintegrative Disorder, Asperger’s Disorder, and Pervasive Development Disorder Not Otherwise Specified (Table 31.5-4). The authors of Synopsis believe these subtypes to be clinically useful, and each is described below. The reader should be aware, however, that according to DSM-5, each is subsumed under the rubric of Autism Spectrum Disorder and should so be diagnosed.

**Rett Syndrome**

In 1965, Andreas Rett, an Australian physician, identified a syndrome in 22 girls who appeared to have developed normally for at least 6 months followed by devastating developmental deterioration. Rett syndrome is a progressive condition that has its onset after some months of what appears to be normal development. Head circumference is normal at birth and developmental milestones are unremarkable in early life. Between 5 and 48 months of age, generally between 6 months and 1 year, head growth begins to decelerate.
Table 31.5-4
ICD-10 Diagnostic Criteria for Pervasive Developmental Disorders

**Childhood autism**

A. Abnormal or impaired development is evident before the age of 3 years in at least one of the following areas:

1. receptive or expressive language as used in social communication;
2. the development of selective social attachments or of reciprocal social interaction;
3. functional or symbolic play.

B. A total of at least six symptoms from (1), (2), and (3) must be present, with at least two from (1) and at least one from each of (2) and (3):

1. Qualitative abnormalities in reciprocal social interaction are manifest in at least two of the following areas:
   a. failure adequately to use eye-to-eye gaze, facial expression, body posture, and gesture to regulate social interaction;
   b. failure to develop (in a manner appropriate to mental age, and despite ample opportunities) peer relationships that involve a mutual sharing of interests, activities, and emotions;
   c. lack of socioemotional reciprocity as shown by an impaired or deviant response to other person's emotions; or lack of modulation of behavior according to social context; or a weak integration of social, emotional, and communicative behaviors;
   d. lack of spontaneous seeking to share enjoyment, interests, or achievements with other people (e.g., a lack of showing, bringing, or pointing out to other people objects of interest to the individual).

2. Qualitative abnormalities in communication are manifest in at least one of the following areas:
   a. a delay in, or total lack of, development of spoken language that is not accompanied by an attempt to compensate through the use of gesture or mime as an alternative mode of communication (often preceded by a lack of communicative babbling);
   b. relative failure to initiate or sustain conversational interchange (at whatever level of language skills is present), in which there is reciprocal responsiveness to the communications of the other person;
   c. stereotyped and repetitive use of language or idiosyncratic use of words or phrases;
   d. lack of varied spontaneous make-believe or (when young) social imitative play.

3. Restricted, repetitive, and stereotyped patterns of behavior, interests, and activities are manifest in at least one of the following areas:
   a. an encompassing preoccupation with one or more stereotyped and restricted patterns of interest that are abnormal in content or focus; or one or more interests that are abnormal in their intensity and circumscribed nature though not in their content or focus;
   b. apparently compulsive adherence to specific, nonfunctional routines or rituals;
   c. stereotyped and repetitive motor mannerisms that involve either hand or finger flapping or twisting, or complex whole body movements;
   d. preoccupations with part-objects or nonfunctional elements of play materials (such as their odor, the feel of their surface, or the noise or vibration that they generate).

C. The clinical picture is not attributable to the other varieties of pervasive developmental disorder: specific developmental disorder of receptive language with secondary socioemotional problems; reactive attachment disorder or disinhibited attachment disorder, mental retardation with some associated emotional or behavioral disorder; schizophrenia of unusually early onset; and Rett's syndrome.

**Atypical autism**

A. Abnormal or impaired development is evident at or after the age of 3 years (criteria as for autism except for age of manifestation).

B. There are qualitative abnormalities in reciprocal social interaction or in communication, or restricted, repetitive, and stereotyped patterns of behavior, interests, and activities. (Criteria as for autism except that it is unnecessary to meet the criteria for number of areas of abnormality.)

C. The disorder does not meet the diagnostic criteria for autism. Autism may be atypical in either age of onset or symptomatology; the two types are differentiated with a fifth character for research purposes. Syndromes that are atypical in both respects should be coded. Atypicality in both ages of onset and symptomatology.

**Atypicality in age of onset**

A. The disorder does not meet Criterion A for autism; that is, abnormal or impaired development is evident only at or after the age of 3 years.

B. The disorder meets Criteria B and C for autism.

**Atypicality in symptomatology**

A. The disorder meets Criterion A for autism; that is, abnormal or impaired development is evident before the age of 3 years.

B. There are qualitative abnormalities in reciprocal social interactions or in communication, or restricted, repetitive, and stereotyped patterns of behavior, interests, and activities. (Criteria as for autism except that it is unnecessary to meet the criteria for number of areas of abnormality.)

C. The disorder meets Criterion C for autism.

D. The disorder does not fully meet Criterion B for autism.

**Atypicality in both age of onset and symptomatology**

A. The disorder does not meet Criterion A for autism; that is, abnormal or impaired development is evident only at or after the age of 3 years.

B. There are qualitative abnormalities in reciprocal social interactions or in communication, or restricted, repetitive, and stereotyped patterns of behavior, interests, and activities. (Criteria as for autism except that it is unnecessary to meet the criteria for number of areas of abnormality.)

C. The disorder meets Criterion C for autism.

D. The disorder does not fully meet Criterion B for autism.
A. Development is apparently normal up to the age of at least 2 years. The presence of normal age-appropriate skills in communication, social relationships, play, and adaptive behavior at age 2 years or later is required for diagnosis.

B. There is a definite loss of previously acquired skills at about the time of onset of the disorder. The diagnosis requires a clinically significant loss of skills (not just a failure to use them in certain situations) in at least two of the following areas:

1. expressive or receptive language;
2. play;
3. social skills or adaptive behavior;
4. bowel or bladder control;
5. motor skills.

C. Qualitatively abnormal social functioning is manifest in at least two of the following areas:

1. qualitative abnormalities in reciprocal social interaction (of the type defined for autism);
2. qualitative abnormalities in communication (of the type defined for autism);
3. restricted, repetitive, and stereotyped patterns of behavior, interests, and activities, including motor stereotypies and mannerisms;
4. a general loss of interest in objects and in the environment.

D. The disorder is not attributable to the other various pervasive developmental disorders; acquired aphasia with epilepsy; elective mutism; Rett's syndrome; or schizophrenia.

Overactive disorder associated with mental retardation and stereotyped movements

A. Severe motor hyperactivity is manifest by at least two of the following problems in activity and attention:

1. continuous motor restlessness, manifest in running, jumping, and other movements of the whole body;
2. marked difficulty in remaining seated; the child will ordinarily remain seated for a few seconds at most except when engaged in a stereotypic activity (see Criterion B);
3. grossly excessive activity in situations where relative stillness is expected;
4. very rapid changes of activity, so that activities generally last for less than a minute (occasional longer periods spent in highly favored activities do not exclude this, and very long periods spent in stereotypic activities can also be compatible with the presence of this problem at other times).

B. Repetitive and stereotyped patterns of behavior and activity are manifest by at least one of the following:

1. fixed and frequently repeated motor mannerisms: these may involve either complex movements of the whole body or partial movements such as hand-flapping;
2. excessive and nonfunctional repetition of activities that are constant in form: this may be play with a single object (e.g., running water) or a ritual of activities (either alone or involving other people);
3. repetitive self-injury.

C. IQ is less than 50.

D. There is no social impairment of the autistic type, i.e., the child must show at least three of the following:

1. developmentally appropriate use of eye gaze, expression, and posture to regulate social interaction;
2. developmentally appropriate peer relationships that include sharing of interests, activities, etc.;
3. approaches to other people, at least sometimes, for comfort and affection;
4. ability to share other people's enjoyment at times; other forms of social impairment, e.g., a disinhibited approach to strangers, are compatible with the diagnosis.

E. The disorder does not meet diagnostic criteria for autism, childhood disintegrative disorder, or hyperkinetic disorders.

Asperger's syndrome

A. There is no clinically significant general delay in spoken or receptive language or cognitive development. Diagnosis requires that single words should have developed by 2 years of age or earlier and that communicative phrases be used by 3 years of age or earlier. Self-help skills, adaptive behavior, and curiosity about the environment during the first 3 years should be at a level consistent with normal intellectual development. However, motor milestones may be somewhat delayed and motor clumsiness is usual (although not a necessary diagnostic feature). Isolated special skills, often related to abnormal preoccupations, are common, but are not required for diagnosis.

B. There are qualitative abnormalities in reciprocal social interaction (criteria as for autism).

C. The individual exhibits an unusually intense, circumscribed interest or restricted, repetitive, and stereotyped patterns of behavior, interests, and activities (criteria as for autism); however, it would be less usual for these to include either motor mannerisms or preoccupations with part-objects or nonfunctional elements of play materials.

D. The disorder is not attributable to the other various pervasive developmental disorder: simple schizophrenia; schizotypal disorder; obsessive-compulsive disorder; anankastic personality disorder; reactive and disinhibited attachment disorders of childhood.

Other pervasive developmental disorders

Pervasive developmental disorder, unspecified

This is a residual diagnostic category that should be used for disorders which fit the general description for pervasive developmental disorders but in which contradictory findings or a lack of adequate information mean that the criteria for any of the other pervasive developmental disorders codes cannot be met.

(From World Health Organization. The ICD-10 Classification of Mental and Behavioral Disorders: Diagnostic Criteria for Research. Copyright, World Health Organization, Geneva, 1993, with permission.)

1165
Available data indicate a prevalence of 6 to 7 cases of Rett syndrome per 100,000 girls. Originally, it was believed that Rett syndrome occurred only in females, but males with the disorder or syndromes that are very close to this disorder have now been described. Rett syndrome is not fully included within autism spectrum disorder, and if present along with autism spectrum disorder it should be diagnosed as an associated disorder.

**Etiology.** The cause of Rett syndrome is unknown, although the progressive deteriorating course after an initial normal period is compatible with a metabolic disorder. In some patients with Rett syndrome, the presence of hyperammonemia has led to postulation that an enzyme metabolizing ammonia is deficient, but hyperammonemia has not been found in most patients with Rett syndrome. It is likely that Rett syndrome has a genetic basis. It has been seen primarily in girls, and case reports so far indicate complete concordance in monozygotic twins.

**Diagnosis and Clinical Features.** During the first 5 months after birth, infants have age-appropriate motor skills, normal head circumference, and normal growth. Social interactions show the expected reciprocal quality. At 6 months to 2 years of age, however, these children develop progressive encephalopathy with a number of characteristic features. The signs often include the loss of purposeful hand movements, which are replaced by stereotypic motions, such as hand-wringer; the loss of previously acquired speech; psychomotor retardation; and ataxia. Other stereotypical hand movements may occur, such as licking or biting the fingers and tapping or slapping. The head circumference growth decelerates and produces microcephaly. All language skills are lost, and both receptive and expressive communicative and social skills seem to plateau at developmental levels between 6 months and 1 year. Poor muscle coordination and an apraxic gait with an unsteady and stiff quality develop.

Associated features include seizures in up to 75 percent of affected children and disorganized EEG findings with some epileptiform discharges in almost all young children with Rett syndrome, even in the absence of clinical seizures. An additional associated feature is irregular respiration, with episodes of hyperventilation, apnea, and breath holding. The disorganized breathing occurs in most patients while they are awake; during sleep, the breathing usually normalizes. Many patients with Rett syndrome also have scoliosis. As the disorder progresses, muscle tone seems to change from an initial hypotonic condition to spasticity to rigidity.

Although children with Rett syndrome may live for well over a decade after the onset of the disorder, after 10 years, many patients are wheelchair-bound, with muscle wasting, rigidity, and virtually no language ability. Long-term receptive and expressive communication and socialization abilities remain at a developmental level of less than 1 year.

Dana was born as a full-term and healthy baby term after an uncomplicated pregnancy. An amniocentesis had been obtained because of advanced maternal age of 40 years, and findings were normal. At birth, Dana received good Apgar scores and her weight, height, and head circumference were all near the 50th percentile. Her development during the first months of life was unremarkable. At approximately 8 months of age, her development seemed to wane, and her interest in the environment, including the social environment, declined. Dana's developmental milestones failed to progress, and she became markedly delayed; she was just starting to walk at her second birthday and had no spoken language. Evaluation at that time revealed that head growth had decelerated. Self-stimulatory behaviors emerged, and in addition, marked cognitive and communicative delays were noted on formal testing. Dana began to lose purposeful hand movements and developed unusual stereotypical hand-washing behaviors. By age 6, her EEG was abnormal and abnormal hand movements were prominent. Subsequently, Dana developed truncal ataxia and breath-holding spells, and motor skills further deteriorated. (Adapted from Fred Volkmar, M.D.)

**Differential Diagnosis.** Rett syndrome shares some features with autism spectrum disorder; however, the two disorders have some predictable differences. In Rett syndrome, there is deterioration of developmental milestones, head circumference, and overall growth, whereas in autism spectrum disorder, aberrant development is usually present from early on. In Rett syndrome, specific and characteristic hand motor movements are always present; in autism spectrum disorder hand mannerisms may or may not appear. Poor coordination, ataxia, and apraxia are predictably part of Rett syndrome; however, individuals with autism spectrum disorder may have unremarkable gross motor function. In Rett syndrome, verbal abilities are usually lost completely, whereas in autism spectrum disorder language is widely variable from markedly aberrant to relatively mildly impaired. Respiratory irregularity is characteristic of Rett syndrome, and seizures often appear early. In autistic disorder, no respiratory disorganization is seen, and seizures do not develop in most patients; when seizures do develop, they are more likely in adolescence than in childhood. For autism spectrum disorder that is associated with another neurodevelopmental disorder such as Rett syndrome, the latter disorder is diagnosed in association with autism spectrum disorder.

**Course and Prognosis.** Rett syndrome is progressive, and those individuals who live into adolescence and adulthood function at a cognitive and social level equivalent to that in the first year of life.

**Treatment.** Treatment is symptomatic. Physiotherapy has been beneficial for the muscular dysfunction, and anticonvulsant treatment is usually necessary to control the seizures. Behavior therapy, along with medication, may help control self-injurious behaviors, as it does in the treatment of autistic disorder, and it may help regulate the breathing disorganization.

**Childhood Disintegrative Disorder**

The previous diagnosis of childhood disintegrative disorder, now included in autism spectrum disorder, is characterized by marked regression in several areas of functioning after at least 2 years of apparently normal development. Childhood disintegrative disorder, also called Heller's syndrome and disintegrative psychosis, was described in 1908 as a deterioration over
s several months of intellectual, social, and language function occurring in 3- and 4-year-olds with previously normal function. After the deterioration, the children closely resembled children with autistic disorder.

**Epidemiology.** Epidemiological data have been complicated by the variable diagnostic criteria used, but childhood disintegrative disorder is estimated to be much less common than the formerly diagnosed autistic disorder. The prevalence has been estimated to occur in about 1 in 100,000 boys. The ratio of boys to girls is estimated to be between 4 and 8 boys to 1 girl.

**Etiology.** The cause of childhood disintegrative disorder is unknown, but it has been associated with other neurological conditions, including seizure disorders, tuberous sclerosis, and various metabolic disorders.

**Diagnosis and Clinical Features.** The diagnosis is made based on features that fit a characteristic age of onset, clinical picture, and course. Cases reported have ranged in onset from ages 1 to 9 years, but in most, the onset is between 3 and 4 years. Whereas previously diagnosed as a separate entity, DSM-5 conceives of childhood disintegrative disorder as a subset of autism spectrum disorder. The onset may be insidious over several months or relatively abrupt, with abilities diminishing in days or weeks. In some cases, a child displays restlessness, increased activity level, and anxiety before the loss of function. The core features of the disorder include loss of communication skills, marked regression of reciprocal interactions, and the onset of stereotyped movements and compulsive behavior. Affective symptoms are common, particularly anxiety, as is the regression of self-help skills, such as bowel and bladder control.

To receive the diagnosis, a child must exhibit loss of skills in two of the following areas: language, social or adaptive behavior; bowel or bladder control; play; and motor skills. Abnormalities must be present in both of the following categories: reciprocal social communication skills, and restricted and repetitive behavior. The main neurological associated feature is seizure disorder.

Ron’s early history was within normal limits. By age 2, he was speaking in sentences, and his development appeared to be proceeding appropriately. At 3½ years of age, he abruptly exhibited a period of marked behavioral regression shortly after the birth of a sibling. Ron lost previously acquired skills in communication and was no longer toilet trained. Ron became more withdrawn and less interested in social interaction, exhibiting various self-stimulatory behaviors repeatedly. Comprehensive medical examination failed to reveal any conditions that might account for this developmental regression. Behaviorally, Ron exhibited features of autism spectrum disorder. At follow-up at age 12, he spoke only an occasional single word and had severe mental retardation. (Adapted from Fred Volkmar, M.D.)

**Differential Diagnosis.** The differential diagnosis of the formerly diagnosed childhood disintegrative disorder includes receptive and expressive language disorder, mental retardation with behavioral problems, and Rett syndrome. Childhood disintegrative disorder is characterized by the loss of previously acquired development. Before the onset of childhood disintegrative disorder (occurring at 2 years or older), language has usually progressed to sentence formation. This skill is strikingly different from the premorbid history of even high-functioning patients with autistic disorder, in whom language generally does not exceed single words or phrases before diagnosis of the disorder. Once the disorder occurs, however, those with childhood disintegrative disorder are more likely to have no language abilities than are high-functioning patients with autistic disorder. In Rett syndrome, the deterioration occurs much earlier than in childhood disintegrative disorder, and the characteristic hand stereotypes of Rett syndrome do not occur in childhood disintegrative disorder.

**Course and Prognosis.** The course of childhood disintegrative disorder is variable, with a plateau reached in most cases, a progressive deteriorating course in rare cases, and some improvement in occasional cases to the point of regaining the ability to speak in sentences. Most patients are left with at least moderate mental retardation.

**Treatment.** Treatment of childhood disintegrative disorder includes the same components available in the treatment of autistic disorder.

**Asperger’s Disorder**

The former diagnosis of Asperger’s disorder is characterized by impairment and oddity of social interaction and restricted interest and behavior. Unlike the former autistic disorder, in Asperger’s disorder there are no significant delays in language or cognitive development. In 1944, Hans Asperger, an Austrian physician, described a syndrome that he named “autistic psychopathy.” His original description of the syndrome described individuals with normal intelligence who exhibit a qualitative impairment in reciprocal social interaction and behavioral oddities without delays in language development. Asperger’s disorder occurs in a wide variety of severities, including cases in which very subtle social cues are missed, but overall social interactions are mastered.

**Etiology.** Asperger’s disorder, a version of autism spectrum disorder, has a complex etiology including genetic contribution and potentially environmental and perinatal contributing factors.

**Diagnosis and Clinical Features.** The clinical features include at least two of the following indications of qualitative social impairment: Markedly abnormal nonverbal communicative gestures, the failure to develop peer relationships at the expected level. Restricted interests and patterns of behavior are present, but when they are subtle, they may not be immediately identified or singled out as different from those of other children. According to DSM-IV-TR, individuals with Asperger’s disorder exhibit no language delay, clinically significant cognitive delay, or adaptive impairment. Currently, the clinical phenotype of Asperger’s disorder is subsumed within the DSM-5 diagnosis of autism spectrum disorder.
Differential Diagnosis. The differential diagnosis includes social anxiety disorder, obsessive-compulsive disorder, and schizoid personality disorder. According to the previous DSM-IV-TR, the most obvious characteristics of Asperger's disorder compared to autistic disorder are the absence of language delay and dysfunction. The lack of language delay and impaired use of language were previous requirements for Asperger's disorder; however, social and communication deficits are present. Studies comparing children with Asperger's disorder and autistic disorder found that children with Asperger's disorder were more likely to seek social interaction, and due to their awareness of their impairment sought more vigorously to make friends. Although in this subgroup within autism spectrum disorder significant delay in language is not a feature, some delay in the acquisition of language, and some impairment in verbal communication has been noted in more than one third of clinical samples.

Course and Prognosis. The factors associated with a good prognosis in this subgroup within autism spectrum disorder are a normal IQ and more competencies in social skills. Reports of some adults diagnosed with Asperger's disorder indicate that their social and communication deficits remain and they continue to relate in an awkward way and appear socially uncomfortable.

Treatment. Treatment of individuals who meet the criteria for the previous Asperger's disorder diagnosis aims to promote social communication and peer relationships. Interventions are initiated with the goal of shaping interactions so that they better match those of peers. Very often children with Asperger's disorder are highly verbal and have excellent academic achievement. The tendency of children and adolescents with Asperger's disorder to rely on rigid rules and routines can become a source of difficulty for them and be an area that requires therapeutic intervention. A comfort with routines, however, can be utilized to foster positive habits that may enhance the social life of a child with Asperger's disorder. Self-sufficiency and problem-solving techniques are often helpful for these individuals in social situations and work settings. Some of the same techniques used for autistic disorder are likely to benefit patients with Asperger's disorder with severe social impairment.

Pervasive Developmental Disorder Not Otherwise Specified

Whereas the DSM-IV-TR defines pervasive disorder not otherwise specified as a condition with severe pervasive impairment in communication skills or the presence of restricted and repetitive activities and associated impairment in social interactions, DSM-5 conceives of this as encompassed within a diagnosis of autism spectrum disorder.

Anna was the older of two children. She had been a difficult baby who was not easy to console but her motor and communicative development seemed appropriate. She was socially related and sometimes enjoyed interaction, but she was easily overstimulated. She exhibited some hand flapping behavior, especially when she was excited. Anna's parents sought evaluation when she was 4 years of age because of problems with getting along with other children. At evaluation Anna was found to have language and cognitive function within the normal range. Anna had difficulty relating to her parents as sources of support and comfort. She displayed behavioral rigidity and a tendency to impose routines on social skills. Anna was placed in a special education kindergarten and did well academically, although problems in peer interactions and unusual affective responses persisted. As an adolescent, Anna describes herself as a "loner," who often retreats from others and avoids social interaction and tends to be comfortable with solitary activities. (Adapted from Fred Volkmar, M.D.)

Treatment. The treatment approach is identical to that of other autism spectrum disorder. Mainstreaming in school may be possible. Compared with previously diagnosed autistic children, those with the former pervasive developmental disorder not otherwise specified generally have less impairment in language skills and more self-awareness.

References

Attention-Deficit/Hyperactivity Disorder (ADHD) is a neurodevelopmental condition affecting schoolchildren, children, adolescents, and adults around the world, characterized by a pattern of diminished sustained attention, and increased impulsivity or hyperactivity. Based on family history, genotyping, and neuroimaging studies, there is clear evidence to support a biological basis for ADHD. Although multiple regions of the brain and several neurotransmitters have been implicated in the emergence of symptoms, dopamine continues to be a focus of investigation regarding ADHD symptoms. The prefrontal cortex of the brain has been implicated because of its high utilization of dopamine and its reciprocal connections with other brain regions involved in attention, inhibition, decision-making, response inhibition, working memory, and vigilance. ADHD affects up to 5 to 8 percent of school-aged children, with 60 to 85 percent of those diagnosed as children continuing to meet criteria for the disorder in adolescence, and up to 60 percent continuing to be symptomatic into adulthood. Children, adolescents, and adults with ADHD often have significant impairment in academic functioning as well as in social and interpersonal situations. ADHD is frequently associated with comorbid disorders including learning disorders, anxiety disorders, mood disorders, and disruptive behavior disorders.

The Fifth Edition of the American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders (DSM-5) has made several changes to the diagnostic criteria of ADHD in youth and in adults. Whereas in the past, ADHD symptoms had to be present by age 7 years, in DSM-5, “several inattentive or hyperactive-impulsive symptoms” must be present by age 12 years. Previously, there were two subtypes: Inattentive and Hyperactive/Impulsive type. In DSM-5, however, subtypes have been replaced by the following three specifiers, which essentially denote the same groups: (1) combined presentation, (2) predominantly inattentive presentation, and (3) predominantly hyperactive/impulsive presentation. Additional changes in DSM-5 include permitting a comorbid ADHD and autism spectrum diagnosis to be made. Finally, in DSM-5, for adolescents 17 years and older and for adults, only five symptoms, rather than six symptoms of either inattention or hyperactivity and impulsivity are required. In addition, to reflect the developmental differences in ADHD across the life span, examples of symptoms have been added to the DSM-5 criteria for ADHD. To confirm a diagnosis of ADHD, impairment from inattention and/or hyperactivity and impulsivity must be present in at least two settings and interfere with developmentally appropriate social or academic functioning. For current DSM-5 changes see Table 31.6-1.
A persistent pattern of inattention and/or hyperactivity-impulsivity that interferes with functioning or development, as characterized by (1) and/or (2):

1. **Inattention**: Six (or more) of the following symptoms have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities:

   **Note**: The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or failure to understand tasks or instructions. For older adolescents and adults (age 17 and older), at least five symptoms are required.

   a. Often fails to give close attention to details or makes careless mistakes in schoolwork, at work, or during other activities (e.g., overlooks or misses details, work is inaccurate).

   b. Often has difficulty sustaining attention in tasks or play activities (e.g., has difficulty remaining focused during lectures, conversations, or lengthy reading).

   c. Often does not seem to listen when spoken to directly (e.g., mind seems elsewhere, even in the absence of any obvious distraction).

   d. Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (e.g., starts tasks but quickly loses focus and is easily sidetracked).

   e. Often has difficulty organizing tasks and activities (e.g., difficulty managing sequential tasks; difficulty keeping materials and belonging in order; messy, disorganized work; has poor time management; fails to meet deadlines).

   f. Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (e.g., schoolwork or homework; for older adolescents and adults, preparing reports, completing forms, reviewing lengthy papers).

   g. Often loses things necessary for tasks or activities (e.g., school materials, pencils, books, tools, wallets, keys, paperwork, eyeglasses, mobile telephones).

   h. Is often easily distracted by extraneous stimuli (for older adolescents and adults, may include unrelated thoughts).

   i. Is often forgetful in daily activities (e.g., doing chores, running errands; for older adolescents and adults, returning calls, paying bills, keeping appointments).

2. **Hyperactivity and impulsivity**: Six (or more) of the following symptoms have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities:

   **Note**: The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or failure to understand tasks or instructions. For older adolescents and adults (age 17 and older), at least five symptoms are required.

   a. Often fidgets with or taps hands or feet or squirms in seat.

   b. Often leaves seat in situations when remaining seated is expected (e.g., leaves his or her place in the classroom, in the office or other workplace, or in other situations that require remaining in place).

   c. Often runs about or climbs in situations where it is inappropriate. (Note: In adolescents or adults, may be limited to feeling restless.)

   d. Often unable to play or engage in leisure activities quietly.

   e. Is often “on the go,” acting as if “driven by a motor” (e.g., is unable to be or uncomfortable being still for extended time, as in restaurants, meetings; may be experienced by others as being restless or difficult to keep up with).

   f. Often talks excessively.

   g. Often blurts out an answer before a question has been completed (e.g., completes people's sentences; cannot wait for turn in conversation).

   h. Often has difficulty waiting or her turn (e.g., while waiting in line).

   i. Often interrupts or intrudes on others (e.g., butts into conversations, games, or activities; may start using other people's things without asking or receiving permission; for adolescents and adults, may intrude into or take over what others are doing).

B. Several inattentive or hyperactive-impulsive symptoms were present prior to age 12 years.

C. Several inattentive or hyperactive-impulsive symptoms are present in two or more settings (e.g., at home, school, or work; with friends or relatives; in other activities).

D. There is clear evidence that the symptoms interfere with, or reduce the quality of, social, academic, or occupational functioning.

E. The symptoms do not occur exclusively during the course of schizophrenia or another psychotic disorder and are not better explained by another mental disorder (e.g., mood disorder, anxiety disorder, dissociative disorder, personality disorder, substance intoxication or withdrawal).

Specify whether:

- **314.01 (F90.2) Combined presentation**: If both Criterion A1 (inattention) and Criterion A2 (hyperactivity-impulsivity) are met for the past 6 months.

- **314.00 (F90.0) Predominantly inattentive presentation**: If Criterion A1 (inattention) is met but Criterion A2 (hyperactivity-impulsivity) is not met for the past 6 months.

- **314.01 (F90.1) Predominantly hyperactive/impulsive presentation**: If Criterion A2 (hyperactivity-impulsivity) is met and Criterion A1 (inattention) is not met for the past 6 months.

Specify if:

- **In partial remission**: When full criteria were previously met, fewer than the full criteria have been met for the past 6 months, and the symptoms still result in impairment in social, academic, or occupational functioning.

Specify current severity:

- **Mild**: Few, if any, symptoms in excess of those required to make the diagnosis are present, and symptoms result in no more than minor impairments in social or occupational functioning.

- **Moderate**: Symptoms or functional impairment between "mild" and "severe" are present.

- **Severe**: Many symptoms in excess of those required to make the diagnosis, or several symptoms that are particularly severe, are present, or the symptoms result in marked impairment in social or occupational functioning.

ADHD has historically been described in the literature using different terminology. In the early 1900s, impulsive, disinhibited, and hyperactive children—many of whom also had neurological damage due to encephalitis—were grouped under the label hyperactive syndrome. In the 1960s, a heterogeneous group of children with poor coordination, learning disabilities, and emotional liability, but without specific neurological disorders, were described as having “minimal brain damage”; however, over time, it became clear that this was an inappropriate term. Many hypotheses have been suggested to explain ADHD symptoms including theories of abnormal arousal and poor ability to modulate emotions. This theory was initially supported by the observation that stimulant medications increased sustained attention and improved focus. ADHD is one of the most well-researched childhood psychiatric disorders with strong evidence-based treatments.

Epidemiology

Rates of ADHD have been reported to be 7 to 8 percent in prepubertal elementary school children. Epidemiologic studies suggest that ADHD occurs in about 5 percent of youth including children and adolescents, and about 2.5 percent of adults. The rate of ADHD in parents and siblings of children with ADHD is 2 to 8 times greater than in the general population. ADHD is more prevalent in boys than in girls, with the ratio ranging from 2:1 to as high as 9:1. First-degree biological relatives (e.g., siblings of probands with ADHD) are at high risk for developing ADHD as well as other psychiatric disorders, including disruptive behavior disorders, anxiety disorders, and depressive disorders. Siblings of children with ADHD are also at higher risk than the general population for learning disorders and academic difficulties. The parents of children with ADHD show an increased incidence of substance use disorders. Symptoms of ADHD are often present by age 3 years, but unless they are very severe, the diagnosis is frequently not made until the child is in kindergarten, or elementary school, when teacher information is available comparing the index child peers of the same age.

Etiology

Data suggest that the etiology of ADHD is largely genetic, with a heritability of approximately 75 percent. ADHD symptoms are the product of complex interactions of neuroanatomical and neurochemical systems evidenced by data from twin and adoption family genetic studies, dopamine transport gene studies, neuroimaging studies, and neurotransmitter data. Most children with ADHD have no evidence of gross structural damage in the central nervous system (CNS). In some cases, contributory factors for ADHD may include prenatal toxic exposures, prematurity, and prenatal mechanical insult to the fetal nervous system. Food additives, colorings, preservatives, and sugar have been proposed as possible contributing causes of hyperactive behavior; however, studies have not confirmed these theories. Neither artificial food coloring nor sugar have been established as causes of ADHD. There is no clear evidence that omega-3 fatty acids are beneficial in the treatment of ADHD.

Genetic Factors. Evidence for a significant genetic contribution to ADHD has emerged from family studies, which reveal an increased concordance in monozygotic compared to dizygotic twins, as well as a marked increased risk of 2 to 8 times for siblings as well as parents of an ADHD child, compared to the general population. Clinically, one sibling may have predominantly impulsivity/hyperactivity symptoms and others may have predominantly inattention symptoms. Up to 70 percent of children with ADHD meet criteria for a comorbid psychiatric disorder, including learning disorders, anxiety disorders, mood disorder conduct disorders, and substance use disorders. Several hypotheses of the mode of transmission of ADHD have been proposed, including a sex-linked hypothesis, which would explain the significantly increased rates of ADHD in males. Other theories have focused on a model of interaction of multiple genes that produces the various symptoms of ADHD. Numerous investigations continue to identify specific genes involved in ADHD. Cook and colleagues have found an association of the dopamine transporter gene (DAT1) with ADHD, although data from other research groups have not confirmed that result. Family studies and population-based studies have found an association between the dopamine 4 receptor seven-repeat allele gene (DRD4) gene and ADHD. Most molecular research on ADHD has focused on genes that influence the metabolism or action of dopamine. Continued investigation is necessary to clarify the complex relationships between multiple interactive genes and the emergence of ADHD.

Neurochemical Factors. Many neurotransmitters are postulated to be associated with ADHD symptoms; however, dopamine is a major focus of clinical investigation, and the prefrontal cortex has been implicated based on its role in attention and regulation of impulse control. Animal studies have shown that other brain regions such as locus ceruleus, which consists predominantly of noradrenergic neurons, also play a major role in attention. The noradrenergic system includes the central system (originating in the locus ceruleus) and the peripheral sympathetic system. Dysfunction in peripheral epinephrine, which causes the hormone to accumulate peripherally, may potentially feed back to the central system and “reset” the locus ceruleus to a lower level. In part, hypotheses regarding the neurochemistry of ADHD have arisen from the predictable effect of medications. Stimulants, known to be the most effective medications in the treatment of ADHD, affect both dopamine and norepinephrine, leading to neurotransmitter hypotheses that may include dysfunction in both the adrenergic and dopaminergic systems. Stimulants increase catecholamine concentrations by promoting their release and blocking their uptake.

Neuropsychological Factors. EEG studies in ADHD children and adolescents over the last several decades have found evidence of increased theta activity, especially in the frontal regions. Further studies of youth with ADHD have provided data showing elevated beta activity in their electroencephalography (EEG) studies. Clarke and colleagues, studying EEG findings in children and adolescents over the last two decades found that those ADHD children with combined type of ADHD were the ones who showed significantly elevated beta activity on EEG, and further studies indicate that these youth also tend to show increased mood lability and temper tantrums. Current investigation of EEG in youth with ADHD have identified behavioral symptom clusters among children with similar EEG profiles.
Neuroanatomical Aspects. Researchers have hypothesized networks within the brain for promoting components of attention including focusing, sustaining attention, and shifting attention. They describe neuroanatomical correlations for the superior and temporal cortices with focusing attention; external parietal and corpus striatal regions with motor executive functions; the hippocampus with encoding of memory traces; and the prefrontal cortex with shifting from one stimulus to another. Further hypotheses suggest that the brainstem, which contains the reticular thalamic nuclei function, is involved in sustained attention. A review of magnetic resonance imaging (MRI), positron emission tomography (PET), and single photon emission computerized tomography (SPECT) suggests that populations of children with ADHD show evidence of both decreased volume and decreased activity in prefrontal regions, anterior cingulated, globus pallidus, caudate, thalamus, and cerebellum. PET scans have also shown that female adolescents with ADHD have globally lower glucose metabolism than both control female and male adolescents without ADHD. One theory postulates that the frontal lobes in children with ADHD do not adequately inhibit lower brain structures, an effect leading to disinhibition.

Developmental Factors. Higher rates of ADHD are present in children who were born prematurely and whose mothers were observed to have maternal infection during pregnancy. Perinatal insult to the brain during early infancy caused by infection, inflammation, and trauma may, in some cases, be contributing factors in the emergence of ADHD symptoms. Children with ADHD have been observed to exhibit nonfocal (soft) neurological signs at higher rates than those in the general population. Reports in the literature indicate that September is a peak month for births of children with ADHD and without comorbid learning disorders. The implication is that prenatal exposure to winter infections during the first trimester may contribute to the emergence of ADHD symptoms in some susceptible children.

Psychosocial Factors. Severe chronic abuse, maltreatment, and neglect are associated with certain behavioral symptoms that overlap with ADHD including poor attention and poor impulse control. Predisposing factors may include the child's temperament and genetic-familial factors.

Diagnosis

The principal signs of inattention, impulsivity, and hyperactivity may be elicited on the basis of a detailed history of a child's early developmental patterns along with direct observation of the child, especially in situations that require sustained attention. Hyperactivity may be more severe in some situations (e.g., school) and less marked in others (e.g., one-on-one interviews), and may be less obvious in pleasant structured activities (sports). The diagnosis of ADHD requires persistent, impairing symptoms of either hyperactivity/impulsivity or inattention in at least two different settings. For example, most children with ADHD have symptoms in school and at home. The diagnostic criteria for ADHD are outlined in Table 31.6-1.

Distinguishing features of ADHD are short attention span and high levels of distractibility for chronological age and developmental level. In school, children with ADHD often exhibit difficulties following instructions and require increased individualized attention from teachers. At home, children with ADHD frequently have difficulty complying with their parents' directions and may need to be asked multiple times to complete relatively simple tasks. Children with ADHD typically act impulsively, are emotionally labile, explosive, lack focus, and are irritable.

Children for whom hyperactivity is a predominant feature are more likely to be referred for treatment earlier than are children whose primarily symptoms are attention deficit. Children with the combined inattentive and hyperactive-impulsive symptoms of ADHD, or predominantly hyperactive-impulsive symptoms of ADHD, are more apt to have a stable diagnosis over time and to exhibit comorbid conduct disorder than those children with inattentive ADHD. Specific learning disorders in the areas of reading, arithmetic, language, and writing occur frequently in association with ADHD. Global developmental assessment must be considered to rule out other sources of inattention.

School history and teachers' reports are critical in evaluating whether a child's difficulties in learning and school behavior are caused primarily by inattention or compromised understanding of the academic material. In addition to intellectual limitations, poor performance in school may result from maturational problems, social rejection, mood disorders, anxiety, or poor self-esteem due to learning disorders. Assessment of social relationships with siblings, peers, and adults, and engagement in free and structured activities may yield valuable diagnostic clues to the presence of ADHD.

The mental status examination in a given child with ADHD who is aware of his or her impairment may reflect a demoralized or depressed mood; however, thought disorder or impaired reality testing is not expected. A child with ADHD may exhibit distractibility and perseveration and signs of visual-perceptual, auditory-perceptual, or language-based learning disorders. A neurological examination may reveal visual, motor, perceptual, or auditory discriminatory immaturity or impairments without overt signs of visual or auditory disorders. Children with ADHD often have problems with motor coordination and difficulty copying age-appropriate figures, rapid alternating movements, right-left discrimination, ambidexterity, reflex asymmetries, and a variety of subtle nonfocal neurological signs (soft signs).

If there are indications of possible absence spells, clinicians should obtain a neurological consultation and an EEG to rule out seizure disorders. A child with an unrecognized temporal lobe seizure focus may have behavior disturbances, which can resemble those of ADHD.

Clinical Features

ADHD can have its onset in infancy, although it is rarely recognized until a child is at least toddler age. More commonly, infants with ADHD are active in the crib, sleep little, and cry a great deal.

In school, children with ADHD may attack a test rapidly, but may answer only the first two questions. They may be unable to wait to be called on in school and may respond before everyone else. At home, they cannot be put off for even a minute. Impulsiveness and an inability to delay gratification are characteristic. Children with ADHD are often susceptible to accidents.

The most cited characteristics of children with ADHD, in order of frequency, are hyperactivity, attention deficit (short
attention span, distractibility, perseveration, failure to finish tasks, inattentiveness, poor concentration), impulsivity (action before thought, abrupt shifts in activity, lack of organization, jumping up in class), memory and thinking deficits, specific learning disabilities, and speech and hearing deficits. Associated features often include perceptual motor impairment, emotional liability, and developmental coordination disorder. A significant percent of children with ADHD show behavioral symptoms of aggression and defiance. School difficulties, both learning and behavioral, commonly exist with ADHD. Comorbid communication disorders or learning disorders that hamper the acquisition, retention, and display of knowledge complicate the course of ADHD.

Justin was a 9-year-old African American adopted boy who was referred for an evaluation by his 4th grade teacher, who informed his adoptive parents that she was unable to manage Justin’s impulsive and aggressive behaviors in the classroom. Justin was attending public school and was in a regular classroom with two resource room periods per day to help him with reading and math. Justin also received speech therapy once a week. Justin had been referred in the past for psychiatric evaluation, but his adoptive parents were opposed to medication so they did not follow through. Justin’s adoptive parents knew very little about his biological family other than that his biological mother was known to be a polydrug abuser and was currently incarcerated. Justin was adopted as an infant and his pediatrician had told his adoptive parents that Justin was entirely healthy at birth. However, ever since kindergarten, Justin’s teachers had complained that Justin did “not seem to listen,” had “poor concentration,” and was unable to stay in his seat. Because Justin was an engaging and cute child, his teachers in kindergarten and first grade made accommodations for him in their classrooms despite their complaints. When Justin entered the 2nd grade, however, it became clear that he was struggling with reading and writing, and an individualized educational program (IEP) evaluation was initiated. Justin was provided with resource room periods for remediation during the school day, but Justin continued to have additional problems getting along with his peers during lunch, and even at recess. Justin was often found arguing or fighting with other children who said that he did not know the rules of their games. Justin became angry when he was criticized by his peers and would often push his classmates. At home, Justin’s adoptive parents were becoming more and more frustrated with Justin because he seemed to take hours to do a few math problems, and was unable to write a paragraph without a lot of help. Justin would become easily annoyed when frustrated with himself and then run around the house in a silly and disruptive manner. Justin was a good-hearted child who seemed to get along best with children who were younger than he was. Justin did not seem to make any close friends among his classmates, and the teachers indicated that Justin’s peers sometimes avoided him because he was too rough during play and he did not follow the rules of their games. Justin had a difficult time waiting his turn and he became easily provoked when he was reprimanded. Consequently, Justin became alienated and often bullied by his classmates. Justin was aware that he was not able to keep up with the coursework, and he told his adoptive parents that he was just “stupid.” Although Justin acted in a rambunctious and impulsive manner, he also appeared sad, and one day after a fight with several peers, he told his adoptive parents that he was going to “kill” himself. At this point, Justin’s parents became worried and decided that Justin’s teacher was right, and they would seek a psychiatric evaluation for Justin. During the initial evaluation with a child and adolescent psychiatrist, Justin was found to be a well-developed, cute, and active child, who appeared distracted and fidgety and somewhat sad. When asked about it, Justin said that he wanted to do “better” in school but that nobody liked him, he was failing his classes, and that he didn’t like doing homework. He denied suicidal thoughts and reported that he had only said that to his parents because he was angry at his peers. Justin admitted that it was very difficult for him to understand his school work and impossible to complete his assignments. During the evaluation, several parent and teacher rating scales were obtained. These included The Child Behavior Checklist, and the SNAP Rating Scale. Justin’s teacher and parents endorsed similar symptoms including poor organization, inability to follow directions, being forgetful in daily activities, impulsivity, with several episodes of running into the street without looking, blurtting things out in the classroom without raising his hand, and recurrent fights with peers. Justin was observed to look dejected in school when he was excluded from play activities by peers, and sul­len or angry at home when he was asked to read or do homework. Based on the clinical history, the rating scales and teacher’s report, a diagnosis of Attention-Deficit/Hyperactivity Disorder, with the DSM-5 specifier of combined presentation, was made. In addition, Justin was noted to have a mood disorder with depressed mood, which did not qualify for a major depression. A treatment plan was suggested including a behavioral plan allowing Justin to receive rewards for effort on his homework along with a trial of a stimulant medication. After an extensive medical history was obtained and a recent physical examination by his pediatrician did not reveal any systemic illnesses, an EEG was decided upon, mainly because it was not possible to obtain a full medical and cardiac history due to an absence of early medical records, and his adoptive parents did not have access to his birth and neonatal medical records. After obtaining a normal EEG, Justin was started on a trial dose of a short-acting stimulant, methylphenidate (Ritalin) at 10 mg, to determine if he could tolerate a stimulant without any unexpected sensitivities. Justin had no adverse effects and was shortly switched to the long-acting stimulant Concerta, 36 mg which would last between 10 and 12 hours. Justin became more vigilant in class and seemed to be less restless and more focused, and his teacher reported that he was not getting out of his seat as often, although he continued to blurt out in class when he was not called on, and he continued to have difficulty following directions and forgetting things. Because Justin was not experiencing any adverse effects and was still displaying some ADHD symptoms, his Concerta was increased to 54 mg per day. At this dose both his teacher and parents noticed a marked improvement in his ability to sit and finish his classwork and homework. However, he began to have significant problems with insomnia and was becoming fatigued from not being able to fall asleep until about 2 a.m. on a nightly basis. The child and adolescent psychiatrist and Justin’s parents discussed two options to address the insomnia. One was to add a dose of short-acting clonidine in the evenings to cause a calming effect along with some sedative properties, and the other was to initiate a trial of Daytrana, the methylphenidate transdermal patch, which could be applied to deliver a similar dose of methylphenidate throughout the day, and the patch could be removed at approximately 4 P.M or 5 P.M to determine which produced the desired effect for the target symp­toms for the most optimal amount of time. Because the Daytrana patch may deliver medication for an hour or so after its removal, Justin would need to try several different removal times to find the optimal treatment time. Justin’s family and his child psychiatrist determined that it would be the best next step for Justin to try the Daytrana patch rather than add an additional medication to treat his insomnia. Justin was tried on the Daytrana transdermal 20 mg patch and found that if it was removed by 5 p.m., he was able to fall asleep within 30 to 45 minutes after getting into bed. Despite some mild
Pathology and Laboratory Examination

A child being evaluated for ADHD should receive a comprehensive psychiatric and medical history. Prenatal, perinatal, and toddler information should be included in the history. Complications of mother's pregnancy should also be obtained. Medical problems that may produce symptoms overlapping with ADHD include petit mal epilepsy, hearing and visual impairments, thyroid abnormalities, and hypoglycemia. A thorough cardiac history should be taken, including an investigation of the lifetime history of syncope, family history of sudden death, and a cardiac examination of the child. Although it is reasonable to obtain an electrocardiography (ECG) study prior to treatment, if any cardiac risk factors are present, a cardiology consultation and examination are warranted. No specific laboratory measures are pathognomonic of ADHD.

A continuous performance task, a computerized task in which a child is asked to press a button each time a particular sequence of letters or numbers is flashed on a screen, is not specifically a useful diagnostic tool for ADHD; however, it may be useful in comparing a child's performance before and after medication treatment, particularly at different doses. Children with poor attention tend to make errors of omission—that is, they fail to press the button when the sequence has flashed. Impulsivity is often manifested by errors of commission, in which an impulsive child cannot resist pushing the button, even when the desired sequence has not yet appeared on the screen.

Differential Diagnosis

A temperamental constellation of high activity level and short attention span, in the normal range for the child's age, and without impairment, should be ruled out. Differentiating these temperamental characteristics from the cardinal symptoms of ADHD before the age of 3 years is difficult, mainly because of the overlapping features of a normally immature nervous system and the emerging signs of visual-motor-perceptual impairments frequently seen in ADHD. Anxiety in a child needs to be evaluated. Anxiety can accompany ADHD as a symptom or comorbid disorder, and anxiety can manifest with overactivity and easy distractibility.

It is not uncommon for a child with ADHD to become demoralized or, in some cases, to develop depressive symptoms in reaction to persistent frustration with academic difficulties and resulting low self-esteem. Mania and ADHD share many core features, such as excessive verbalization, motoric hyperactivity, and high levels of distractibility. In addition, in children with mania, irritability seems to be more common than euphoria. Although mania and ADHD can coexist, children with bipolar I disorder exhibit more waxing and waning of symptoms than those with ADHD. Recent follow-up data for children who met the criteria for ADHD and subsequently developed bipolar disorder suggest that certain clinical features occurring during the course of ADHD predict future mania. Children with ADHD who had developed bipolar I disorder at 4-year follow-up had a greater co-occurrence of additional disorders and a greater family history of bipolar disorders and other mood disorders than children without bipolar disorder.

Frequently, oppositional defiant disorder, or conduct disorder and ADHD may coexist, and when that occurs, both disorders are diagnosed. Specific learning disorders of various kinds must also be distinguished from ADHD; a child may be unable to read or do mathematics because of a learning disorder, rather than because of inattention. ADHD often coexists with one or more learning problems, including deficits in reading, mathematics or written expression.

Course and Prognosis

The course of ADHD is variable. Symptoms have been shown to persist into adolescence in 60 to 85 percent of cases, and into adult life in approximately 60 percent of cases. The remaining 40 percent of cases may remit at puberty, or in early adulthood. In some cases, the hyperactivity may disappear, but the decreased attention span and impulse-control problems persist. Overactivity is usually the first symptom to remit, and distractibility is the last. ADHD does not usually remit during middle childhood. Persistence is predicted by a family history of the disorder, negative life events, and comorbidity with conduct symptoms, depression, and anxiety disorders. When remission occurs, it is usually between the ages of 12 and 20. Remission can be accompanied by a productive adolescence and adult life, satisfying interpersonal relationships, and few significant sequelae. Most patients with the disorder, however, undergo partial remission and are vulnerable to antisocial behavior, substance use disorders, and mood disorders. Learning problems often continue throughout life.

In about 60 percent of cases, some symptoms persist into adulthood. Those who persist with the disorder may show diminished hyperactivity but remain impulsive and accident-prone. Although the educational attainments of people with ADHD as a group are lower than those of people without ADHD, early employment histories do not differ from those of people with similar educations.

Children with ADHD whose symptoms persist into adolescence are at higher risk for developing conduct disorder.
Children with both ADHD and conduct disorder are also at risk for developing substance use disorders. The development of substance abuse disorders among ADHD youth in adolescence appears to be more related to the presence of conduct disorder rather than to ADHD.

Most children with ADHD have some social difficulties. Socially dysfunctional children with ADHD have significantly higher rates of comorbid psychiatric disorders, and experience more problems with behavior in school as well as with peers and family members. Overall, the outcome of ADHD in childhood seems to be related to the degree of persistent comorbid psychopathology, especially conduct disorder, social disability, and chaotic family factors. Optimal outcomes may be promoted by ameliorating children’s social functioning, diminishing aggression, and improving family situations as early as possible.

Treatment

Pharmacotherapy. Pharmacologic treatment is considered the first line of treatment for ADHD. Central nervous system stimulants are the first choice of agents that in they have been shown to have the greatest efficacy with generally mild tolerable side effects. Stimulants are contraindicated in children, adolescents, and adults with known cardiac risks and abnormalities. In medically healthy youth, however, excellent safety records are documented for short- and sustained-release preparations of methylphenidate (Ritalin, Ritalin-SR, Concerta, Metadate CD, Metadate ER), dextroamphetamine (Dexedrine, Dexedrine spansules, Vyvanse), and dextroamphetamine and amphetamine salt combinations (Adderall, Adderall XR). Newer preparations of methylphenidate, include Methylx, a chewable form of methylphenidate; Daytrana, a methylphenidate patch; and dexmethylphenidate, the d-enantiomer (Focalin), and its longer acting form Focalin XR. These newer preparations aim to maximize the target effects and minimize the adverse effects in individuals with ADHD who obtain partial response from methylphenidate or whose dose was limited by side effects. Vyvanse (lisdexamfetamine dimesylate) is a pro-drug of dextroamphetamine, which requires intestinal metabolism in order to reach its active form. Vyvanse is approved by the U.S. Food and Drug Administration (FDA) for children 6 years and older. Vyvanse, inactive until it is metabolized, is a less likely agent to have risks of abuse or overdose. It has side effects and efficacy similar to the other forms of amphetamines used in the treatment of ADHD.

Current strategies favor once a day sustained-release stimulant preparations for their convenience and diminished rebound side effects. Advantages of the sustained-release preparations for children are that one dose in the morning will sustain the effects all day, and the child is no longer required to interrupt his or her school day, as well as the physiologic advantage that the medication is sustained at an approximately even level in the body throughout the day so that periods of rebound and irritability are avoided. Table 31.6-2 contains comparative information on the above medications.

Nonstimulant medications approved by the FDA in the treatment of ADHD include atomoxetine (Strattera), a norepinephrine uptake inhibitor. Unlike the stimulants, Strattera carries with it a black box warning for potential increases in suicidal thoughts or behaviors and requires children with ADHD to be monitored for these symptoms, similarly to children who are administered antidepressants. A-agonists including clonidine (Catapres) and guanfacine (Tenex) have also been found to be effective in treating ADHD. The FDA has recently approved the extended-release forms of clonidine (Kapvay) and the extended release form of guanfacine (Intuniv) for the treatment

of ADHD in children 6 years and older. Antidepressants, such as bupropion (Wellbutrin, Wellbutrin SR), have been used with variable success in the treatment of ADHD. (Table 31.6-3 contains comparative information on the nonstimulant medications and Table 31.6-4 indicates FDA-approved ages for ADHD medications.)

**STIMULANT MEDICATIONS.** Methylphenidate and amphetamine preparations are dopamine agonists; however, the precise mechanism of the stimulant's central action remains unknown. Methylphenidate preparations have been shown to be highly effective in up to three fourths of children with ADHD, with relatively few adverse effects. Concerta, the 10- to 12-hour extended-release OROS (osmotic controlled-release extended delivery system) form of methylphenidate, is administered once daily in the morning and is effective during school hours as well as after school during the afternoon and early evening. Both shorter- and longer-acting preparations of methylphenidate and Concerta have similar common adverse effects including headaches, stomachaches, nausea, and insomnia. Some children experience a rebound effect, in which the release time continues for 12 hours after the pill is taken. This is in contrast to oral sustained-release forms of methylphenidate, such as Concerta, in which the release time continues for 12 hours after the pill is

swallowed. A double-blind randomized study in children with ADHD who wore the methylphenidate patch for 12 hours at a time, showed efficacy of the patch preparation doses ranging from patches delivering 0.45 mg per hour to 1.8 mg per hour of methylphenidate. The effectiveness of the patch reached a plateau without much further improvement as dose was increased, but intensive behavioral interventions were also being administered. A delay in the onset of the transdermal medication effect was approximately an hour. Side effects were similar to oral preparations of methylphenidate. Approximately half of the children exhibited at least minor erythematous reactions to the patch; however, these side effects are usually well tolerated by children on the patch. Dextroamphetamine and dextroampheta-
mine/amphetamine salt combinations are usually the second drugs of choice when methylphenidate is not effective. Vyvanse is advantageous because it is inactive until it is metabolized.

NONSTIMULANT MEDICATIONS. Atomoxetine HCl (Strattera) is a norepinephrine uptake inhibitor approved by the FDA for the treatment of ADHD in children age 6 years and older. The mechanism of action is not well understood, but it is believed to involve selective inhibition of presynaptic norepinephrine transporter. Atomoxetine is well absorbed by the gastrointestinal tract, and maximal plasma levels are reached in 1 to 2 hours after ingestion. It has been shown to be effective for inattention as well as impulsivity in children and in adults with ADHD. Its half-life is approximately 5 hours and it is usually adminis-
tered twice daily. Most common side effects include diminished appetite, abdominal discomfort, dizziness, and irritability. In some cases, increases in blood pressure and heart rate have been reported. Atomoxetine is metabolized by the cytochrome P450 (CYP) 2D6 hepatic enzyme system. A small fraction of the population are poor metabolizers of CYP 2D6–metabolized drugs and, for those individuals, plasma concentrations of the drug may rise as much as fivefold for a given dose of medica-
tion. Drugs that inhibit CYP 2D6, including fluoxetine, parox-
etine, and quinidine, may lead to increased plasma levels of this medication. Despite its short half-life, atomoxetine has been shown in a recent study to be effective in reducing symptoms of ADHD in children during the school day when administered once daily. Another recent study of a combination of atomoxet-
eine alone and combined with fluoxetine in the treatment of 127 children with ADHD and symptoms of anxiety or depres-
sion suggested that atomoxetine alone can lead to improve-
ments in mood and anxiety. Children who received combined atomoxetine and fluoxetine experienced greater increases in blood pressure and pulse than those who were treated with ato-

moxetine only.

α-Agonists, short-acting, and the extended-release forms of clonidine hydrochloride (Kapvay) and Guanfacine (Intuniv) are FDA approved for the treatment of ADHD in children and adolescents from 6 to 7 years of age. Kapvay, a centrally ac-
ting α-2-adrenergic receptor agonist is believed to exert its effect on the prefrontal cortex, although the mechanism of action is unknown. Kapvay is available in 0.1 mg and 0.2 mg tablets, and is generally used twice daily, once in the morning and once at night, to provide a round-the-clock effect. Kapvay is initiated at 0.1 mg at bedtime and can be increased in increments of 0.1 mg at weekly intervals. The maximal dose recommended is 0.2 mg twice daily. Kapvay is not used interchangeably with the short-
acting clonidine. Because Kapvay is an antihypertensive agent, it causes a decrease in blood pressure and heart rate. These vital signs must be monitored in patients, especially during initiation and titration of the dose. Common side effects include somno-

lence, headache, upper abdominal pain, and fatigue. When Kap-
vay is tapered, it is recommended to taper no more than 0.1 mg every 3 to 7 days. Intuniv, the extended release preparation of guanfacine, is a once-a-day medication for children between 6 and 17 years of age, available in 1 mg, 2 mg, 3 mg, and 4 mg tabs. Intuniv is a tablet that is swallowed whole, and should be taken with water, milk or other liquids; it is not recommended to take Intuniv with a high-fat meal. Intuniv is typically initi-
ated as a 1 mg tab daily and titrated by 1 mg per day at 1-week intervals. The maximum dose approved is 4 mg per day. As a monotherapy, improvement in ADHD symptoms have been found to occur at 0.05 to 0.08 mg/kg once daily. As an adjunctive treatment, optimal doses are reported to range from 0.05 to 0.12 mg/kg/day. Common side effects for Intuniv include somno-

lence, sedation, fatigue, nausea, hypotension, insomnia, and dizziness. Heart rate and blood pressure must be monitored as in Kapvay. When discontinuing Intuniv, a gradual taper decreas-
ing by 1 mg every 3 to 7 days is recommended. α-Adrenergic agents including the short- and extended-release preparations of guanfacine and clonidine are sometimes preferred treatments in children with ADHD and comorbid tic disorders that have been exacerbated while the patient was taking stimulants. Bupropion has been shown to be somewhat effective for some children and adolescents in the treatment of ADHD. One multisite, double-

blind, placebo-controlled study found a positive result regard-
ing the efficacy of bupropion. No further studies have compared bupropion with other stimulants. The risk of seizure develop-
ment while on this drug is increased when using doses of greater than 400 mg per day.

Few data confirm the efficacy of selective serotonin reuptake inhibitors (SSRIs) in the treatment of ADHD, but due to the frequency of comorbid depression and anxiety with ADHD, in cases of comorbidity, the SSRIs are likely to be considered at least in conjunction with a stimulant.

Tricyclic drugs are not recommended in the treatment of ADHD due to potential cardiac arrhythmia effects. The reports of sudden death in at least four children with ADHD who were being treated with desipramine (Norpramin, Pertofrane) have made the tricyclic antidepressants an unlikely choice. Antipsy-

chotics are occasionally introduced to treat refractory severely hyperactive children and adolescents who are significantly dysfunctional. Antipsychotics are generally not chosen in the treatment of ADHD due to the risks of tardive dyskinesia, withdrawal dyskinesia, neuroleptic malignant syndrome, and weight gain.

Modafinil (Provigil), another type of CNS stimulant, origi-
nally developed to reduce daytime sleepiness in patients with narcolepsy, has been tried clinically in the treatment of adults with ADHD. Only one randomized, double-blind, placebo-con-
trolled study of the efficacy and safety of modafinil film-coated tablets in approximately 250 adolescents with ADHD showed that 48 percent of those on active treatment were rated as “much” or “very much” improved compared with 17 percent of patients receiving placebo. The dosage range was from 170 to 425 mg administered once daily, titrated to optimal doses based on effi-
cacy and tolerability. Modafinil failed to receive FDA approval
based on a Stevens-Johnson skin rash that occurred in a patient during the trial. The most common side effects included insomnia, headache, and decreased appetite.

Venlafaxine has been tried in clinical practice, especially for children and adolescents with combinations of ADHD and depression or anxiety features. No clear empirical evidence supports the use of venlafaxine in the treatment of ADHD.

One open-label report of reboxetine, a selective norepinephrine reuptake inhibitor in 31 children and adolescents with ADHD who were resistant to methylphenidate treatment suggested that this agent may have efficacy. In this open trial, reboxetine was initiated and maintained at 4 mg per day. Most common side effects included drowsiness, sedation, and gastrointestinal symptoms. Reboxetine and other new agents in this class await controlled studies to further evaluate their potential efficacy.

TREATMENT OF CNS STIMULANT SIDE EFFECTS. CNS stimulants are generally well tolerated, and current consensus is that once a day dosing is preferable for convenience and to minimize rebound side effects. Long-term tolerability of once-daily mixed amphetamine salts has shown mild side effects, most commonly decreased appetite, insomnia, and headache. A variety of strategies have been suggested for children and/or adolescents with ADHD who respond favorably to methylphenidate, but for whom insomnia has become a significant problem. Clinical strategies to manage insomnia include use of diphenhydramine (25 to 75 mg), low dose of trazodone (25 to 50 mg), or the addition of an α-adrenergic agent, such as guanfacine. In some cases, insomnia may attenuate on its own after several months of treatment.

Monitoring Pharmacological Treatment

STIMULANTS. Stimulant medications have adrenergic effects and cause moderate increases in blood pressure and pulse rate. At baseline, the most recent American Academy of Child and Adolescent Psychiatry (AACAP) practice parameters recommend the following workup before starting use of stimulant medications: physical examination, blood pressure, pulse, weight, and height.

It is recommended that children and adolescents being treated with stimulants have their height, weight, blood pressure, and pulse checked on a quarterly basis and have a physical examination annually. Monitoring starts with the initiation of medication. Because school performance is most markedly affected, special attention and effort should be given to establishing and maintaining a close collaborative working relationship with a child's school personnel. In most patients, stimulants reduce overactivity, distractibility, impulsiveness, explosiveness, and irritability. No evidence indicates that medications directly improve any existing impairments in learning, although, when the attention deficits diminish, children can learn more effectively. In addition, medication can improve self-esteem when children are no longer constantly reprimanded for their behavior. Children treated with medications should be taught the purpose of the medication and given the opportunity to describe any side effects that they may be experiencing.

Psychosocial Interventions. Psychosocial interventions for children with ADHD include psychoeducation, academic organization skills remediation, parent training, behavior modification in the classroom and at home, cognitive behavioral therapy (CBT), and social skills training. Social skills groups, behavioral training for parents of children with ADHD, and behavioral interventions at school and at home have been studied alone and in combination with medication management for ADHD. Evaluation and treatment of coexisting learning disorders or additional psychiatric disorders is important.

When children are helped to structure their environment, their anxiety diminishes. It is beneficial for parents and teachers to work together to develop a concrete set of expectations for the child and a system of rewards for the child when the expectations are met.

A common goal of therapy is to help parents of children with ADHD recognize and promote the notion that, although the child may not "voluntarily" exhibit symptoms of ADHD, he or she is still capable of being responsible for meeting reasonable expectations. Parents should also be helped to recognize that, despite their child's difficulties, every child faces the normal tasks of maturation, including significant building of self-esteem when he or she develops a sense of mastery. Therefore, children with ADHD do not benefit from being exempted from the requirements, expectations, and planning applicable to other children. Parental training is an integral part of the psychotherapeutic interventions for ADHD. Most parental training is based on helping parents develop usable behavioral interventions with positive reinforcement that target both social and academic behaviors.

Group therapy aimed at both refining social skills and increasing self-esteem and a sense of success may be very useful for children with ADHD who have great difficulty functioning in group settings, especially in school. A recent year-long group therapy intervention in a clinical setting for boys with the disorder described the goals as helping the boys improve skills in game playing and feeling a sense of mastery with peers. The boys were first asked to do a task that was fun, in pairs, and then were gradually asked to do projects in a group. They were directed in following instructions, waiting, and paying attention, and were praised for successful cooperation.

MULTIMODAL TREATMENT STUDY OF CHILDREN WITH ADHD (MTA STUDY)

The National Institute of Mental Health (NIMH)-supported Multimodal Treatment Study of Children with ADHD (The MTA Cooperative Group, 1999) was a 14-month-long randomized clinical trial involving six clinical sites comparing four treatment strategies. More than 500 children diagnosed with DSM-IV ADHD, combined type, were randomly assigned to (1) systematic medication management utilizing an initial placebo-controlled titration and t.i.d. dosing 7 days per week and monthly 30-minute clinic visits, (2) behavior therapy consisting of 27 sessions of group parent training, eight individual parent sessions, an 8-week summer treatment program, 12 weeks of classroom administered behavior therapy with a half-time aide, and 10 teacher consultation sessions, (3) a combination of medication and behavior therapy, or (4) usual community care. All groups showed improvement over baseline; however, a combination of medication management and behavior therapy led to greater
Etiology

Currently, ADHD is believed to be largely transmitted genetically, and increasing evidence supports this hypothesis, including the genetic studies, twin studies, and family studies outlined in the child and adolescent ADHD section. Brain imaging studies have obtained data suggesting that adults with ADHD exhibit decreased prefrontal glucose metabolism on PET compared with adults without ADHD. It is unclear whether these data reflect the presence of the disorder or a secondary effect of having ADHD over a period of time. Further studies using SPECT have revealed increased dopamine transporter (DAT) binding densities in the striatum of the brain in samples of adults with ADHD. This finding may be understood within the context of treatment for ADHD, in that standard stimulant treatment for ADHD, such as methylphenidate, acts to block DAT activity, possibly leading to a normalization of the striatal brain region in individuals with ADHD.

Diagnosis and Clinical Features

The clinical phenomenology of ADHD features inattention and manifestations of impulsivity prevailing as the core of this disorder. A leading figure in the development of criteria for adult manifestations of ADHD is Paul Wender, from the University of Utah, who began his work on adult ADHD in the 1970s. Wender developed criteria that could be applied to adults (Table 31.6-5). They included a retrospective diagnosis of ADHD in childhood, and evidence of current impairment from ADHD symptoms in adulthood. Furthermore, evidence exists of several additional symptoms that are typical of adult behavior as opposed to childhood behaviors.

In adults, residual signs of the disorder include impulsivity and attention deficit (e.g., difficulty in organizing and completing work, inability to concentrate, increased distractibility, and sudden decision-making without thought of the consequences). Many people with the disorder have a secondary depressive

⁴Parent report aided with 10-item Parent Rating Scale of Childhood Behavior.
⁵Patient self-report of retrospective childhood symptoms aided by Wender Utah Rating Scale.

ADULT MANIFESTATIONS OF ADHD

ADHD was historically believed to be a childhood condition resulting in delayed development of impulse control that would be generally outgrown by adolescence. In the last few decades many more adults with ADHD have been identified, diagnosed, and successfully treated. Longitudinal follow-up has shown that up to 60 percent of children with ADHD have persistent impairment from symptoms into adulthood. Genetic studies, brain imaging, and neurocognitive and pharmacological studies in adults with ADHD have replicated findings demonstrated in children with ADHD. Increased public awareness and treatment studies within the last decade have led to widespread acceptance of the need for diagnosis and treatment of adults with ADHD.

Epidemiology

Among adults, evidence suggests an approximate 4 percent prevalence of ADHD in the population. ADHD in adulthood is generally diagnosed by self-report, given the lack of school information and observer information available; therefore, it is more difficult to make an accurate diagnosis.

 UNSPECIFIED ATTENTION-DEFICIT/HYPERACTIVITY DISORDER

The DSM-5 includes Unspecified ADHD as a category for disturbances of inattention or hyperactivity that cause impairment, but do not meet the full criteria for ADHD.

Results

A follow-up of the MTA sample at 6 and 8 years revealed that the clinical presentation of the disorder, including severity of ADHD, comorbid conduct disturbance, and intellect were stronger predictors of later functioning than the type of treatment received in childhood during the 14-month study period. Although treatment-related improvements for the children who participated in the MTA study are maintained as long as treatment continues, the differential treatment efficacy appeared to be lost at approximately the 3-year mark.

Overall, the evidence suggests that medication and psychosocial interventions for the combined type of ADHD in childhood provides the broadest benefit in functioning for this population. This is especially pertinent in view of the comorbidity of learning disorders, anxiety, mood disorders, and other disruptive behavior disorders that occur in children with ADHD.

reduction in symptoms in children with ADHD alone or ADHD and Oppositional Defiant Disorder than behavior therapy alone or community care. The combination treatment had significantly better outcomes for those children with ADHD and anxiety and/or mood disorders compared to behavioral treatment and community care. Combined treatment but not medication management was superior for improvement in oppositional and aggressive symptoms, anxiety and mood symptoms, teacher rated social skills, parent–child relationships, and reading achievement. Furthermore, mean dose of medication per day was less in the combination group than in the medication-only management group.
Disorder associated with low self-esteem related to their impaired performance and which affects both occupational and social functioning.

Brett was a 26-year-old man convinced by his new wife to seek an evaluation for his distractibility, forgetfulness, and “not listening” after a minor traffic accident. After consulting his mother, Brett reported that in grade school, he was often “in trouble” for talking out of turn, and his mother recalled teachers’ reports that Brett often made careless mistakes on tests, forgot his assignments, and had great difficulty sitting still. Although as a young child he was considered gifted intellectually, when he got to the third grade his grades were only average, and he seemed more interested in getting his work done quickly than correctly. Brett was talkative and loud and enjoyed sports, although he was not particularly talented at them. Nevertheless, Brett had acquaintances and superficial friends because he was likeable, funny, and even entertaining. Brett had no idea what he wanted to do when he grew up, and during his senior year in high school, he neglected to finish any of his college applications on time, and ended up attending a community college part-time.

During the two years after high school, Brett held down a series of jobs only briefly, including a construction job, a waiter position in a restaurant, and a Fed-Ex driver, and then decided that he wanted to become an actor. Brett went on a series of auditions, but found that he was likeable, funny, and even entertaining. Brett had no idea what he wanted to do when he grew up, and during his senior year in high school, he neglected to finish any of his college applications on time, and ended up attending a community college part-time. During the two years after high school, Brett held down a series of jobs only briefly, including a construction job, a waiter position in a restaurant, and a Fed-Ex driver, and then decided that he wanted to become an actor. Brett went on a series of auditions, but found that he would become distracted and did poorly remembering his lines and even spaced out during readings. Despite that, he was chosen for one commercial. Brett reported that he had never had problems with abuse of drugs or alcohol, and he occasionally drank beer socially. During his evaluation with a child and adolescent psychiatrist, Brett disclosed that his greatest difficulties were with tasks that seemed boring to him. He had difficulty maintaining his attention, was easily distracted, felt restless most of the time, and became frustrated when he was expected to sit still for long periods of time. Brett endorsed 6 inattentive and 5 hyperactive/impulsive symptoms on a DSM ADHD Checklist of current symptoms. Brett met the diagnostic criteria for Adult ADHD, combined type, with a probable onset in childhood. Brett’s medical history was negative for all major illnesses, and neither he nor his parents had a history of cardiac abnormalities. He took no prescribed medications. After discussing the situation with his psychiatrist and his wife, Brett decided that he would like to try a stimulant medication. A trial of a once-a-day extended-release formulation of a stimulant medication was selected: Adderall XR 10 mg. At his first follow-up visit, a week later, Brett reported that he felt a slight effect from this medication but it was not enough to improve his functioning, so Brett and his psychiatrist agreed that he would increase his dose to 20 mg per day. At his next follow-up appointment, Brett reported that he had noticed significant improvement in his ability to focus, concentrate, and remember his lines in auditions. In fact, he had just received a small part in an upcoming movie. Brett and his wife were both thrilled with the results, and Brett continued to return monthly for follow up visits. (Adapted from McGough J. Adult manifestations of attention-deficit/hyperactivity disorder. In: Sadock BJ, Sadock VA, Ruiz P, eds. Kaplan & Sadock’s Comprehensive Textbook of Psychiatry. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:3577.)

Differential Diagnosis

A diagnosis of ADHD is likely when symptoms of inattention and impulsivity are described by adults as a life-long problem, not as episodic events. The overlap of ADHD and hypomania, bipolar II disorder, and cyclothymia is controversial and difficult to sort out retrospectively. Clear-cut histories of discrete episodes of hypomania and mania, with or without periods of depression, are suggestive of a mood disorder rather than a clinical picture of ADHD; however, ADHD may have predated the emergence of a mood disorder in some individuals. In such a case, ADHD and bipolar disorder may be diagnosed comorbidly. Adults with an early history of chronic school difficulties related to paying attention, activity level, and impulsive behavior are generally diagnosed with ADHD, even when a mood disorder occurs later in life. Anxiety disorders can coexist with ADHD, and are less difficult than hypomania to distinguish from it.

Course and Prognosis

The prevalence of ADHD diminishes over time, although at least half of children and adolescents may have the disorder into adulthood. Many children initially diagnosed with ADHD, combined type, exhibit fewer impulsive-hyperactive symptoms as they get older and, by the time they are adults, will meet criteria for ADHD, inattentive type. As with children, adults with ADHD demonstrate higher rates of learning disorders, anxiety disorders, mood disorders, and substance use disorder compared with the general population.

Treatment

Treatment of ADHD in adults targets pharmacotherapy, mainly long-acting stimulants, similar to that used with children and adolescents with ADHD. In adults, only the long-acting stimulants are FDA approved in the treatment of ADHD. Signs of a positive response are an increased attention span, decreased impulsiveness, and improved mood. Psychopharmacological therapy may be needed indefinitely. Clinicians should use standard ways to monitor drug response and patient compliance.

BMC Medicine.
Specific learning disorder in youth is a neurodevelopmental disorder produced by the interactions of heritable and environmental factors that influence the brain's ability to efficiently perceive or process verbal and nonverbal information. It is characterized by persistent difficulty learning academic skills in reading, written expression, or mathematics, beginning in early childhood, that is inconsistent with the overall intellectual ability of a child. Children with specific learning disorder often find it difficult to keep up with their peers in certain academic subjects, whereas they may excel in others. Academic skills that may be compromised in specific learning disorder include reading single words and sentences fluently, written expression and spelling, and calculation and solving mathematical problems. Specific learning disorder results in underachievement that is unexpected based on the child's potential as well as the opportunity to have learned more. Specific learning disorder in reading, spelling, and mathematics appears to aggregate in families. There is an increased risk of four to eight times in first-degree relatives for reading deficits, and about five to ten times for mathematics defects, compared to the general population. Specific learning disorder occurs two to three times more often in males than in females. Learning problems in a child or adolescent identified in this manner can establish eligibility for academic services through the public school system.

The American Psychiatric Association's Fifth Edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5), combines the DSM-IV diagnoses of reading disorder, mathematics disorder, and disorder of written expression and learning disorder not otherwise specified into a single diagnosis: Specific learning disorder. Learning deficits in reading, written expression, and mathematics in the DSM-5 are designated using specifiers. DSM-5 notes that the term dyslexia is an equivalent term describing a pattern of learning difficulties, including deficits in accurate or fluent word recognition, poor decoding, and poor spelling skills. Dyscalcula is noted to be an alternative term referring to a pattern of deficits related to learning arithmetic facts, processing numerical information, and performing accurate calculations.

Specific learning disorder of all types affects approximately 10 percent of youth. This represents approximately half of all public school children who receive special education services in the United States. In 1975, Public Law 94–142 (the Education for All Handicapped Children Act now known as the Individual with Disabilities Education Act [IDEA]) mandated all states to provide free and appropriate educational services to all children. Since that time, the number of children identified with learning disorders has increased, and a variety of definitions of learning disabilities have arisen. To meet the criteria for specific learning disorder, a child's achievement must be significantly lower than expected in one or more of the following: reading skills, comprehension, spelling, written expression, calculation, mathematical reasoning, and/or the learning problems interfere with academic achievement or activities of daily living. It is common for specific learning disorder to include more than one area of skills deficits.

Children with specific learning disorder in the area of reading can be identified by poor word recognition, slow reading rate, and impaired comprehension compared with most children of the same age. Current data suggest that most children with reading difficulties have deficits in speech sound processing skills, regardless of their intelligence quotient (IQ), and in DSM-5, there is no longer a diagnostic criterion for specific learning disorder comparing the specific deficit to overall IQ. Current consensus is that children with reading impairment have trouble with word recognition and “sounding out” words because they cannot efficiently process and use phonemes (the smaller bits of words that are associated with particular sounds). A recent epidemiologic study found four profiles including (1) weak reading, (2) weak language, (3) weak math, or (4) combined weak math and reading, accounting for 70 percent of children with specific learning impairments. Low scores in short-term memory for speech sounds characterized the profile with weak language, whereas, low speech sound awareness was associated with the weak reading group, but not the weak language group. Finally, in another recent study it was found that the weak math group did not show speech sound deficits.

Severe specific learning disorder may make it agonizing for a child to succeed in school, often leading to demoralization, low self-esteem, chronic frustration, and compromised peer relationships. Specific learning disorder is associated with an increased risk of comorbid disorders, including attention-deficit/hyperactivity disorder (ADHD), communication disorders, conduct disorders, and depressive disorders. Adolescents with specific learning disorder are at least 1.5 times more likely to drop out of school, approximating rates of 40 percent. Adults with specific learning disorder are at increased risk for difficulties in employment and social adjustment. Specific learning disorder often extends to skills deficits in multiple areas such as reading, writing, and mathematics.

Moderate to high heritability is believed to contribute to specific learning disorder, and furthermore, it appears that many cognitive traits are polygenic. In addition, there is pleiotropy, that is, the same genes may affect skills necessary for diverse learning tasks. Factors such as perinatal injury and specific neurological conditions may contribute to the development of specific learning disorder. Conditions such as lead poisoning, fetal alcohol syndrome, and in utero drug exposure are also associated with increased rates of specific learning disorder.
SPECIFIC LEARNING DISORDER WITH IMPAIRMENT IN READING

Reading impairment is present in up to 75 percent of children and adolescents with specific learning disorder. Students who have learning problems in other academic areas most commonly experience difficulties with reading as well.

Reading impairment is characterized by difficulty in recognizing words, slow and inaccurate reading, poor comprehension, and difficulties with spelling. Reading impairment is often comorbid with other disorders in children, particularly ADHD. The term developmental alexia was historically used to define a developmental deficit in the recognition of printed symbols. This was simplified by adopting the term dyslexia in the 1960s. Dyslexia was used extensively for many years to describe a reading disability syndrome that often included speech and language deficits and right–left confusion. Reading impairment is frequently accompanied by disabilities in other academic skills, and the term dyslexia remains as an alternate term for a pattern of reading and spelling difficulties.

Epidemiology

An estimated 4 to 8 percent of youth in the United States have been identified with dyslexia, encompassing a variety of reading, spelling, and comprehension deficits. Three to four times as many boys as girls are reported to have reading impairments in clinically referred samples. In epidemiological samples, however, rates of reading impairments are much closer among boys and girls. Boys with reading impairment are referred for psychiatric evaluation more often than girls due to comorbid ADHD and disruptive behavior problems. No clear gender differential is seen among adults who report reading difficulties.

Comorbidity

Children with reading difficulties are at high risk for additional learning deficits including mathematics and written expression. The DSM-5 Language disorder, also known as specific language impairment, has traditionally been viewed as distinct from dyslexia and dyscalculia. Children with language disorder have poor word knowledge, limited abilities to form accurate sentence structure, and impairments in the ability to put words together to produce clear explanations. Children with language disorder may have delayed development of language acquisition, and difficulties with grammar and syntactical knowledge. Specific learning disorder in the areas of reading and mathematics frequently occur comorbidly with language disorder. In one study, it was found that among dyslexic samples, 19 percent to 63 percent also have language impairment. Conversely, reading impairment has been found in 12.5 percent to 85 percent of individuals with language disorder. In twin studies, reading impairments were found to be significantly higher in those children with specific learning impairment and in family members of children with the disorder. There are also high rates of comorbidity between reading impairment and mathematics impairment; in some studies the comorbidity has been reported to be up to 60 percent. It appears that children with both reading and math impairment may perform more poorly in mathematics; however, the reading skills of the comorbid children were no different from children who had only reading disorder and not math disorder. Comorbid psychiatric disorders are also frequent, such as ADHD, Oppositional Defiant Disorder, Conduct Disorders, and Depressive Disorders, especially in adolescents. Data suggest that up to 25 percent of children with reading impairment may have comorbid ADHD. Conversely, it is estimated that between 15 and 30 percent of children diagnosed with ADHD have specific learning disorder. Family studies suggest that ADHD and reading impairment may share some degree of heritability. That is, some genetic factors contribute to both reading impairment and attentional syndromes. Youth with reading impairments have higher than average rates of depression on self-report measures and experience higher levels of anxiety symptoms than children without specific learning disorder. Furthermore, children with reading impairment are at increased risk for poor peer relationships and exhibit less skill in responding to subtle social cues.

Etiology

Data from cognitive, neuroimaging, and genetic studies suggest that reading impairment is a neurobiological disorder with a significant genetic contribution. It reflects a deficiency in processing sounds of speech sounds, and thus, spoken language. Children who struggle with reading most likely also have a deficit in speech sound processing skills. Children with this deficit cannot effectively identify the parts of words that denote specific sounds, leading to difficulty in recognizing and “sounding out” words. Youth with reading impairment are slower than peers in naming letters and numbers. The core deficits for children with reading impairment include poor processing of speech sounds and deficits in comprehension, spelling, and sounding out words.

Because reading impairment typically includes a language deficit, the left brain has been hypothesized to be the anatomical site of this dysfunction. Several studies using magnetic resonance imaging (MRI) studies have suggested that the planum temporale in the left brain shows less asymmetry than the same site in the right brain in children with both language disorders and specific learning disorder. Positron emission tomographic (PET) studies have led some researchers to conclude that left temporal blood flow patterns during language tasks differ between children with and without learning disorders. Cell analysis studies suggest that in reading impaired individuals, the visual magnocellular system (which normally contains large cells) contains more disorganized and smaller cell bodies than expected. Studies indicate that 35 to 40 percent of first-degree relatives of children with reading deficits also have reading disability. Several studies have suggested that phonological awareness (i.e., the ability to decode sounds and sound out words) is linked to chromosome 6. Furthermore, the ability to identify single words has been linked to chromosome 15. Impairment in reading and spelling has now been linked to susceptibility loci on multiple chromosomes, including chromosomes 1, 2, 3, 6, 15, and 18. Although a recent research study identified a locus on chromosome 18 as a strong influence on single word reading and phoneme awareness, generalist genes have also been implicated as responsible for learning disorders. Many genes believed to be associated with specific learning disorder, may also influence normal variation in learning abilities. In addition, genes that affect abilities in reading, for example,
are hypothesized to also affect written expression and potentially mathematics skills.

Several historical hypotheses about the origin of reading deficits are now known to be untrue. The first myth is that reading impairments are caused by visual–motor problems, or what has been termed scotopic sensitivity syndrome. There is no evidence that children with reading impairment have visual problems or difficulties with their visual–motor system. The second false theory is that allergies can cause, or contribute to, reading disability. Finally, unsubstantiated theories have implicated the cerebellar–vestibular system as the source of reading disabilities.

Research in cognitive neuroscience and neuropsychology supports the hypothesis that encoding processes and working memory, rather than attention or long-term memory, are areas of weakness for children with reading impairment. One study found an association between dyslexia and birth in the months of May, June, and July, suggesting that prenatal exposure to a maternal infectious illness, such as influenza, in the winter months may contribute to reading disabilities. Complications during pregnancy and prenatal and perinatal difficulties are common in the histories of children with reading disabilities. Extremely low birth weight and severely premature children are at higher risk for specific learning disorder. Children born very preterm have been noted to be at increased risk of minor motor, behavioral, and specific learning disorder.

An increased incidence of reading impairment occurs in intellectually average children with cerebral palsy and epilepsy. Children with postnatal brain lesions in the left occipital lobe, resulting in right visual-field blindness, as well as youth with lesions in the splenium of the corpus callosum that blocks transmission of visual information from the intact right hemisphere to the language areas of the left hemisphere experience reading impairments.

Children malnourished for long periods during early childhood are at increased risk of compromised performance cognition, including reading.

**Diagnosis**

Reading impairment is diagnosed when a child’s reading achievement is significantly below that expected of a child of the same age (Table 31.7-1). Characteristic diagnostic features include difficulty recalling, evoking, and sequencing printed letters and words; processing sophisticated grammatical constructions; and making inferences. School failure and ensuing poor self-esteem can exacerbate the problems as a child becomes more consumed with a sense of failure and spends less time focusing on academic work. Students with reading impairment are entitled to an educational evaluation through the school district to determine eligibility for special education services. Special education classification, however, is not uniform across states or regions, and students with identical reading difficulties may be eligible for services in one region, but ineligible in another.

**Clinical Features**

Children with reading disabilities are usually identified by the age of 7 years (second grade). Reading difficulty may be apparent among students in classrooms where reading skills are expected as early as the first grade. Children can sometimes compensate for reading disorder in the early elementary grades by the use of memory and inference, particularly in children with high intelligence. In such instances, the disorder may not be apparent until age 9 (fourth grade) or later. Children with reading impairment make many errors in their oral reading. The errors are characterized by omissions, additions, and distortions of words. Such children have difficulty in distinguishing between printed letter characters and sizes, especially those that differ only in spatial orientation and length of line. The problems in managing printed or written language can pertain to individual letters, sentences, and even a page. The child’s reading speed is slow, often with minimal comprehension. Most children with reading disability have an age-appropriate ability to copy from a written or printed text, but nearly all spell poorly.

Associated problems include language difficulties: discrimination and difficulty in sequencing words properly. A child with reading disorders may start a word either in the middle or at the end of a printed or written sentence. Most children with reading disorder dislike and avoid reading and writing. Their anxiety is heightened when they are confronted with demands that involve printed language. Many children with specific learning disorder who do not receive remedial education have a sense of shame and humiliation because of their continuing failure and subsequent frustration. These feelings grow more intense with time. Older children tend to be angry and depressed and exhibit poor self-esteem.

---

Jackson, a 10-year-old boy, was referred for evaluation of failing to complete in-class assignments and homework, and failing tests in reading, spelling, and arithmetic. For the past 2 years (grades 5 and 6), he had been attending a special education class every morning in the local community school, based on an assessment from the second grade. A subsequent psychoeducational assessment by a clinical psychologist confirmed reading problems. Jackson was eligible for a full-day special education class, whereupon he started attending a program with eight other students ranging from 6 to 12 years of age.

Clinical interview with his parents revealed a normal pregnancy and neonatal period, and a history of language delay. In preschool and kindergarten, Jackson was reported to have had difficulty with rhyming games and showed a lack of interest in books and preferred to play with construction toys. In the first grade, Jackson had more difficulty learning to read than other boys in his class and continued to have problems pronouncing multisyllabic words (e.g., he said “animals” for “animals” and “ablation” for “explanation”). Family history was positive for reading deficits and ADHD. Jackson’s father disclosed a history of his own reading problems, and Jackson’s older brother, 15 years of age, had ADHD, which was well controlled with stimulant medication. Jackson’s parents were concerned about his poor focus in school, and wondered whether he had ADHD. In the clinical interview with Jackson, he rarely made eye contact, mumbled a lot, and struggled to find the right words (e.g., manifested many false starts, hesitations, and nonspecific terms, such as “the thing that you draw ... um ... pencil—no ... um ... lines with”). He admitted to disliking school, adding “Reading is boring and stupid—I’d rather be skateboarding.” Jackson complained about how much reading he was given—even in math—and commented, “Reading takes so much time. By the time I figure out a word, I can’t remember what I just read and so have to read the stuff again.”

Psychoeducational assessment included the Wechsler Intelligence Scale for Children-IV, Clinical Evaluation of Language
A. Difficulties learning and using academic skills, as indicated by the presence of at least one of the following symptoms that have persisted for at least 6 months, despite the provision of interventions that target those difficulties:
   1. Inaccurate or slow and effortful word reading (e.g., reads single words aloud incorrectly or slowly and hesitantly, frequently guesses words, has difficulty sounding out words).
   2. Difficulty understanding the meaning of what is read (e.g., may read text accurately but not understand the sequence, relationships, inferences, or deeper meanings of what is read).
   3. Difficulties with spelling (e.g., may add, omit, or substitute vowels or consonants).
   4. Difficulties with written expression (e.g., makes multiple grammatical or punctuation errors within sentences; employs poor paragraph organization; written expression of ideas lacks clarity).
   5. Difficulties mastering number sense, number facts, or calculation (e.g., has poor understanding of numbers, their magnitude, and relationships; counts on fingers to add single-digit numbers instead of recalling the math fact as peers do; gets lost in the midst of arithmetic computation and may switch procedures).
   6. Difficulties with mathematical reasoning (e.g., has severe difficulty applying mathematical concepts, facts, or procedures to solve quantitative problems).

B. The affected academic skills are substantially and quantifiably below those expected for the individual's chronological age, and cause significant interference with academic or occupational performance, or with activities of daily living, as confirmed by individually administered standardized achievement measures and comprehensive clinical assessment. For individuals age 17 years and older, a documented history of impairing learning difficulties may be substituted for the standardized assessment.

C. The learning difficulties begin during school-age years but may not become fully manifest until the demands for those affected academic skills exceed the individual's limited capacities (e.g., as in timed tests, reading or writing lengthy complex reports for a tight deadline, excessively heavy academic loads).

D. The learning difficulties are not better accounted for by intellectual disabilities, uncorrected visual or auditory acuity, other mental or neurological disorders, psychosocial adversity, lack of proficiency in the language of academic instruction, or inadequate educational instruction.

Note: The four diagnostic criteria are to be met based on a clinical synthesis of the individual's history (developmental, medical, family, educational), school reports, and psychoeducational assessment.

Coding note: Specify all academic domains and subskills that are impaired. When more than one domain is impaired, each one should be coded individually according to the following specifiers.

Specify if:

315.00 (F81.0) With impairment in reading:
   - Word reading accuracy
   - Reading rate or fluency
   - Reading comprehension
   Note: Dyslexia is an alternative term used to refer to a pattern of learning difficulties characterized by problems with accurate or fluent word recognition, poor decoding, and poor spelling abilities. If dyslexia is used to specify this particular pattern of difficulties, it is important also to specify any additional difficulties that are present, such as difficulties with reading comprehension or math reasoning.

315.2 (F81.81) With impairment in written expression:
   - Spelling accuracy
   - Grammar and punctuation accuracy
   - Clarity or organization of written expression

315.1 (F81.2) With impairment in mathematics:
   - Number sense
   - Memorization of arithmetic facts
   - Accurate or fluent calculation
   - Accurate math reasoning
   Note: Dyscalculia is an alternative term used to refer to a pattern of difficulties characterized by problems processing numerical information, learning arithmetic facts, and performing accurate or fluent calculations. If dyscalculia is used to specify this particular pattern of mathematic difficulties, it is important also to specify any additional difficulties that are present, such as difficulties with math reasoning or word reasoning accuracy.

Specify current severity:

Mild: Some difficulties learning skills in one or two academic domains, but of mild enough severity that the individual may be able to compensate or function well when provided with appropriate accommodations or support services, especially during the school years.

Moderate: Marked difficulties learning skills in one or more academic domains, so that the individual is unlikely to become proficient without some intervals of intensive and specialized teaching during the school years. Some accommodations or supportive services at least part of the day at school, in the workplace, or at home may be needed to complete activities accurately and efficiently.

Severe: Severe difficulties learning skills, affecting several academic domains, so that the individual is unlikely to learn those skills without ongoing intensive individualized and specialized teaching for most of the school years. Even with an array of appropriate accommodations or services at home, at school, or in the workplace, the individual may not be able to complete all activities efficiently.

Pathology and Laboratory Examination

No specific physical signs or laboratory measures are helpful in the diagnosis of reading deficits. Psychoeducational testing, however, is critical in determining these deficits. The diagnostic battery generally includes a standardized spelling test, written composition, processing and using oral language, design copying, and judgment of the adequacy of pencil use. The reading subtests of the Woodcock-Johnson Psycho-Educational Battery-Revised, and the Peabody Individual Achievement Test-Revised are useful in identifying reading disability. A screening projective battery may include human-figure drawings, picture-story tests, and sentence completion. The evaluation should also include systematic observation of behavioral variables.

Course and Prognosis

Children with reading disability may gain knowledge of printed language during their first 2 years in grade school, without remedial assistance. By the end of the first grade, many children with reading problems, in fact, have learned how to read a few words; however, by the third grade, keeping up with classmates is exceedingly difficult without remedial educational intervention. When remediation is instituted early, in milder cases, it may not be necessary after the first or second grade. In severe cases and depending on the pattern of deficits and strengths, remediation may be continued into the middle and high school years.

Differential Diagnosis

Reading deficits are often accompanied by comorbid disorders, such as language disorder, disability in written expression, and ADHD. Data indicate that children with reading disability consistently present difficulties with linguistic skills, whereas children with ADHD only, do not. Children with reading disability, without ADHD, however, may have some overlapping deficits in cognitive inhibition, for example, they perform impulsively on continuous performance tasks. Deficits in expressive language and speech discrimination along with reading disorder may lead to a comorbid diagnosis of language disorder. Reading impairment must be differentiated from intellectual disability syndromes in which reading, along with most other skills, are below the achievement expected for a child’s chronological age. Intellectual testing helps to differentiate global deficits from more specific reading difficulties.

Poor reading skills resulting from inadequate schooling can be detected by comparing a given child’s achievement with classmates on reading performance on standardized reading tests. Hearing and visual impairments should be ruled out with screening tests.

Treatment

Remediation strategies for children with reading impairments focus on direct instruction that leads a child’s attention to the connections between speech sounds and spelling. Effective remediation programs begin by teaching the child to make accurate associations between letters and sounds. This approach is based on the theory that the core deficits in reading impairments are related to difficulty recognizing and remembering the associations between letters and sounds. After individual letter-sound associations have been mastered, remediation can target larger components of reading such as syllables and words. The exact focus of any reading program can be determined only after accurate assessment of a child’s specific deficits and weaknesses. Positive coping strategies include small, structured reading groups that offer individual attention and make it easier for a child to ask for help.

Children and adolescents with reading difficulties are entitled to an individual education program (IEP) provided by the public school system. Yet, for high school students with persistent reading disorders and ongoing difficulties with decoding and work identification, IEP services may not be sufficient to remediate their problems. A study of students with reading disorders in 54 schools indicated that, at the high school level, specific goals are not adequately met solely through school remediation. It is likely that high schoolers with persisting reading difficulties may have greater benefit from individualized reading remediation.

Reading instruction programs such as the Orton Gillingham and Direct Instructional System for Teaching and Remediation (DISTAR) approaches begin by concentrating on individual letters and sounds, advance to the mastery of simple phonetic units, and then blend these units into words and sentences. Thus, if children are taught to cope with graphemes, they will learn to read. Other reading remediation programs, such as the Merrill program, and the Science Research Associates, Inc. (SRA) Basic Reading Program, begin by introducing whole words first and
then teach children how to break them down and recognize the sounds of the syllables and the individual letters in the word. Another approach teaches children with reading disorders to recognize whole words through the use of visual aids and bypasses the sounding-out process. One such program is called the Bridge Reading Program. The Fernald method uses a multisensory approach that combines teaching whole words with a tracing technique so that the child has kinesthetic stimulation while learning to read the words.

SPECIFIC LEARNING DISORDER WITH IMPAIRMENT IN MATHEMATICS

Children with mathematics difficulties have difficulty learning and remembering numerals, cannot remember basic facts about numbers, and are slow and inaccurate in computation. Poor achievement in four groups of skills have been identified in mathematics disorder: linguistic skills (those related to understanding mathematical terms and converting written problems into mathematical symbols), perceptual skills (the ability to recognize and understand symbols and order clusters of numbers), mathematical skills (basic addition, subtraction, multiplication, division, and following sequencing of basic operations), and attentional skills (copying figures correctly and observing operational symbols correctly). A variety of terms over the years, including dyscalculia, congenital arithmetic disorder, acalculia, Gerstmann syndrome, and developmental arithmetic disorder have been used to denote the difficulties present in mathematics disorder. Core deficits in dyscalculia are in processing numbers, and good language abilities are skills needed for accurate counting, calculating, and understanding mathematical principles.

Mathematics deficits can, however, occur in isolation or in conjunction with language and reading impairments. According to the DSM-5, the diagnosis of specific learning disorder with impairment in mathematics consists of deficits in arithmetic counting and calculations, has difficulty remembering mathematics facts, and may count on fingers instead. Additional deficits include difficulty with mathmatic concepts and reasoning, leading to difficulties in applying procedures to solve quantitative problems. These deficits lead to skills that are substantially below what is expected for the child’s chronological age and cause significant interference in academic success, as documented by standardized academic achievement testing.

Epidemiology

Mathematics disability alone is estimated to occur in about 1 percent of school-age children, that is about one of every five children with specific learning disorder. Epidemiological studies have indicated that up to 6 percent of school-age children have some difficulty with mathematics, and prevalence estimates of 3.5 to 6.5 percent have been reported for impairing forms of dyscalculia. Although specific learning disorder overall occurs two to three times more often in males, mathematics deficits may be relatively more frequent in girls than reading deficits. Many studies of learning disorders in children have grouped reading, writing, and mathematics disability together, which makes it more difficult to ascertain the precise prevalence of mathematics disability.

Comorbidity

Mathematics deficits are commonly found to be comorbid, with deficits in both reading and written expression. Children with mathematics difficulties may also be at higher risk for expressive language problems, and developmental coordination disorder.

Etiology

Mathematics deficiency, as with other areas of specific learning disorder, has a significant genetic contribution. High rates of comorbidity with reading deficits have been reported in the range of 17 percent up to 60 percent. One theory proposed a neurological deficit in the right cerebral hemisphere, particularly in the occipital lobe areas. These regions are responsible for processing visual–spatial stimuli that, in turn, are responsible for mathematical skills. This theory, however, has received little support in subsequent neuropsychiatric studies.

Causes of deficits in mathematics are believed to be multifactorial, including genetic, maturational, cognitive, emotional, educational, and socioeconomic factors. Prematurity and very low birth weight are also a risk factor for specific learning disorder, including mathematics. Compared with reading abilities, arithmetic abilities seem to depend more on the amount and quality of instruction.

Diagnosis

The diagnosis of specific learning disorder in mathematics is made when a child’s skill in mathematical reasoning, or calculation, remain significantly below what is expected for that child’s age, for a period of at least 6 months, even when remedial interventions have been administered. Many different skills contribute to mathematics proficiency. These include linguistic skills, conceptual skills, and computational skills. Linguistic skills involve being able to understand mathematical terms, understand word problems, and translate them into the proper mathematical process. Conceptual skills involve recognition of mathematical symbols and being able to use mathematical signs correctly. Computational skills include the ability to line up numbers correctly and to follow the “rules” of the mathematical operation. The DSM-5 diagnostic criteria for specific learning disorder with impairment in mathematics are provided in Table 31.7-1.

Clinical Features

Common features of mathematics deficit include difficulty learning number names, remembering the signs for addition and subtraction, learning multiplication tables, translating word problems into computations, and performing calculations at the expected pace. Most children with mathematics deficits can be detected during the second and third grades in elementary school. A child with poor mathematics abilities typically has problems with concepts, such as counting and adding even one-digit numbers, compared with classmates of the same age. During the first 2 or 3 years of elementary school, a child with poor mathematics skill may just get by in mathematics by relying on rote memory. But soon, as mathematics problems require discrimination and manipulation of spatial and numerical relations, a child with mathematics difficulties is overwhelmed.
Some investigators have classified mathematics deficiencies into the following categories: difficulty learning to count meaningfully; difficulty mastering cardinal and ordinal systems; difficulty performing arithmetic operations; and difficulty envisioning clusters of objects as groups. Children with mathematics difficulty have trouble associating auditory and visual symbols, understanding the conservation of quantity, remembering sequences of arithmetic steps, and choosing principles for problem-solving activities. Children with these problems are presumed to have good auditory and verbal abilities; however, in many cases, the mathematics deficits may occur in conjunction with reading, writing, and language problems. In these cases, the other deficiencies may compound the impairment of the poor mathematics skill.

Mathematics difficulty, in fact, often coexists with other disorders affecting reading, expressive writing, coordination, and language. Spelling problems, deficits in memory or attention, and emotional or behavioral problems may be present. Young grade-school children may exhibit specific learning problems in reading and writing, and these children should also be evaluated for mathematics deficits. The exact relationship between mathematics deficits and the deficits in language and dyslexia is not clear. Although children with language disorder do not necessarily experience mathematics deficiencies, these conditions often coexist, and both are associated with impairments in decoding and encoding processes.

Lena, an 8-year-old girl, was referred for evaluation of impairing problems in attention and academic achievement, which were first noted in kindergarten but were now causing difficulty at home and school. Lena attended a regular third-grade class in a local public school, which she had been attending since midway through kindergarten.

Lena's history included a mild delay in speech acquisition (e.g., first words at approximately 18 months of age and short sentences at approximately 3 years of age), but otherwise she had no major developmental problems until kindergarten, when her teacher had raised concerns about inattentiveness, difficulty following instructions, and her difficulty in mastering basic number concepts (e.g., inaccurate counting of sets of objects). A speech, language, and hearing assessment completed at the end of kindergarten revealed mild language problems that did not warrant specific intervention. School reports from grades 1 and 2 noted ongoing concerns about inattention, poor reading skills, and difficulty mastering simple arithmetic facts, and "making careless mistakes in copying numbers from the board and in doing addition and subtraction." These problems continued through grade 2, despite some in-school accommodations (e.g., moving Lena's seat closer to the teacher) and modifications (e.g., providing her with printed sheets of arithmetic problems so she did not need to copy them herself). Lena's parents reported a 3-year history of losing things, fidgeting at the dinner table, and difficulty concentrating on games and homework, and forgetting to bring notes to and from school.

Psychological assessment included the Wechsler Intelligence Scale for Children-III, Clinical Evaluation of Language Fundamentals-IV, Comprehensive Test of Phonological Processing, and the Woodcock-Johnson Psycho-Educational Battery—III. Results indicated average intelligence, with relatively weaker performance on tests of perceptual organization, weak phonological (speech sound) awareness, mild deficits in receptive and expressive language, and reading and arithmetic abilities that were well below grade level. Parent and teacher ratings on a standardized behavior questionnaire (Conners' Rating Scales—Long Form) were above clinical threshold for ADHD.

Lena was given a diagnosis of ADHD, predominantly inattentive type, and specific learning disorder with impairment in reading, based on the history, school achievement, and standardized assessment. She did not meet criteria for communication disorder, and it was speculated that her mathematics problems did not cause impairment like her reading disorder and ADHD did. Recommendations included the following: family psychoeducation clarifying the ADHD and specific learning disorder, remedial interventions for reading, and treatment of her ADHD with a long-acting stimulant agent.

At 1-year follow-up, Lena and her parents reported noticeable improvement with inattention, but ongoing problems with reading and more significant deficits in mathematics. Mathematics remediation was added to her weekly schedule. Two years later, when Lena was 11 years of age, her parents called for an "urgent reevaluation" due to a sudden worsening of her difficulties at home and school. Clinical evaluation revealed adequate stimulant treatment response of her ADHD, more marked deficits in reading speed accuracy compared to others her age, and significant deficits in mathematics. Lena's parents reported that she had started lying about having mathematics homework or refused to do it, was suspended from mathematics class twice in the past 3 months because of oppositional behavior, and had failed sixth-grade mathematics. Lena acknowledged disliking and worrying about math: "whenever the teacher starts asking questions and looks in my direction, my mind just goes blank and I feel sort of shaky—it's so bad in tests that I have to leave class to get myself together." At this point, an additional component of anxiety was noted to be contributing to her school impairments. Recommendations were expanded to include increased specific educational remediation for mathematics. At follow-up, Lena reported that the resource teacher had taught her some helpful strategies to address her anxiety about mathematics, as well as ways of classifying word problems and differentiating critical information from irrelevant information. She continued to be a robust responder to long-acting stimulants for her ADHD, and had only minimal difficulties concentrating on homework after school. (Adapted from case material by Rosemary Tannock, Ph.D.)

Pathology and Laboratory Examination

No physical signs or symptoms indicate mathematics disorder, but educational testing and standardized measurement of intellectual function are necessary to make this diagnosis. The Keymath Diagnostic Arithmetic Test measures several areas of mathematics including knowledge of mathematical content, function, and computation. It is used to assess ability in mathematics of children in grades 1 to 6.

Course and Prognosis

A child with a specific learning disorder in mathematics can usually be identified by the age of 8 years (third grade). In some children, the disorder is apparent as early as 6 years (first grade); in others, it may not be apparent until age 10 (fifth grade) or later. Too few data are currently available from longitudinal studies to predict clear patterns of developmental and academic progress of children classified as having mathematics disorder in early school grades. On the other hand, children with a moderate mathematics disorder who do not receive intervention may have complications, including continuing academic difficulties, shame, poor self-concept, frustration, and depression. These complications can lead to reluctance to attend school, and demoralization about academic success.
Differential Diagnosis

Mathematics deficits must be differentiated from global causes of impaired functioning such as intellectual disability. Arithmetic difficulties in intellectual disability are accompanied by similar impairments in overall intellectual functioning. Inadequate schooling can affect a child’s arithmetic performance on a standardized arithmetic test. Conduct disorder or ADHD can occur comorbidly with specific learning disorder in mathematics and, in these cases, both diagnoses should be made.

Treatment

Mathematics difficulties for children are best remediated with early interventions that lead to improved skills in basic computation. The presence of specific learning disorder in reading along with mathematics difficulties can impede progress; however, children are quite responsive to remediation in early grade school. Children with indications of mathematics disorder as early as in kindergarten require help in understanding which digit in a pair is larger, counting abilities, identification of numbers, and remembering sequences of numbers. Flash cards, workbooks, and computer games can be a viable part of this treatment. One study indicated that mathematics instruction is most helpful when the focus is on problem-solving activities, including word problems, rather than only computation. Project MATH, a multimedia self-instructional or group-instructional in-service training program, has been successful for some children with mathematics disorder. Computer programs can be helpful and can increase compliance with remediation efforts.

Social skills deficits can contribute to a child’s hesitation in asking for help, so a child identified with a mathematics disorder may benefit from gaining positive problem-solving skills in the social arena as well as in mathematics.

SPECIFIC LEARNING DISORDER WITH IMPAIRMENT IN WRITTEN EXPRESSION

Written expression is the most complex skill acquired to convey an understanding of language and to express thoughts and ideas. Writing skills are highly correlated with reading for most children; however, for some youth, reading comprehension may far surpass their ability to express complex thoughts. Written expression in some cases is a sensitive index of more subtle deficits in language usage that typically are not detected by standardized reading and language tests.

Deficits in written expression are characterized by writing skills that are significantly below the expected level for a child’s age and education. Such deficits impair the child’s academic performance and writing in everyday life. Components of writing disorder include poor spelling, errors in grammar and punctuation, and poor handwriting. Spelling errors are among the most common difficulties for a child with a writing disorder. Spelling mistakes are most often phonetic errors; that is, an erroneous spelling that sounds like the correct spelling. Examples of common spelling errors are: fone for phone, or beleve for believe.

Historically, dysgraphia (i.e., poor writing skills) was considered to be a form of reading disorder; however, it is now clear that impairment in written expression can occur on its own. Terms once used to describe writing disability include spelling disorder and spelling dystexia. Writing disabilities are often associated with other forms of specific learning disorders; however, impaired writing ability may be identified later than other forms because it is generally acquired later than verbal language and reading.

In contrast with the DSM-5, which includes specific learning disorder in written expression, the 10th Edition of the International Statistical Classification of Diseases and Related Health Problems (ICD-10) includes a separate specific spelling disorder.

Epidemiology

The prevalence of specific learning disorder with impairment in written expression has been reported to occur in the range of 5 to –15 percent of school-age children. Over time, specific learning disorder remits in many youth, leading to a persistent rate of specific learning disorder of 4 percent in adults. The gender ratio in writing deficits is two to three to one in boys compared with girls. Impaired written expression often occurs along with deficits in reading, but not always.

Comorbidity

Children with impaired writing ability are significantly more likely to have language disorder and impairments in reading and mathematics compared to the general population of youth. ADHD occurs with greater frequency in children with writing disability than in the general population. Youth with specific learning disorder, including writing disability, are at higher risk for social skills difficulties, and some develop poor self-esteem and depressive symptoms.

Etiology

Causes of writing disability are believed to be similar to those of reading disorder, that is, underlying deficits in using the components of language related to letter sounds. Genetic factors are a significant factor in the development of writing disability. Writing difficulties often accompany language disorder, leading an affected child to have trouble with understanding grammatical rules, finding words, and expressing ideas clearly. According to one hypothesis, impairment in written expression may result from combined effects of language disorder, and reading disorder. Hereditary predisposition to writing impairment is supported by the finding that most youth with impaired written expression have first-degree relatives with similar difficulties. Children with limited attention spans and high levels of distractibility may find writing an arduous task.

Diagnosis

The DSM-5 diagnosis of specific learning disorder with impairment in written expression is based on a child’s poor ability to use punctuation and grammar accurately in sentences, inability to organize paragraphs, or to clearly articulate ideas in writing.
Poor performance on composing written text may also include poor handwriting and impaired ability to spell and to place words sequentially in coherent sentences, compared to others of the same age. In addition to spelling mistakes, youth with impaired written expression make grammatical mistakes, such as using incorrect tenses, forgetting words in sentences, and placing words in the wrong order. Punctuation may be incorrect, and the child may have poor ability to remember which words begin with capital letters. Additional symptoms of impaired written expression include the formation of letters that are not legible, inverted letters, and mixtures of capital and lowercase letters in a given word. Other features of writing disorders include poor organization of written stories, which lack critical elements such as “where,” “when,” and “who” or clear expression of the plot.

**Clinical Features**

Youth with impairments in written expression struggle early in grade school with spelling words and expressing their thoughts according to age-appropriate grammatical norms. Their spoken and written sentences contain an unusually large number of grammatical errors and poor paragraph organization. Affected children commonly make simple grammatical errors, even when writing a short sentence. For example, despite constant reminders, affected youth frequently fail to capitalize the first letter of the first word in a sentence, and fail to end the sentence with a period. Typical features of impaired written expression include spelling errors, grammatical errors, punctuation errors, poor paragraph organization, and poor handwriting.

In higher grades in school, affected youth’s written sentences become more conspicuously primitive, odd, and inaccurate compared to what is expected of students at their grade level. For youth with impaired written expression, word choices are often erroneous and inappropriate, paragraphs are disorganized and not in proper sequence, and spelling accuracy becomes increasingly difficult as their vocabulary becomes larger and more abstract. Associated features of writing impairments may include reluctance to go to school, refusal to do assigned written homework, and concurrent academic difficulties in other areas.

Many children with impaired written expression understandably become frustrated and angry, and harbor feelings of shame and inadequacy regarding poor academic achievement. In some cases, depressive disorders can result from a growing sense of isolation, estrangement, and despair. Young adults with impaired written expression who do not receive remedial intervention continue to have writing skills deficits and a persistent sense of incompetence and inferiority.

Brett, an 11-year-old boy, was referred for evaluation of increasing problems in school over a 2-year period, including failure to complete assigned schoolwork and homework, inattention and oppositional behavior, and deteriorating grades and test scores. At the time of assessment, he was enrolled in a regular fifth-grade class in a public school, which he had been attending since grade 1.

Clinical interview with parents revealed that Brett had a twin brother (monozygotic) with a history of language problems for which he had received speech-language therapy in the preschool years and remedial reading in the primary grades. Brett, however, had not exhibited difficulty in speech or language development, according to parental report and scores on standardized tests of oral language administered in the preschool years. His current and previous school reports indicate that Brett participated well in class discussions and had no difficulty in reading or mathematics; however, his written work was far below grade level. In each of the last 2 years, his teachers had expressed increasing concerns about Brett’s refusal to complete written work, failure to hand in homework, daydreaming and fidgeting in class, and withdrawal from class activities. Brett admitted to an increasing dislike of school and especially writing assignments. He explained, “It’s writing, writing all day long—even in math and science. I know how to do the problems and the experiments, but I hate having to write it all down—my mind just goes blank.” Brett complained “My teacher is always on at me, telling me that I’m lazy and haven’t done enough, and that my writing is atrocious. He tells me, I’ve got a bad attitude—so why would I want to go to school?” Brett and his parents reported that, over the past year, he has been down, increasingly frustrated with school, and has refused to do homework. They all agree that Brett has had a few brief episodes of depressed mood.

Testing by a clinical psychologist revealed average to high-average scores on the verbal and performance scales of the Wechsler Intelligence Scale for Children-III and average scores on the reading and arithmetic subtests of the Wide Range Achievement Test-3 (WRAT-3). However, scores on the WRAT-3 spelling subtest were below the 9th percentile, which was significantly below expectations for age and ability. Examination of his spelling errors revealed that, although his spelling was typically phonologically accurate (i.e., could plausibly be pronounced to sound like the target word), it was unacceptable in that he used letter sequences that did not resemble English, regardless of pronunciation (e.g., “housis” was written as “howisss,” “phones” was written as “fonse,” and “exact” was written as “egsazkt”). Moreover, his performance was well below age and grade on standardized tests of written expression (TOWL-3), as well as on a brief (5-minute) informal assessment of expository text generation on a favorite topic (e.g., newspaper article on recent sports event). During the 5-minute writing activity, he was observed to frequently stare out of the window, to shift positions and to chew on his pencil, to get up to sharpen his pencil and to sigh when he did put pencil to paper, and to write slowly and laboriously. At the end of 5 minutes, he had produced three short sentences without any punctuation or capitalization that were barely legible, containing several misspellings and grammatical errors, and that were not linked semantically. By contrast, later in the assessment, he described the sporting event with detail and enthusiasm. A speech-language evaluation revealed average scores on standard tests of oral language (Clinical Evaluation of Language Fundamentals-IV), but he was noted to omit sounds or syllables in a multisyllabic word in a nonword repetition test, which has been found to be sensitive to mild residual language impairments and written language impairments.

The clinical team formulated a diagnosis of specific learning disorder with impairment in written expression, based on Brett’s inability to compose written text, poor spelling, and grammatical errors, without problems in reading or mathematics or a history of language impairments. He did not meet full diagnostic criteria for any other DSM-5 disorder, including oppositional defiant disorder, ADHD, or mood disorder. Recommendations included the following: psychoeducation, the need for educational accommodations (e.g., provision of additional time for test taking and written assignments, specific educational intervention to facilitate written expression and to teach note taking, and use of specific computer software to support written composition and spelling), and counseling should his depressed mood continue or worsen. (Adapted from case material from Rosemary Tannock, Ph.D.)
Pathology and Laboratory Examination

Whereas no physical signs of a writing disorder exist, educational testing is used in making a diagnosis of writing disorder. Diagnosis is based on a child’s writing performance being markedly below expected production for his age, as confirmed by an individually administered standardized expressive writing test. Currently available tests of written language include the Test of Written Language (TOWL), the DEWS, and the Test of Early Written Language (TEWL). Evaluation for impaired vision and practice in spelling and sentence writing as well as a review of grammatical rules. Intensive and continuous administration of individually tailored, one-on-one expressive and creative writing therapy appears to effect favorable outcome. Teachers in some special schools devote as much as 2 hours a day to such writing instruction. The effectiveness of a writing intervention depends largely on an optimal relationship between the child and the writing specialist. Success or failure in sustaining the patient’s motivation greatly affects the treatment’s long-term efficacy. Associated secondary emotional and behavioral problems should be given prompt attention, with appropriate psychiatric treatment and parental counseling.

Course and Prognosis

Specific learning disorder with impairment in writing, reading, and mathematics often coexist, and additional language disorder may be present as well. A child with all of the above disabilities will likely be diagnosed with language disorder first and impaired written expression last. In severe cases, an impaired written expression is apparent by age 7 (second grade); in less severe cases, the disorder may not be apparent until age 10 (fifth grade) or later. Youth with mild and moderate impairment in written expression fare well if they receive timely remedial education early in grade school. Severely impaired written expression requires continual, extensive remedial treatment through the late part of high school and even into college.

The prognosis depends on the severity of the disorder, the age or grade when the remedial intervention is started, the length and continuity of treatment, and presence or absence of associated or secondary emotional or behavioral problems.

Differential Diagnosis

It is important to determine whether disorders such as ADHD or major depression are interfering with a child’s focus and thereby preventing the production of adequate writing in the absence of a specific writing impairment. If true, treatment for the other disorder should improve a child’s writing performance. Commonly comorbid disorders with writing disability are language disorder, mathematics disorder, developmental coordination disorder, disruptive behavior disorders, and ADHD.

Treatment

Remedial treatment for writing disability includes direct practice in spelling and sentence writing as well as a review of grammatical rules. Intensive and continuous administration of individually tailored, one-on-one expressive and creative writing therapy appears to effect favorable outcome. Teachers in some special schools devote as much as 2 hours a day to such writing instruction. The effectiveness of a writing intervention depends largely on an optimal relationship between the child and the writing specialist. Success or failure in sustaining the patient’s motivation greatly affects the treatment’s long-term efficacy. Associated secondary emotional and behavioral problems should be given prompt attention, with appropriate psychiatric treatment and parental counseling.

Course 31: Child Psychiatry

Coordinat e Disorder

Developmental coordination disorder is a neurodevelopmental disorder in which a child’s fine and/or gross motor coordination is slower, less accurate, and more variable than in peers of the same age. Affecting about 5 to 6 percent of school-age children, 50 percent of children with developmental coordination disorder...
disorder also have comorbid attention-deficit/hyperactivity disorder (ADHD) or dyslexia. A meta-analysis of recent research on developmental coordination disorder concluded that three general areas of deficits contribute to the disorder: (1) Poor predictive control of motor movements; (2) deficits in rhythmic coordination and timing; and (3) deficits in executive functions, including working memory, inhibition, and attention.

Children with developmental motor coordination struggle to perform accurately the motor activities of daily life, such as jumping, hopping, running, or catching a ball. Children with coordination problems may also agonize to use utensils correctly, tie their shoelaces, or write. A child with developmental coordination disorder may exhibit delays in achieving motor milestones, such as sitting, crawling, and walking, because of clumsiness, and yet excel at verbal skills.

Developmental coordination disorder, thus, may be characterized by either clumsy gross and/or fine motor skills, resulting in poor performance in sports and even in academic achievement because of poor writing skills. A child with developmental coordination disorder may bump into things more often than siblings or drop things. In the 1930s, the term clumsy child syndrome began to be used in the literature to denote a condition of awkward motor behaviors that could not be correlated with any specific neurological disorder or damage. This term continues to be used to identify imprecise or delayed gross and fine motor behavior in children, resulting in subtle motor inabilities, but often significant social rejection. Gross and fine motor impairment in developmental coordination disorder cannot be explained on the basis of a medical condition, such as cerebral palsy, muscular dystrophy, or a neuromuscular disorder. Currently, certain indications are that perinatal problems, such as prematurity, low birth weight, and hypoxia may contribute to the emergence of developmental coordination disorders. Children with developmental coordination disorder are at higher risk for language and learning disorders. A strong association is seen between speech and language problems and coordination problems, as well as an association of coordination difficulties with hyperactivity, impulsivity, and poor attention span.

Children with developmental coordination disorder may resemble younger children because of their inability to master motor activities typical for their age group. For example, children with developmental coordination disorder in elementary school may not be adept at bicycle riding, skateboarding, running, skipping, or hopping. In the middle school years, children with this disorder may have trouble in team sports, such as soccer, baseball, or basketball. Fine motor skill manifestations of developmental coordination disorder typically include clumsiness using utensils and difficulty with buttons and zippers in the preschool age group. In older children, using scissors and more complex grooming skills, such as styling hair or putting on makeup, is difficult. Children with developmental coordination disorder are often ostracized by peers because of their poor skills in many sports, and they often have long-standing difficulties with peer relationships. Developmental coordination disorder is categorized in the Fifth Edition of the American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders (DSM-5) as a Motor Disorder, along with stereotypic movement disorder and tic disorders.

**EPIDEMIOLOGY**

The prevalence of developmental coordination disorder has been estimated at about 5 to 6 percent of school-age children. The male-to-female ratio in referred populations tends to show increased rates of the disorder in males, but schools refer boys more often for testing and special education evaluations. Reports in the literature of the male-to-female ratio have ranged from 3 to 1 to as high as 7 to 1; however, the most current estimates are approximately 2 males for every one female.

**COMORBIDITY**

Developmental coordination disorder is strongly associated with ADHD, specific learning disorder, particularly in reading, as well as language disorder. Children with coordination difficulties have higher than expected rates of language disorder, and studies of children with language disorder report very high rates of “clumsiness.” Developmental coordination disorder is also associated, but less strongly, with specific learning disorder with impairment in mathematics, and in written expression. A study of children with developmental coordination disorder reported that, although motor coordination is critical for accuracy in tasks that require speed, poor motor coordination is not directly correlated with degree of inattention. Thus, in children comorbid for ADHD and developmental coordination disorder, children with the most severe ADHD do not necessarily have the worst developmental coordination disorder. Functional neuroimaging, pharmacological, and neuroanatomical studies suggest that motor coordination depends on the integration of sensory input and an action response, not purely through sensorimotor function and higher level thinking. Investigations of comorbid developmental coordination disorder and ADHD are trying to ascertain whether this comorbidity is due to overlapping genetic factors.

Peer relationship problems are common among children with developmental coordination disorders, because of rejection that often occurs along with their poor performance in sports and games that require good motor skill. Adolescents with coordination problems often exhibit poor self-esteem and academic difficulties. Recent studies underscore the importance of attention to both victimization of children and adolescents with developmental motor coordination by peers and the potential resulting damage to self-worth. Children and adolescents with developmental coordination disorder who are bullied have higher rates of poor self-esteem that often deserves clinical attention.

**ETIOLOGY**

The causes of developmental coordination disorder are believed to be multifactorial, and likely include both genetic and developmental factors. Risk factors postulated to contribute to this disorder include prematurity, hypoxia, perinatal malnutrition, and low birth weight. Prenatal exposure to alcohol, cocaine, and nicotine has also been hypothesized to contribute to both low birth weight and cognitive and behavioral abnormalities. Developmental coordination disorder rates of up to 50 percent have been reported in children born prematurely. Researchers have proposed that the cerebellum may be the neurological substrate for comorbid cases of developmental coordination disorder and
ADHD. Neurochemical abnormalities and parietal lobe lesions have also been suggested to contribute to coordination deficits. Studies of postural control, that is, the ability to regain balance after being in motion, indicate that children with developmental coordination disorder who have adequate balance when standing still, are unable to accurately correct for movement, resulting in impaired balance, compared with other children. A study concluded that, in children with developmental coordination disorder, neural signals from the brain to particular muscles involved in balance, are neither being optimally sent or received. These findings have also implicated the cerebellum as a potential anatomical site for the dysfunction of developmental coordination disorder. Two mechanisms of developmental coordination disorder have been hypothesized for the disabilities of the disorder. The first one, called the automatization deficit hypothesis, suggests that, similar to dyslexia, children with developmental coordination disorder have difficulty developing automatic motor skills. The second hypothesis, the internal modeling deficit hypothesis, suggests that children with developmental coordination disorder are unable to perform the typical internal cognitive models that predict the sensory consequences of motor commands. In both scenarios, the cerebellum is believed to play an important role in motor coordination and in developmental coordination disorder.

**DIAGNOSIS**

The diagnosis of developmental coordination disorder depends on poor performance in activities requiring coordination for a child’s age and intellectual level. Diagnosis is based on a history of the child’s delay in achieving early motor milestones, as well as on direct observation of current deficits in coordination. An informal screen for developmental coordination disorder involves asking the child to perform tasks involving gross motor coordination (e.g., hopping, jumping, and standing on one foot); fine motor coordination (e.g., finger-tapping and shoelace tying); and hand-eye coordination (e.g., catching a ball and copying letters). Judgments regarding poor performance must be based on what is expected for a child’s age. A child who is mildly clumsy, but whose functioning is not impaired, does not qualify for a diagnosis of developmental coordination disorder.

The diagnosis may be associated with below-normal scores on performance subtests of standardized intelligence tests and by normal or above-normal scores on verbal subtests. Specialized tests of motor coordination can be useful, such as the Bender Visual Motor Gestalt Test, the Frostig Movement Skills Test Battery, and the Bruininks-Oseretsky Test of Motor Development. The child's chronological age must be taken into account, and the disorder cannot be caused by a neurological or neuromuscular condition. Examination, however, may occasionally reveal slight reflex abnormalities and other soft neurological signs.

**CLINICAL FEATURES**

The clinical signs suggesting the existence of developmental coordination disorder are evident as early as infancy in some cases, when a child begins to attempt tasks requiring motor coordination. The essential clinical feature is significantly impaired performance in motor coordination. The difficulties in motor coordination may vary with a child’s age and developmental stage (Table 31.8a-1).

In infancy and early childhood the disorder may be manifested by delays in developmental motor milestones, such as turning over, crawling, sitting, standing, walking, buttoning shirts, and zipping up pants. Between the ages of 2 and 4 years, clumsiness appears in almost all activities requiring motor coordination. Affected children cannot hold objects and drop them easily, their gait may be unsteady, they often trip over their own feet, and they may bump into other children while attempting to go around them. Older children may display impaired motor coordination in table games, such as putting together puzzles or building blocks, and in any type of ball game. Although no specific features are pathognomonic of developmental coordination disorder, developmental milestones are frequently delayed. Many children with the disorder also have speech and language difficulties. Older children may have secondary problems, including academic difficulties, as well as poor peer relationships based on social rejection. It has been reported widely that children with motor coordination problems are more likely to have problems understanding subtle social cues and are often rejected by peers. A recent study indicated that children with motor difficulties were found to perform more poorly on scales that measure recognition of static and changing facial expressions of emotion. This finding is likely to be correlated to the clinical observations that children with motor coordination have difficulties in social behavior and peer relationships.

</table>
Billy was brought for evaluation of suicidal ideation at 8 years of age, after complaining to his parents that he was being bullied by peers for being “bad” in sports, and that nobody liked him. He only had one friend who also laughed at him sometimes, because he always dropped the ball and he looked “funny” while running. He was so upset about being rejected by peers when he tried to play sports that he refused to go to physical education class. Instead, he voluntarily went to the school counselor’s office and stayed there until the period was over. Billy was already irritated because he had been diagnosed with ADHD and was on medication, and on top of that, he had difficulty with reading. Billy became so distraught that one day he told his school counselor that he wanted to kill himself. A developmental history revealed that he had been delayed for sitting, which he finally did at 10 months of age, and he could not walk without falling over until 30 months of age. Billy’s parents were aware that he was very clumsy, but they believed that he would outgrow that. Even at 8 years of age, Billy’s parents reported that, during meals, Billy often spilled his drinks and was quite awkward when he used a fork. Some of his food typically fell off of his fork or spoon before it reached his mouth, and he had great difficulty using a knife and a fork.

A comprehensive assessment of fine and gross motor skills demonstrated the following: Billy was able to hop, but he could not skip without briefly stopping after each step. Billy could stand with both feet together, but was unable to stand on tiptoe. Although Billy could catch a ball, he held a ball bouncing at chest level and was unable to catch a ball bounced to him on the ground from a distance of 15 feet. Billy’s agility and coordination were measured with the Bruininks-Oseretsky Test of Motor Development, which revealed functioning levels commensurate with those of an average 6-year-old child.

Billy was referred to a neurologist for a comprehensive evaluation, because he appeared to be generally weak, and his muscles seemed floppy. Neurological evaluation was negative for diagnosable neurological disorders, and his muscle strength was actually found to be normal, despite his appearance. Based on the negative neurological examination and the finding of the Bruininks-Oseretsky Test of Motor Development, Billy was given a diagnosis of developmental coordination disorder. Billy’s symptoms included mild hypotonia and fine motor clumsiness.

After the diagnosis of developmental motor coordination was made, in addition to his already diagnosed ADHD and reading disorder, his treatment plan included private sessions with an occupational therapist who used perceptual-motor exercises to improve Billy’s fine motor skills, targeting particularly writing and use of utensils. A written request was made for an Individualized Educational Plan (IEP) evaluation from the school with a goal of obtaining an adaptive physical education program. In addition, the request for a reading tutor, and a seat close to the front of the classroom were recommended to maximize his attention. Billy was enrolled in a treatment program using motor imagery training to reduce his clumsiness and improve coordination.

Billy was relieved to be receiving help, especially for his reading and for sports activities, and no longer felt suicidal. Over a period of 3 months of treatment, Billy showed a noticeable improvement in his reading. His mood improved further, especially because he was receiving praise from his teachers and parents. Billy’s classmates were not picking on him the way they used to. As Billy began to feel better about himself, he began to play sports informally with his peers, although not competitively. Billy was granted an adaptive physical education program in school, and he was not required to play on teams. Instead, he practiced throwing and catching a ball and playing basketball with a staff member.

Billy continued to show some degree of clumsiness, especially in his fine motor skills over the next few years, yet he was cooperative, with the occupational therapy interventions, his mood was bright, and he demonstrated continual improvement. (Courtesy of Caroly Patak, M.D. and Sarah Spence, M.D.)

Differential Diagnosis

The differential diagnosis includes medical conditions that produce coordination difficulties (e.g., cerebral palsy and muscular dystrophy). In autism spectrum disorder and intellectual disability, coordination usually does not stand out as a significant deficit compared with other skills. Children with neuromuscular disorders may exhibit more global muscle impairment rather than clumsiness and delayed motor milestones. Neurological examination and workup usually reveal more extensive deficits in neurological conditions than in developmental coordination disorder. Extremely hyperactive and impulsive children may be physically careless because of their high levels of motor activity. Clumsy gross and fine motor behavior and ADHD as well as reading difficulties are highly associated.

Course and Prognosis

Historically, it was believed that developmental coordination spontaneously improved over time; however, longitudinal studies have shown that motor coordination problems can persist into adolescence and adulthood. When mild to moderate clumsiness is persistent, some children can compensate by developing interests in other skills. Some studies suggest a more favorable outcome for children who have average or above-average intellectual capacity, in that they come up with strategies to develop friendships that do not depend on physical activities. Clumsiness typically persists into adolescence and adult life. One study following a group of children with developmental coordination problems over a decade found that the clumsy children remained less dexterous, showed poor balance, and continued to be physically awkward. The affected children were also more likely to have both academic problems and poor self-esteem. Children with developmental coordination disorder have also been shown to be at higher risk for obesity, have difficulties with running, and are at greater risk of future cardiovascular diseases.

Treatment

Interventions for children with developmental coordination disorder utilize multiple modalities, including visual, auditory, and tactile materials targeting perceptual motor training for specific motor tasks. Two broad categories of interventions are the following: (1) deficit-oriented approaches, including sensory integration therapy, sensorimotor-oriented treatment, and process-oriented treatment; and (2) task-specific interventions, including neuromotor task training and cognitive orientation to daily occupational performance (CO-OP). More recently, motor imagery training has been incorporated into treatment. These approaches involve visual imagery exercises using CD-ROM; they have a broad range of foci, including predictive timing for motor tasks, relaxation and mental preparation, visual
modeling of fundamental motor skills, and mental rehearsal of various tasks. This type of intervention is based on the notion that improved internal representation of a movement task will improve a child's actual motor behavior.

The treatment of developmental coordination disorder generally includes versions of sensory integration programs and modified physical education. Sensory integration programs, usually administered by occupational therapists, consist of physical activities that increase awareness of motor and sensory function. For example, a child who jumps into objects often might be given the task of trying to balance on a scooter, under supervision, to improve balance and body awareness. Children who have difficulty writing letters are often given tasks to increase awareness of hand movements. School-based occupational therapies for motor coordination problems in writing include utilizing mechanisms that provide resistance or vibration during writing exercises, to improve grip, and practicing vertical writing on a chalk board to increase arm strength and stability while writing. These programs have been shown to improve legibility of student's writing, but not necessarily the quality of the writing. Adapted keyboards may be beneficial. Parental counseling may help reduce parents' anxiety and guilt about their child's impairment, but may also allow and may even encourage children with coordination difficulties that affect writing to use computers to aid in writing reports and long papers.

Adaptive physical education programs are designed to help children enjoy exercise and physical activities without the pressures of team sports. These programs generally incorporate certain sports actions, such as kicking a soccer ball or throwing a basketball. Children with coordination disorder may also benefit from social skills groups and other prosocial interventions. The Montessori technique may promote motor skill development, especially with preschool children, because this educational program emphasizes the development of motor skills. Small studies have suggested that exercise in rhythmic coordination, practicing motor movements, and learning to use word processing keyboards may be beneficial. Parental counseling may help reduce parents' anxiety and guilt about their child's impairment, increase their awareness, and facilitate their confidence to cope with the child.

An investigation of children with developmental coordination disorder showed positive results using a computer game designed to improve ability to catch a ball. These children were able to improve their game score by practicing virtual catching without specific instructions on how to utilize the visual cues. This has implications for treatment, in that certain types of motor task coordination can be positively influenced through the practice of specific motor tasks, even without overt instructions.

31.8b Stereotypic Movement Disorder

Stereotypic movements include a diverse range of repetitive behaviors that usually emerge in the early development period, appear to lack a clear function, and sometimes cause interruption in daily life. These movements are typically rhythmic, such as hand flapping, body rocking, hand waving, hair-twirling, lip-licking, skin picking, or self-hitting. Stereotypic movements often appear to be self-soothing or self-stimulating; however, they can result in self-injury in some cases. Stereotypic movements appear to be involuntary; however, they frequently can be suppressed with a concentrated effort. Stereotypic movement disorder occurs with increased frequency in children with autism spectrum disorder and intellectual disability, but they also exist in typically developing children. Stereotypic movements, such as head-banging, face slapping, eye poking, or hand-biting, can cause significant self-harm. Nail-biting, thumb-sucking, and nose-picking are often not included as symptoms of stereotypic movement disorder because they rarely cause impairment. When impairment occurs, however, they can be included in stereotypic movement disorder. Stereotypic movements share several features with tics, including the repetitive, seemingly involuntary, and characteristically identical nature of the movements each time they are displayed. However, distinguishing features of stereotypical movements compared to tics include a younger age of onset, lack of changing anatomical locations, lack of premonitory “urge,” and decreased response to medication management.

According to the Fifth Edition of the American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders (DSM-5), stereotypic movement disorder is characterized
by repetitive, seemingly driven, and apparently purposeless motor behavior that interferes with social, academic, or other activities and may result in self-harm.

EPIDEMIOLOGY
Repetitive movements are common in infants and young children, with greater than 60 percent of parents of children between the ages of 2 and 4 years reporting transient emergence of these behaviors. The most frequent age of onset is in the second year of life. Epidemiologic surveys estimate that up to 7 percent of otherwise typically developing children exhibit stereotypic behaviors. A prevalence of about 15 to 20 percent in children younger than the age of 6 years display stereotypic behavior, with diminishing rates over time. The prevalence of self-injurious behaviors, however, has been estimated to be in the range of 2 to 3 percent among children and adolescents with intellectual disability. Stereotypic movements appear to occur in about twice as many boys as girls. Determining which cases are sufficiently severe to confirm a diagnosis of stereotypic movement disorder may be difficult. Stereotypic behaviors occur in 10 to 20 percent of children with intellectual disability, with increased rates being proportional to level of severity. Self-injurious behaviors frequently occur in genetic syndromes, such as Lesch-Nyhan syndrome, and in children with sensory impairments, such as blindness and deafness.

ETIOLOGY
The etiology of stereotypic movement disorder includes environmental, genetic, and neurobiological factors. Although the neurobiological mechanisms of stereotypic movement disorder have yet to be proven, given their similarity to other involuntary movements, stereotypic movement disorder is hypothesized to originate from the basal ganglia. Dopamine and serotonin are likely to be involved in their emergence. Dopamine agonists tend to induce or increase stereotypic behaviors, whereas dopamine antagonists sometimes decrease them. One study found that 17 percent of typically developing children with stereotypic movement disorder had a first-degree relative with the disorder, and 25 percent had a first- or second-degree relative with stereotypic movement disorder. Transient stereotypic behaviors in very young children can be considered a normal developmental phenomenon. Genetic factors likely play a role in some stereotypic movements, such as the X-linked recessive deficiency of enzymes leading to Lesch-Nyhan syndrome, which has predictable features including intellectual disability, hyperuricemia, spasticity, and self-injurious behaviors. Other minimal stereotypic movements that do not usually cause impairment (e.g., nail-biting) appear to run in families as well. Some stereotypic behaviors seem to emerge or become exaggerated in situations of neglect or deprivation; such behaviors as head-banging have been associated with psychosocial deprivation.

DIAGNOSIS AND CLINICAL FEATURES
The presence of multiple repetitive stereotyped symptoms tends to occur frequently among children with autism spectrum disorder and intellectually disability, particularly when the intellectual disability is severe. Patients with multiple stereotyped movements frequently have other significant mental disorders, including disruptive behavior disorders, or neurological conditions. In extreme cases, severe mutilation and life-threatening injuries can result from self-inflicted trauma.

Head-Banging
Head-banging exemplifies a stereotypic movement disorder that can result in functional impairment. Typically, head-banging begins during infancy, between 6 and 12 months of age. Infants strike their heads with a definite rhythmic and monotonous continuity against the crib or another hard surface. They seem to be absorbed in the activity, which can persist until they become exhausted and fall asleep. The head-banging is often transitory, but sometimes persists into middle childhood. Head-banging that is a component of temper tantrums differs from stereotypic head-banging and ceases after the tantrums and their secondary gains have been controlled.

Nail-Biting
Nail-biting begins as early as 1 year of age and increases in incidence until age 12. Most cases are not sufficiently severe to meet the DSM-5 diagnostic criteria for stereotypic movement disorder. In rare cases, children cause physical damage to the fingers themselves, usually by associated biting of the cuticles, which leads to secondary infections of the fingers and nail beds. Nail-biting seems to occur or increase in intensity when a child is either anxious or stressed. Some of the most severe nail-biting occurs in children with severe or profound intellectual disability, however many nail-biters have no obvious emotional disturbance.

PATHOLOGY AND LABORATORY EXAMINATION
No specific laboratory measures are helpful in the diagnosis of stereotypic movement disorder.

Tim, a 14-year-old with autism spectrum disorder (ASD), and severe intellectual disability was evaluated when he transferred to a new private school for children with ASD. Observed in his classroom, he was noted to be a small boy who appeared younger than his age. He held his hands in his pockets and spun around in place. When offered a toy he took it and manipulated it for a while. When he was prompted to engage in various tasks that required that he use his hands out of his pockets, he began hitting his head with his hands. If his hands were held by the teacher, he hit his head with his knees. He was adept in contorting himself, so that he could hit or kick himself in almost any position, even while walking. Soon, his face and forehead were covered with bruises. His development was delayed in all spheres, and he never developed language. He lived at home and attended a special educational program. His self-injurious behaviors developed early in life, and, when his parents tried to stop him, he became aggressive. Gradually, he became too difficult to be managed in public school, and, at 5 years of age, he was placed in a special school. The self-abusive and self-restraining (i.e., holding his hands in his pockets) behavior was present throughout his stay there, and, virtually all of the time; he had been tried on several second-generation antipsychotics.
with only minimal improvement. Although the psychiatrist’s notes mentioned some improvement in his self-injurious behavior, it was described as continuing and fluctuating. He was transferred to a new school because of lack of progress and difficulties in managing him as he became bigger and stronger. His intellectual functioning was within the 34 to 40 intelligence quotient (IQ) range. His adaptive skills were poor. He required full assistance in self-care, could not provide even for his own simple needs, and required constant supervision for his safety.

In a few months, Tim settled into the routine in his new school. His self-injurious behavior fluctuated. It was reduced or even absent when he restrained himself by holding his hands in his pockets or inside his shirt or even by manipulating some object with his hands. If left to himself, he could contort himself, while holding his hands inside his shirt. Because the stereotypic self-injurious and self-restraining behavior interfered with his daily activities and education, it became a primary focus of a behavior modification program. For a few months, he did well, especially when he developed a good relationship with a new teacher, who was firm, consistent, and nurturing. With him, Tim could successfully engage in some school tasks. When the teacher left, Tim regressed. To prevent injuries, the staff started blocking his self-hitting with a pillow. He was offered activities that he liked and in which he could engage without resorting to self-injury. After several months, his antipsychotic medication was slowly discontinued, over a period of 11 months, without any behavioral deterioration. (Adapted from case material from Bhavik Shah, M.D.)

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of stereotypic movement disorder includes obsessive-compulsive disorder (OCD) and tic disorders, both of which are exclusionary criteria in DSM-5. Although stereotypic movements can often be voluntarily suppressed, and are not spasmodic, it is difficult to differentiate these features from tics in all cases. A study of stereotyped movements compared with tics found that stereotyped movements tended to be longer in duration, and displayed more rhythmic qualities than tics. Tics seemed to occur more when a child was in an “alone” condition, rather than when the child was in a play condition, whereas stereotypic movements occurred with the same frequency in these two different conditions. Stereotypic movements are often observed to seem self-soothing, whereas tics are often associated with distress.

Differentiating dyskinetic movements from stereotypic movements can be difficult. Because antipsychotic medications can sometimes suppress stereotypic movements, clinicians should note any stereotypic movements before initiating treatment with an antipsychotic agent. Stereotypic movement disorder may be diagnosed concurrently with substance-related disorders (e.g., amphetamine use disorders), severe sensory impairments, central nervous system and degenerative disorders (e.g., Lesch-Nyhan syndrome), and severe schizophrenia.

COURSE AND PROGNOSIS

The duration and course of stereotypic movement disorder vary, and the symptoms may wax and wane. Up to 60 to 80 percent of normal toddlers show transient rhythmic activities that seem purposeful and comforting and tend to disappear by 4 years of age. When stereotypic movements emerge more severely later in childhood they typically range from brief episodes occurring under stress, to an ongoing pattern in the context of a chronic condition, such as ASD or intellectual disability. Even in chronic conditions, stereotypic behaviors may come and go. In many cases, stereotypic movements are prominent in early childhood and diminish as a child gets older.

The severity of the dysfunction caused by stereotypic movements varies with the frequency, amount, and degree of associated self-injury. Children who exhibit frequent, severe, self-injurious stereotypic behaviors have the poorest prognosis. Repetitive episodes of head-banging, self-biting, and eye-poking can be difficult to control without physical restraints. Most nail-biting is benign and often does not meet the diagnostic criteria for stereotypic movement disorder. In severe cases in which the nail beds are repetitively damaged, bacterial and fungal infections can occur. Although chronic stereotypic movement disorders can severely impair daily functioning, several treatments help control the symptoms.

TREATMENT

When stereotypic movements occur in the absence of any other symptoms or disorders, they may not warrant pharmacologic treatment. Treatment modalities yielding the most promising effects include behavioral techniques, such as habit reversal and differential reinforcement of other behavior, as well as pharmacological interventions. A recent report on utilizing both habit reversal (in which the child is trained to replace the undesired repetitive behavior with a more acceptable behavior) and reinforcement for reducing the unwanted behavior, indicated that these treatments had efficacy among 12 typically developing children between 6 and 14 years. One case report detailed a successful habit reversal treatment of a 3-year-old with severe stereotypic movements, which was largely implemented at home by her parents. The estimated change in stereotypic behaviors during regular recorded intervals during treatment diminished from presence in 85 percent of recordings to presence in less than 2 percent of recordings over a period of 4 weeks.

Pharmacological interventions have been used in clinical practice to minimize self-injury in children whose stereotyped movements caused significant harm to their bodies. Small open-label studies have reported benefit of atypical antipsychotics, and case reports have indicated use of selective serotonin reuptake inhibitor (SSRIs) in the management of self-injurious stereotypes. The dopamine receptor antagonists have been tried most often for treating stereotypic movements and self-injurious behavior. The SSRI agents may be influential in diminishing stereotypes; however, this is still under investigation. Open trials suggest that both clomipramine and fluoxetine may decrease self-injurious behaviors and other stereotypic movements in some patients.

31.8c Tourette’s Disorder

Tics are neuropsychiatric events characterized by brief rapid motor movements or vocalizations that are typically performed in response to irresistible premonitory urges. Although frequently rapid, tics may include more complex patterns of movements and longer vocalizations. Converging evidence from many lines of research suggests that the production of tics involves dysfunction in the basal ganglia region of the brain, particularly of dopaminergic transmission in the cortico-striato-thalamic circuits. Because tic disorders are significantly more common in children than in adults, the postulated alterations in dopamine circuitry in many affected children appear to spontaneously improve over time. Tics may be transient or chronic, with a waxing and waning course. Tics typically emerge at age 5 to 6 years of age and tend to reach their greatest severity between 10 and 12 years. About one half to two thirds of children with tic disorders will be much improved or in remission by adolescence or early adulthood. Tic disorder is distinguished by the type of tics, their frequency, and the pattern in which they emerge over time. Motor tics most commonly affect the muscles of the face and neck, such as eye-blinking, head- jerking, mouth-grimacing, or head-shaking.典型 vocal tics include throat-clearing, grunting, sniffing, and coughing. Tics are repetitive muscle contractions resulting in movements or vocalizations that are experienced as involuntary, although they can sometimes be suppressed voluntarily. Children and adolescents may exhibit tic behaviors that occur after a stimulus or in response to a premonitory internal urge.

The most widely studied and most severe tic disorder is Gilles de la Tourette syndrome, also known as Tourette’s disorder. Georges Gilles de la Tourette (1857–1904) first described a patient with a syndrome, which became known as Tourette’s disorder in 1885, while he was studying with Jean-Martin Charcot in France. De la Tourette noted a syndrome in several patients that included multiple motor tics, coprolalia, and echolalia. Tics often consist of motions that are used in volitional movements. One half to two thirds of children with Tourette’s disorder exhibit a reduction in or complete remission of tic symptoms during adolescence. There are many common comorbid psychiatric disorders and behavioral problems likely to emerge along with Tourette’s disorder. For example, the relationship between Tourette’s disorder, attention-deficit/hyperactivity disorder (ADHD), and obsessive-compulsive disorder (OCD) has not been clearly delineated. Epidemiological surveys indicate that more than half of children with Tourette’s disorder also meet criteria for ADHD. There appears to be a bidirectional relationship between Tourette’s disorder and OCD, with 20 to 40 percent of Tourette’s disorder patients meeting full criteria for OCD.

First-degree relatives of patients with OCD have been shown to have higher rates of tic disorders compared to the general population. There have been a few small reports suggesting that the obsessive-compulsive symptoms most likely to occur in Tourette’s disorder are characteristically related to ordering and symmetry, counting, and repetitive touching, whereas OCD symptoms in the absence of tic disorders are more often associated with fears of contamination and fears of doing harm. Motor and vocal tics are divided into simple and complex types. Simple motor tics are those composed of repetitive, rapid contractions of functionally similar muscle groups—for example, eye-blinking, neck-jerking, shoulder-shrugging, and facial-grimacing. Common simple vocal tics include coughing, throat-clearing, grunting, sniffing, sniffing, and barking. Complex motor tics appear to be more purposeful and ritualistic than simple tics. Common complex motor tics include grooming behaviors, the smelling of objects, jumping, touching behaviors, echopraxia (imitation of observed behavior), and copropraxia (display of obscene gestures). Complex vocal tics include repeating words or phrases out of context, coprolalia (use of obscene words or phrases), palilalia (a person’s repeating his or her words), and echolalia (repetition of the last-heard words of others). Although older children and adolescents with tic disorders may be able to suppress their tics for minutes or hours, young children are often not cognizant of their tics or experience their urges to perform their tics as irresistible. Tics may be attenuated by sleep, relaxation, or absorption in an activity. Tics often disappear during sleep.

EPIDEMIOLOGY

The estimated prevalence of Tourette’s disorder ranges from 3 to 8 per 1,000 school-age children. Males are affected between 2 and 4 times more often than females. The unique features of Tourette’s disorder in which tics wax and wane and may change in character, frequency, and severity over relatively short periods of time, has made ascertainment of its prevalence challenging. Furthermore, remission of tics is particularly age-dependent in that tics tend to emerge and increase from ages 5 to 10 years of age, and in many cases, decrease in frequency and severity after the age of 10 to 12 years. At age 13 years, however, using stringent criteria, the prevalence rate for Tourette’s disorder drops to 0.3 percent. The lifetime prevalence of Tourette’s disorder is estimated to be approximately 1 percent.
ETIOLOGY

Genetic Factors

Twin studies, adoption studies, and segregation analysis studies all support a genetic basis, albeit a complex one, for Tourette’s disorder. Twin studies indicate that concordance for the disorder in monozygotic twins is significantly greater than that in dizygotic twins. Tourette’s disorder and chronic motor or vocal tic disorder are likely to occur in the same families; this lends support to the view that the disorders are part of a genetically determined spectrum. The sons of mothers with Tourette’s disorder seem to be at the highest risk for the disorder. Evidence in some families indicates that Tourette’s disorder is transmitted in an autosomal dominant fashion. Studies of a long family pedigree suggest that Tourette’s disorder may be transmitted in a bilinear mode; that is, Tourette’s disorder appears to be inherited through an autosomal pattern in some families, intermediate between dominant and recessive. A study of 174 unrelated probands with Tourette’s disorder identified a greater than chance occurrence of a rare sequence variant in SLITRK1, believed to be a candidate gene on chromosome 13q31.

Up to half of all patients with Tourette’s disorder also have ADHD, and up to 40 percent of those with Tourette’s disorder also have OCD. These frequent comorbidities with Tourette’s disorder can lead to a plethora of overlapping symptoms. Family studies have provided compelling evidence for the association between tic disorders and OCD. First-degree relatives of persons with Tourette’s disorder are at high risk for the development of Tourette’s disorder, chronic motor or vocal tic disorder, and OCD. Current understanding of the genetic bases of Tourette’s disorder implicates multiple vulnerability genes that may serve to mediate the type and severity of tics. Candidate genes associated with Tourette’s disorder include dopamine receptor genes, dopamine transporter genes, several noradrenergic genes, and serotonergic genes.

Neuroimaging Studies

A functional magnetic resonance imaging (fMRI) study of brain activity two seconds before and after a tic, found that paralimbic and sensory association areas were involved. Furthermore, evidence suggests that voluntary tic suppression involves deactivation of the putamen and globus pallidus, along with partial activation of regions of the prefrontal cortex and caudate nucleus. Compelling, but indirect, evidence of dopaminergic system involvement in tic disorders includes the observations that pharmacological agents that antagonize dopamine (haloperidol [Haldol], pimozide [Orap], and fluphenazine [Prolixin]) suppress tics and that agents that increase central dopaminergic activity (methylphenidate [Ritalin], amphetamines, and cocaine) tend to exacerbate tics. The relation of tics to neurotransmitter systems is complex and not yet well understood; for example, in some cases, antipsychotic medications, such as haloperidol, are not effective in reducing tics, and the effect of stimulants on tic disorders reportedly varies. In some cases, Tourette’s disorder has emerged during treatment with antipsychotic medications.

More direct analyses of the neurochemistry of Tourette’s disorder have been possible utilizing brain proton magnetic resonance spectroscopy (MRS). Neuroimaging studies using cerebral blood flow in positron emission tomography (PET) and single photon emission tomography (SPECT) suggest that alterations of activity may occur in various brain regions in patients with Tourette’s disorder compared to controls, including the frontal and orbital cortex, striatum, and putamen. An investigation examining the cellular neurochemistry of patients with Tourette’s disorder utilizing MRS of the frontal cortex, caudate nucleus, putamen, and thalamus demonstrated that these patients had a reduced amount of choline and N-acetylaspartate in the left putamen along with reduced levels bilaterally in the putamen. In the frontal cortex, patients with Tourette’s disorder were found to have lower concentrations of N-acetylaspartate bilaterally, lower levels of creatine on the right side, and reduced myo-inositol on the left side. These results suggest that deficits in the density of neuronal and nonneuronal cells are present in patients with the disorder. Abnormalities in the noradrenergic system have been implicated in some cases by the reduction of tics with clonidine (Catapres). This adrenergic agonist reduces the release of norepinephrine in the central nervous system and, thus, may reduce activity in the dopaminergic system. Abnormalities in the basal ganglia are known to result in various movement disorders, such as Huntington’s disease, and are also implicated as likely sites of disturbance in Tourette’s disorder.

Immunological Factors and Post Infection

An autoimmune process and, in particular, one that is secondary to group A beta-hemolytic streptococcal infections was hypothesized as a potential mechanism for the development of tics and obsessive-compulsive symptoms in some case. Data have been conflicting and controversial, and this mechanism appears to be unlikely as an etiology of Tourette’s disorder in most cases. One case-control study found little evidence of the development or exacerbation of tics, or obsessions or compulsions, in children with well-documented and treated group A beta-hemolytic streptococcal infections.

DIAGNOSIS AND CLINICAL FEATURES

A diagnosis of Tourette’s disorder depends on a history of multiple motor tics that generally emerge over a period of months or years, and the emergence of at least one vocal tic at some point. According to the American Psychiatric Association’s Fifth Edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5), tics may wax and wane in frequency, but must have persisted for more than a year since the first tic emerged to meet the diagnosis. The average age of onset of tics is between 4 years and 6 years of age, although in some cases, tics may occur as early as 2 years of age. The peak age for severity of tics is between 10 and 12 years. To meet diagnostic criteria for Tourette’s disorder, the onset must occur before the age of 18 years.

In Tourette’s disorder, typically the initial tics are in the face and neck. Over time, the tics tend to occur in a downward progression. The most commonly described tics are those affecting the face and head, the arms and hands, the body and lower extremities, and the respiratory and alimentary systems.
In these areas, the tics take the form of grimacing; forehead puckering; eyebrow-raising; eyelid-blinking; winking; nose wrinkling; nostril-trembling; mouth-twitching; displaying the teeth; biting the lips and other parts; tongue-extruding; protruding the lower jaw; nodding, jerking, or shaking the head; twisting the neck; looking sideways; head-rolling; hand-jerking; arm-jerking; plucking fingers; writing fingers; fist-clenching; shoulder-shrugging; foot, knee, or toe shaking; walking peculiarly; body writhing; jumping; hiccupping; sighing; yawning; sniffing; blowing through the nostrils; whistling; belching; sucking or smacking sounds; and clearing the throat. Several assessment instruments are currently available that are useful in making diagnoses of tic disorders, including comprehensive self-report assessment tools, such as the Tic Symptom Self-Report and the Yale Global Tic Severity Scale, administered by a clinician (Table 31.8c-1).

Because Tourette’s disorder is frequently comorbid with attentional, obsessive, and oppositional behaviors, these symptoms often emerge prior to the tics. In some studies, more than 25 percent of children with Tourette’s disorder received stimulants for a diagnosis of ADHD before receiving a diagnosis of Tourette’s disorder. The most frequent initial symptom is an eye-blink tic, followed by a head tic or a facial grimace. Most complex motor and vocal symptoms emerge several years after the initial symptoms. Coprolalia, a very unusual symptom involving shouting or speaking socially unacceptable or obscene words, occurs in less than 10 percent of patients and rarely in the absence of comorbid psychiatric disturbance. Mental coprolalia—in which a patient experiences a sudden, intrusive, socially unacceptable thought or obscene word—occurs more often than coprolalia. In severe cases, physical self-injury has occurred due to tic behaviors.

Jake, age 10 years, came to the Tourette Disorder Clinic for an evaluation of motor tics in the head and neck, occasional coughing and grunting, and a new symptom of throat clearing many times per day. Jake had a past history of ADHD, which included significant hyperactivity, and impulsive and oppositional behavior. He is a fifth-grade student in a regular class at the local public school. Before the consultation, parent and teacher ratings, including the Child Behavior Checklist (CBCL), Swanson, Nolan, and Pelham-IV (SNAP-IV), Conners’ Parent and Teacher Questionnaires, Tic Symptom Self-Report (TSSR), and medical history survey, were sent to his family. His mother and the classroom teacher rated him well above the norm for hyperactivity, inattention, and impulsiveness. He was failing several subjects in school, often argued with adults, was occasionally aggressive, and had few friends. His tics were rated as moderate.

Jake’s mother recalls difficulties with overactivity, oppositional and defiant behaviors and behavior since preschool. At age 5, due to his activity level and argumentative and aggressive behavior, his kindergarten teacher encouraged the family to obtain a psychiatric consultation. Jake’s pediatrician made a diagnosis of ADHD and recommended a trial of Concerta (methylphenidate extended-release tablets) at 36 mg per day, which was started at the beginning of the first grade. Within a week of starting medication, Jake’s overly active and impulsive behavior showed a dramatic improvement; however, he remained argumentative and oppositional. However, when on his Concerta, Jake was able to stay in his seat and complete his work and was better able to wait his turn on the playground. The next few months went well, however, by early spring, Jake seemed to be returning back to some of his old ways. He was talking out of turn in class, and getting out of his seat, which was disruptive to the class. After an increase in Concerta to 54 mg per day, in the spring of his first-grade year, however, he began showing motor and phonic tics consisting of head-jerking, facial movements, coughing, and grunting. The Concerta was discontinued to see if this made a difference and was immediately stopped and, although the tics transiently decreased, they came back in full force within a month. In hindsight, Jake’s mother recalled that Jake had exhibited eye blinking and grunting prior to starting the Concerta, but she had dismissed these events as unimportant and they did not seem to disrupt Jake’s daily life.

While Jake was off Concerta during a period when he began middle school in the 6th grade, Jake was disruptive to his classes and he began to be severely teased by several classmates for his impulsivity, frequent motor tics, and loud grunting and throat clearing. Jake became despondent and began to refuse to go to school. At this point, it was decided to place Jake in a special education class. However, after several months of this placement, Jake felt worse about himself, despaired school, and begged to be returned to regular classes. At this point Jake’s pediatrician made the referral to a child and adolescent psychiatrist at a local university Tourette Disorder Clinic.

During his evaluation at the Tourette Disorder Clinic, Jake was reported to be a healthy child who was the product of an uncomplicated pregnancy, labor, and delivery, and whose developmental milestones were achieved at appropriate times. Intellectual testing completed by the school psychologist revealed a full scale IQ of 105. Jake’s mother noted that Jake has had long-standing trouble falling asleep but sleeps through the night. Jake has always been described as argumentative and easily frustrated with frequent outbursts of temper; however, when he is not having a tantrum, his mood is generally upbeat.

Jake was noted by the child and adolescent psychiatrist to be of average height and weight with no dysmorphic features. His speech was rapid in tempo but normal in tone and volume. His speech is coherent and developmentally appropriate, without evidence of thought disorder; however, vocal tics including grunting, coughing,
and obvious throat clearing were observed. Jake denied depressed mood or suicidal ideation, although he reported distress about everyday issues such as being teased by peers, not having enough friends, and his poor school performance. Jake also denied recurring worries about contamination or harm coming to him or family members, or fears of acting on unwanted impulses. Other than mild touching habits involving the need to touch objects with each hand three times or in combinations of three, Jake denies repetitive rituals. Several motor tics were also observed during the evaluation session, including blinking, head-jerking, and shoulder tics. Jake was restless and easily distracted throughout the session and often needed assistance with entertaining himself when not directly involved in conversation.

Given the history of enduring motor and phonic tics, confirmed by direct observation, the diagnosis of Tourette's disorder and ADHD, as well as oppositional defiant disorder were confirmed.

Jake and his family attended several sessions with the child and adolescent psychiatrist to learn about the waxing and waning nature of tic symptoms and the natural history of Tourette's Disorder, as well as ADHD. Jake and his family were heartened to hear that, in general, tics tend to be at their maximum around his age, and it was somewhat likely that Jake's tics would lessen over time or possibly fully remit. Jake was referred to a behavioral psychologist specializing in habit reversal training. In this treatment Jake was taught to engage in a behavior physically incompatible with his tic (a competing response) each time he experienced the urge to perform this tic. The competing response for Jake's shoulder tic, which consisted of raising his shoulders up as far as he could, was to gently press his shoulders down and extend his neck each time he felt the urge to engage in this tic. With repeated practice of his competing response, Jake's urge to engage in this tic greatly diminished to the point where he was able to manage the urge without performing the tic. Jake was referred to a child and adolescent psychiatrist who decided to re-start the Concerta at 36 mg per day and titrated it back up to 54 mg per day without worsening of the tics. Jake responded well to his behavioral therapy, and over a period of 8 weeks, he had learned how to become aware of the urges that occurred prior to his tics and to voluntarily replace his usual tics with less-distressing and less-disruptive behaviors.

However, when Jake entered the 7th grade, he had an exacerbation of his motor and vocal tics, and was also touching objects repeatedly throughout the day. Jake again became despondent, not wanting to go to school. It was decided by his psychologist to add relaxation training to his behavioral treatment, and his child and adolescent psychiatrist another medication to his pharmacological regimen. Jake was prescribed risperidone, 0.5 mg per day, which was titrated up to 1 mg twice daily. With the addition of these psychological and pharmacological interventions, Jake became stabilized within a month, and was able to continue in his school and even went to some parties. Jake and his parents understood the waxing and waning nature of his tics, and were hopeful that they would begin to see some decrease in his tic symptoms within the next few years. At follow-up, when Jake was 15 years of age, Jake had minimal tic symptoms; an occasional eye blink and rare throat clearing was all that was observable. Jake was not currently in behavioral treatment, however, over the years, he had, on a few occasions received some booster therapy sessions to brush up on his habit reversal training when he had a minor exacerbation of tics. Jake had been taken off his risperidone a 2 years before without an exacerbation of tics. Jake continued on Concerta 54 mg per day and was well controlled on that dose, was doing well in school, and had become more popular since he had joined the soccer team.

PATHOLOGY AND LABORATORY EXAMINATION
No specific laboratory diagnostic test exists for Tourette's disorder, but many patients with Tourette's disorder have nonspecific abnormal electroencephalographic findings. Computed tomography (CT) and magnetic resonance imaging (MRI) scans have revealed no specific structural lesions, although about 10 percent of all patients with Tourette's disorder show some nonspecific abnormality on CT scans.

DIFFERENTIAL DIAGNOSIS
Tics must be differentiated from other movements and movement disorders (e.g., dystonic, choreiform, athetoid, myoclonic, and hemiballismic movements) and the neurological diseases that they may characterize (e.g., Huntington's disease, parkinsonism, Sydenham's chorea, and Wilson's disease), as listed in Table 31.8c-2. Tremors, mannerisms, and stereotypic movement disorder (e.g., head-banging or body-rocking) must also be distinguished from tic disorders. Stereotypic movement disorders, including movements such as rocking, hand-gazing, and other self-stimulatory behaviors, seem to be voluntary and often produce a sense of comfort, in contrast to tic disorders. Although tics in children and adolescents may or may not feel controllable, they rarely produce a sense of well-being. Compulsions are sometimes difficult to distinguish from complex tics and may be on the same continuum biologically. Tic disorders may also occur comorbidly with mood disturbances. In a recent survey, the greater the severity of tics, the higher the probability of both aggressive and depressive symptoms in children. When a child experiences an exacerbation of tic symptoms, behavior and mood also seem to deteriorate.

COURSE AND PROGNOSIS
Tourette's disorder is a childhood-onset neuropsychiatric disorder characterized by both motor and vocal tics, which usually emerge in early childhood, with a natural history leading to reduction or complete resolution of tics symptoms in most cases by adolescence or early adulthood. During childhood, individual tic symptoms may decrease, persist, or increase, and old symptoms may be replaced by new ones. Severely afflicted persons may have serious emotional problems, including major depressive disorder. Impairment may also be associated with the motor and vocal tic symptoms of Tourette's disorder; however, in many cases, interference in function is exacerbated by comorbid ADHD and OCD, both of which frequently coexist with the disorder. When the above three disorders are comorbid, severe social, academic, and occupational problems may ensue. Although most children with Tourette's disorder will experience a decline in the frequency and severity of tic symptoms during adolescence, at present, no clinical measures exist to predict which children may have persistent symptoms into adulthood. Children with mild forms of Tourette's disorder often have satisfactory peer relationships, function well in school, and develop adequate self-esteem, and may not require treatment.

(continued)
Once a diagnosis of Tourette's disorder is made, psychoeducation is a useful intervention in order for families to gain an understanding of the variability of tics, the natural history of the disorder, and ways to support reduction of stress. It is particularly important for families to be well-informed advocates for their children, since tics may be misinterpreted by an uneducated observer as a child's purposeful misbehavior, rather than a response to an irresistible urge. The need for treatment is based on subjective distress of a child with respect to tics as well as observable disruptions in functioning. In mild cases, children with tic disorders who are functioning well socially and academically may not seek, nor require treatment. In more severe cases, children with tic disorders may be ostracized by peers and have academic work compromised by the disruptive nature of tics, and a variety of interventions including psychosocial, pharmacological, and school based may be considered.

The European clinical guidelines for Tourette's syndrome and other tic disorders summarized and reviewed the evidence-based treatments for Tourette's disorder and developed a consensus for psychosocial and pharmacological treatments. This guideline recommends that both behavioral and pharmacological interventions be considered in more severe cases, with behavioral interventions typically the first line of treatment. Indications for treatment include, but are not limited to, the following clinical presentations. Tics require treatment when they cause social and emotional problems, depression, or isolation. Children who are prone to severe persistent complex motor tics or loud vocal tics may be the objects of bullying and social rejection. In these cases, depressive symptoms commonly result. Tic reduction and psychoeducation to the school may be indicated in order to preserve healthy social relationships, and to diminish depressive and anxiety symptoms. Tics may also lead to impairment in academic achievement, when school functioning is disrupted. School difficulties in children with Tourette's disorder are not uncommon, and reduction in tics may support increased academic success. Tics may also lead to physical discomfort, based on the repetitive musculoskeletal exertion, especially in relation to head and neck tics. In some children with Tourette's disorder, tics can worsen headaches and migraines. Behavioral and pharmacological interventions can both target tic reductions, which can lead to improved quality of life.

Evidence-based Behavioral and Psychosocial Treatment

The Canadian guidelines for the evidence-based treatment of tic disorders: behavioral therapy, deep brain stimulation and transcranial magnetic stimulation, and a large multi-site randomized controlled trial of “Comprehensive Behavioral Intervention for Tics,” (CBIT) both found converging evidence supporting habit-reversal training and exposure and response prevention as efficacious treatments for tic reduction. In a randomized controlled trial of CBIT, 61 children received habit reversal training as their main component of treatment, and they also received relaxation treatment and a functional intervention to identify situations that worsened or sustained tics and strategies to decrease exposure to these situations. The control group of 65 children received supportive psychotherapy and psychoeducation. After 10 weeks of treatment, the Yale Global Tic Severity Scale Total Tic score was significantly reduced in the behavioral intervention group compared with the control group.

Habit Reversal. The primary components of habit reversal are awareness training, in which the child uses self-monitoring to enhance awareness of tic behaviors and the premonitory urges or sensations indicating that a tic is about to occur. In competing-response training, the patient is taught to voluntarily perform a behavior that is physically incompatible with the tic, contingent on the onset of the premonitory urge or the tic itself, blocking expression of the tic. The competing-response strategy is based on the self-reported observations of patients that tics
are performed in response to irresistible premonitory urges in order to diminish the urge. Because performing the tic satisfies or reduces the premonitory urges, the tics are reinforced, and over time, become repeated entrenched behaviors. Competing-response training is different from voluntary tic suppression in that the patient initiates a voluntary behavior to manage the premonitory urge and thus disrupts the reinforcement of the tic, rather than simply trying to suppress the tic. Successful competing-response training results in significant reduction in premonitory urge intensity or complete elimination of the urge altogether so that tics are no longer provoked. For motor tics, a behavior that is less noticeable may be chosen, whereas for vocal tics, slow rhythmic breathing is the most common voluntary competing response. The competing responses are designed to be performed without disrupting usual activities.

**Exposure and Response Prevention.** The rationale for this treatment is based on the notion that tics occur as a conditioned response to unpleasant premonitory urges, and since the tics reduce the urge, they become associated with the premonitory urge. Each time the urge is reduced by the tic, their association is further strengthened. Rather than using competing responses, as in habit-reversal training, exposure and response prevention asks the patient to suppress tics for increasingly prolonged periods in order to break the association between the urges and the tics. Theoretically, if a patient learns to resist performing the tic in response to the urge for long enough periods, the urge may become more tolerable, or attenuate, and the need to perform the tic may diminish.

Many other behavioral interventions such as relaxation training, self-monitoring, bio (neuro) feedback, and cognitive-behavioral treatment (CBT), have not been shown to be efficacious in the reduction of tics on their own; however, some of these strategies may be included in comprehensive treatment programs for children with tic disorders who are receiving habit-reversal training. Habit reversal has been the most extensively researched behavioral treatment for tic disorders; it has been shown to be highly effective, and is currently the first-line behavioral treatment for tic disorders.

**Evidence-based Pharmacotherapy**

Several reviews of pharmacological treatments for tics suggest that the following classes of pharmacologic agents have an evidence base for treating tics: typical and atypical antipsychotics; noradrenergic agents; and alternative treatments such as tetra- benzamine, topiramate, and tetrahydrocannabinol.

**Atypical and Typical Antipsychotic Agents.** Risperidone, with its high affinity for dopamine D2 and serotonin 5-HT2 receptors, is the most well-studied atypical antipsychotic in the treatment of tics. There is considerable evidence for its efficacy. Multiple randomized, controlled studies in children and adolescents have shown favorable results compared to placebo as well as in head-to-head studies with the typical antipsychotic agents haloperidol and pimozide. Risperidone was associated with fewer adverse events compared to typical antipsychotics; however, it was frequently associated with weight gain, metabolic side effects, and hyperprolactinemia. In a randomized, double-blind, parallel group study of Tourette’s disorder comparing risperidone to pimozide, risperidone showed superiority in reducing comorbid obsessive-compulsive symptoms as well as reducing tics. In other randomized clinical trials, efficacy of tic reduction was achieved in studies of children, adolescents, and adults with mean daily doses of 2.5 mg daily with a range of 1 to 6 mg daily.

Haloperidol (Haldol) and pimozide (Orap) are the two most well-investigated and Food and Drug Administration (FDA)– approved antipsychotic agents in the treatment of Tourette’s disorder, although atypical antipsychotics such as risperidone are often chosen as first-line agents due to their safer side-effect profiles. Both haloperidol and pimozide have been shown to be efficacious in multiple randomized clinical trials in the treatment of Tourette’s disorder. Both haloperidol and pimozide present significant risks for extrapyramidal side effects; in a long-term naturalistic follow-up study, haloperidol was found to produce more significant acute dyskinesia and dystonia compared to pimozide.

A third typical antipsychotic, fluphenazine, has been used in the United States for many years in the treatment of tic disorders, in the absence of robust data supporting its efficacy. A small controlled study of fluphenazine, trifluoperazine, and haloperidol found similar reductions in tics; however, haloperidol was associated with more extrapyramidal side effects and more sedation. The frequency of sedation, dystonia, and akathisia of typical antipsychotics, probably due to their predominant dopaminergic blockade in the nigrostriatal pathways, limits their use and increases the appeal of the atypical antipsychotics. Risperidone and pimozide were found to be of equal efficacy in one study of children, adolescents, and adults with Tourette’s disorder.

Aripiprazole has become a pharmacological agent of interest in the treatment of tic disorders due to its mode of action; in addition to its D2 receptor antagonistic actions, aripiprazole is also a partial D2 and 5-HT1A receptor agonist and a 5-HT2A antagonist. A multisite double-blind controlled study of aripiprazole in children with Tourette’s disorder in China found a reduction in tic behaviors in about 60 percent of the aripiprazole group compared to about 64 percent reduction in a group treated with tiapride, a benzamide with selective D2 receptor antagonism. There was no significant difference between the two groups. Although sedation and sleep disturbance are common side effects with aripiprazole, weight gain is less pronounced than with risperidone.

Olanzapine and ziprasidone were shown to be efficacious in the treatment of tic disorders in at least one randomized controlled trial. Sedation and weight gain were prominent side effects with olanzapine, and potential QT prolongation was an issue with ziprasidone. Quetiapine has been suggested as a potentially useful agent in the treatment of tics, with its greater affinity for 5-HT2 receptors than for D2 receptors, however, randomized clinical trials are needed. Clozapine, contrary to many other atypical antipsychotics, has not been found to be useful in the treatment of tics.

**Noradrenergic Agents.** Noradrenergic agents including clonidine and guanfacine, as well as atomoxetine, are frequently used in children as primary treatments or adjunctive treatments for comorbid ADHD and tics. Several studies have provided some evidence for the efficacy of clonidine, an alpha
2-adrenergic agent, in the treatment of tics in children, adolescents, and adults with tic disorders. The largest randomized trial with oral clonidine compared to placebo found a modest reduction in tics with clonidine. A multisite randomized double-blind placebo-controlled trial using the clonidine patch in the treatment of tic disorders in children found a significant improvement in tic symptoms (about 69 percent) compared to about 47 percent of the children in the control group. Clonidine has generally been used in dosages ranging from 0.05 mg orally three times daily to 0.1 mg four times daily; and guanfacine is usually used in dosages ranging from 1 to 4 mg per day. When used in these dosage ranges, adverse effects of the α-adrenergic agents may include drowsiness, headache, irritability, and occasional hypotension.

Guanfacine has been used frequently to treat children with ADHD successfully, although its efficacy regarding reducing tics is controversial. In one randomized clinical trial treating 34 children with ADHD and tics, guanfacine was found to be superior to placebo in the reduction of tics. In another double-blind placebo-controlled trial of 24 children with Tourette’s disorder, guanfacine was not superior to placebo.

Atomoxetine, a selective noradrenaline reuptake inhibitor, was found to reduce both tics and ADHD symptoms in a multicenter industry trial of 148 children. Atomoxetine also reduced both tics and ADHD in a subgroup of patients in this study who were diagnosed with Tourette’s disorder. Additional studies are needed to confirm safety and efficacy of atomoxetine in the treatment of children with Tourette’s disorder.

In view of the frequent comorbidity of tic behaviors and obsessive-compulsive symptoms or disorders, the SSRIs have been used alone or in combination with antipsychotics in the treatment of Tourette’s disorder. Data, thus far, have supported the efficacy of SSRIs in the treatment of OCD, however there have not been controlled trials yet to determine the effect of SSRIs on tic reduction.

Although clinicians must weigh the risks and benefits of using stimulants in cases of severe hyperactivity and comorbid tics, data suggest that methylphenidate does not increase the rate or intensity of motor or vocal tics in most children with hyperactivity and tic disorders.

**Alternative Agents: Tetrabenazine, Topiramate, and Tetrahydrocannabinol**

**TETRABENAZINE.** A vesicular monoamine transporter type 2 inhibitor, tetrabenazine depletes presynaptic dopamine and serotonin, and blocks postsynaptic dopamine receptors. There are no randomized clinical trials of this agent in the treatment of Tourette’s disorder in children; however, clinical experience suggests that this agent may have benefit in tic reduction. In a follow-up of 2 years of treatment in 77 children and adolescents, one study reports tic reduction improvement in 80 percent of subjects. Side effects of this agent include sedation, parkinsonism, depression, insomnia, anxiety, and akathisia.

**TOPIRAMATE.** A γ-aminobutyric acid (GABA)ergic drug, used primarily as an anticonvulsant, topiramate was found to be efficacious compared to placebo in reducing tics in a small randomized clinical trial of children and adults with Tourette’s disorder. Side effects were minimal. Although this does not confirm its efficacy, GABA-modulating agents require further study in the treatment of tic disorders.

**TETRAHYDROCANNABINOL.** A suggestion that tetrahydrocannabinol (THC) may be safe and efficacious in the treatment of tics, without neuropsychological impairment, is based on a randomized double-blind placebo-controlled trial with 24 patients treated with THC for 6 weeks at doses of up to 10 mg with significant improvement in tic severity. In this trial, reported adverse effects included dizziness, fatigue, and dry mouth. Potential additional side-effects include anxiety, depressive symptoms, tremor, and insomnia. This small trial does not confirm efficacy for this agent in the treatment of tics, rather it raises questions about the potential improvements in treatment-resistant tic disorders using this agent.

In summary, the greatest evidence for the safe and efficacious pharmacological treatment of Tourette’s disorder seems to be associated with the atypical antipsychotics, in particular, risperidone. Pharmacological treatment may be combined with and enhanced by a variety of behavioral interventions such as habit reversal and school interventions that may diminish stressful situations in the school environment.

31.8d Persistent (Chronic) Motor or Vocal Tic Disorder

Chronic motor or vocal tic disorder is defined as the presence of either motor tics or vocal tics, but not both. Tics may wax and wane but must have persisted for more than 1 year since the first tic onset to meet the diagnosis for persistent (chronic) motor or vocal tic disorder. According to the Fifth Edition of the American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders (DSM-5) criteria, this disorder must have its onset before the age of 18 years. Chronic motor or vocal tic disorder cannot be diagnosed if the criteria for Tourette's disorder have ever been met.

EPIDEMIOLOGY

The rate of chronic motor or vocal tic disorder has been estimated to be 100 to 1,000 times greater than that of Tourette's disorder in school-age children. School-age boys are at highest risk. Although the disorder was once believed to be rare, current estimates of the prevalence of chronic motor or vocal tic disorder range from 1 to 2 percent.

ETIOLOGY

Chronic motor or vocal tic disorder as well as Tourette’s disorder tend to aggregate in the same families. Twin studies have found a high concordance for either Tourette’s disorder or chronic motor tics in monozygotic twins. This finding supports the importance of hereditary factors in the transmission of tic disorders.

DIAGNOSIS AND CLINICAL FEATURES

The onset of chronic motor or vocal tic disorder typically occurs in early childhood. Chronic vocal tics are considerably rarer than chronic motor tics. Chronic vocal tics, in the absence of motor tics, are typically less conspicuous than the vocal tics in Tourette's disorder. The vocal tics are usually not loud or intense and are not primarily produced by the vocal cords; they consist of grunts or other noises caused by thoracic, abdominal, or diaphragmatic contractions.

DIFFERENTIAL DIAGNOSIS

Chronic motor tics must be differentiated from a variety of other motor movements, including choreiform movements, myoclonus, restless legs syndrome, akathisia, and dystonias. Involuntary vocal utterances can occur in certain neurological disorders, such as Huntington’s disease and Parkinson’s disease.

TREATMENT

The treatment of chronic motor or vocal tic disorder depends on several factors including the severity and frequency of the tics; the patient’s subjective distress; the effects of the tics on school or work, job performance, and socialization; and the presence of any other concomitant mental disorder. Psychotherapy may be indicated to minimize the secondary social difficulties caused by severe tics. Behavioral techniques, particularly habit reversal treatments, are effective in treating chronic motor or vocal tic disorder. When severe, tics may be reduced through the use of atypical antipsychotics such as risperidone. If not effective, typical antipsychotics such as pimozide or haloperidol may be helpful. Behavioral interventions are the first line of treatment.

31.9 Feeding and Eating Disorders of Infancy or Early Childhood

Feeding and eating disorders of infancy and childhood are characterized by persistent disturbances in eating or eating-related disorders that can lead to significant impairments in physical health and psychosocial functioning. The American Psychiatric Association’s Fifth Edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) category Feeding
and Eating Disorders includes three disorders that are often, but not always, associated with infancy and early childhood: pica, rumination disorder, and avoidant/restrictive food intake disorder (formerly known as feeding disorder of infancy or early childhood). These three disorders are discussed in this section. Anorexia nervosa, bulimia nervosa, and binge-eating disorder are more often associated with young adulthood and discussed separately in Chapter 15.

### 31.9a Pica

Pica is defined as persistent eating of nonnutritive substances. Typically, no specific biological abnormalities account for pica, and in many cases, pica is identified only when medical problems such as intestinal obstruction, intestinal infections, or poisonings arise, such as lead poisoning due to ingestion of lead containing paint chips. Pica is more frequent in the context of autism spectrum disorder or intellectual disability; however, pica is diagnosed only when it is of sufficient severity and persistence to warrant clinical attention. Pica can emerge in young children, adolescents, or adults; however, a minimum of 2 years of age is suggested by DSM-5 in the diagnosis of pica, in order to exclude developmentally appropriate mouthing of objects by infants that may accidentally result in ingestion. Pica occurs in both males and females, and in rare cases, it may be associated with a cultural belief in the spiritual or medicinal benefit of ingesting nonfood substances. In this context, a diagnosis of pica is not made. Among adults, certain forms of pica, including geophagia (clay eating) and amylophagia (starch eating), have been reported in pregnant women.

#### EPIDEMIOLOGY

The prevalence of pica is unclear. A survey of a large clinic population reported that 75 percent of 12-month-old infants and 15 percent of 2- to 3-year-old toddlers placed nonnutritive substances in their mouth; however, this behavior is developmentally appropriate and typically does not result in ingestion. Pica is more common among children and adolescents with autism spectrum disorder and intellectual disability. It has been reported that up to 15 percent of persons with severe intellectual disability have engaged in pica. Pica appears to affect both sexes equally.

#### ETIOLOGY

Pica is most often a transient disorder that typically lasts for several months and then remits. In younger children, it is more frequently seen among children with developmental speech and social developmental delays. Among adolescents with pica, a substantial number of them exhibited depressive symptoms and use of substances. Nutritional deficiencies in minerals such as zinc or iron have been anecdotally reported in some instances; however, these reports are rare. For example, cravings for dirt and ice have been reported to be associated with iron and zinc deficiencies, which are corrected by their administration. Severe child maltreatment in the form of parental neglect and deprivation has been reported in some cases of pica. Lack of supervision, as well as adequate feeding of infants and toddlers may increase the risk of pica.

#### DIAGNOSIS AND CLINICAL FEATURES

Eating nonedible substances repeatedly after 18 months of age is not typical; however, DSM-5 suggests a minimum age of 2 years when making a diagnosis of pica. Pica behaviors, however, may begin in infants 12 months to 24 months of age. Specific substances ingested vary with their accessibility, and they increase with a child's mastery of locomotion and the resultant increased independence and decreased parental supervision. Typically, in infants, paint, plaster, string, hair, and cloth are objects that may be ingested, whereas older toddlers and young children with pica may ingest dirt, animal feces, small stones, and paper. The clinical implications can be benign or life-threatening, depending on the objects ingested. Among the most serious complications are lead poisoning (usually from lead-based paint), intestinal parasites after ingestion of soil or feces, anemia and zinc deficiency after ingestion of clay, severe iron deficiency after ingestion of large quantities of starch, and intestinal obstruction from the ingestion of hair balls, stones, or gravel. Except in autism spectrum disorder and intellectual disability, pica often remits by adolescence. Pica associated with pregnancy is usually limited to the pregnancy itself.

Chantal was 2½ years of age when her mother urgently brought her to her pediatrician due to severe abdominal pain and lack of appetite. Chantal’s mother complained that she still put everything in her mouth but refused to eat regular food. The pediatrician observed that Chantal to be pale, thin, and withdrawn. She sucked her thumb and quietly looked down while her mother reported that Chantal often chewed on newspapers and put plaster in her mouth.

The medical examination revealed that Chantal was anemic and suffered from lead poisoning. She was admitted to the hospital for treatment, and a child psychiatric consultation was obtained. Further exploration of the history and the observation of mother and child during feeding and play revealed that Chantal's mother was overwhelmed, caring for five young children and had little affection for Chantal. Chantal’s mother was a single mother, living with her five children and four other family members in a three-bedroom apartment in an old housing project. Her 7-year-old daughter had behavior problems, and her 6-year-old and 4-year-old sons were impulsive and hyperactive and required constant supervision. Chantal’s 18-month-old sister was an engaging and active little girl, whereas Chantal was withdrawn, and would sit quietly, rocking herself, sucking her thumb, or chewing on newspaper.

The treatment plan included the involvement of social services and protective services to remove any lead paint from the walls in their current apartment, seek better living arrangements for the family, and provide a safe environment for the children. Chantal’s mother received guidance in enrolling Chantal in a preschool program, and her older sister and two brothers in an after-school program that provided structure and stimulation, and some respite time for her mother. Chantal, her mother, and her younger sister started family therapy to help their mother’s understanding of her children’s needs and to increase her positive interactions with Chantal. Once Chantal’s mother felt more supported and less overwhelmed, she was able to become more empathic and warm toward Chantal. When Chantal began chewing on
No definitive treatment exists for pica per se; most treatment is aimed at education and behavior modification. Treatments emphasize psychosocial, environmental, behavioral, and family guidance approaches. An effort should be made to ameliorate any significant psychosocial stressors. When lead is present in the surroundings, it must be eliminated or rendered inaccessible or the child must be moved to new surroundings.

When pica persists in the absence of any toxic manifestations, behavioral techniques have been utilized. Positive reinforcement, modeling, behavioral shaping, and overcorrection treatment have been used. Increasing parental attention, stimulation, and emotional nurturance may yield positive results. A study found that pica occurred most frequently in impoverished environments, and in some patients, correcting an iron or zinc deficiency has eliminated pica. Medical complications (e.g., lead poisoning) that develop secondarily to the pica must also be treated.

**31.9b Rumination Disorder**

Rumination is an effortless and painless regurgitation of partially digested food into the mouth soon after a meal, which is either swallowed or spit out. Rumination can be observed in developmentally normal infants who put their thumb or hand in the mouth, suck their tongue rhythmically, and arch their back to initiate regurgitation. This behavior pattern may be observed in infants who receive inadequate emotional interaction and have learned to soothe and may stimulate themselves through rumination. However, rumination syndromes can be found to occur in children and adolescents, and rumination is considered to be a functional gastrointestinal disorder. The pathophysiology of rumination is not well understood; however, it often involves a rise in intragastric pressure, generated by either voluntary or unintentional contraction of the abdominal wall muscles causing movement of gastric contents back up into the esophagus. The onset of the disorder can occur in infancy, childhood, or adolescence. In infants, it typically occurs between 3 months and 12 months of age, and once the regurgitation occurs, the food may be swallowed or spit out. Infants who ruminate are characteristically observed to strain with their backs arched and head back to bring the food back into their mouths and appear to find the experience pleasurable. Infants who are “experienced” ruminators are able to bring up the food through tongue movements and may not spit out the food at all, but hold it in their mouths and re-swallow it. The disorder is less common in older children, adolescents, and adults. It varies in severity and is sometimes associated with medical conditions, such as hiatal hernia, that result in esophageal reflux. In its most severe form, the disorder can cause malnutrition and be fatal.

The diagnosis of rumination disorder can be made even if an infant has attained a normal weight for his or her age. Failure to thrive, therefore, is not a necessary criterion of this disorder, but it is sometimes a sequela. According to DSM-5, the disorder must be present for at least 1 month after a period of normal functioning, and not better accounted for by gastrointestinal illness, or psychiatric or medical conditions.
Rumination has been recognized for hundreds of years. An awareness of the disorder is important so that it is correctly diagnosed and that unnecessary surgical procedures and inappropriate treatment are avoided. *Rumination* is derived from the Latin word *ruminare*, which means, “to chew the cud.” The Greek equivalent is *mercyism*, the act of regurgitating food from the stomach into the mouth, re-chewing the food, and re-swallowing it.

**EPIDEMIOLOGY**

Rumination is a rare disorder. It seems to be more common among male infants, and emerges between 3 months and 1 year of age. It persists more frequently among children, adolescents, and adults with intellectual disability. Adults with rumination usually maintain a normal weight.

**ETIOLOGY**

Rumination is associated with high intragastric pressure and the ability to contract the abdominal wall to cause retrograde movement of the gastric contents into the esophagus. Several studies have elucidated other gastrointestinal symptoms such as gastroesophageal reflux that may accompany rumination.

In a study of 2,163 children in Sri Lanka, between the ages of 10 years and 16 years, it was found that rumination behaviors were present in 5.1 percent of boys and 5.0 percent of girls. In 94.5 percent of youth who ruminated, the regurgitation occurred in the first hour after the meal, and 73.6 percent reported re-swallowing of the regurgitated food, whereas the rest spit it out. Only 8.2 percent of this sample reported daily episodes of regurgitation, whereas 62.7 percent experienced weekly symptoms. Associated gastrointestinal symptoms reported in this sample included abdominal pain, bloating, and weight loss. Approximately 20 percent of youth with rumination in this sample also experienced other gastrointestinal symptoms. Another survey of 147 patients from 5 years to 20 years of age found that in their sample, the mean age of onset of rumination was 15 years, and these patients were symptomatic after each meal; 16 percent of this sample met criteria for a psychiatric disorder, 3.4 percent had anorexia or bulimia nervosa, and 11 percent had been treated with a surgical procedure for evaluation of management of their symptoms. Additional gastrointestinal symptoms in this sample included abdominal pain in 38 percent, constipation in 21 percent, nausea in 17 percent, and diarrhea in 8 percent. In some cases, vomiting secondary to gastroesophageal reflux or an acute illness precedes a pattern of rumination that lasts for several months. In many cases, children classified as ruminators are shown to have gastroesophageal reflux or hiatal hernia.

It appears, for some infants, that the rumination behavior is self-soothing or produces a sense of relief, leading to a continuation of behaviors to bring it about. In youth with autism spectrum disorder or intellectual disability, rumination may serve as a self-stimulatory behavior. Overstimulation and tension have also been suggested as contributing factors in rumination. Behaviorists attribute persistent rumination to the positive reinforcement of pleasurable self-stimulation and to the attention a baby receives from others as a consequence of the disorder.

**DIAGNOSIS AND CLINICAL FEATURES**

The DSM-5 notes that the essential feature of the disorder is repeated regurgitation and re-chewing of food for a period of at least 1 month after a period of normal functioning. Partially digested food is brought up into the mouth without retching, retching, or disgust; on the contrary it may appear to be pleasurable. This activity may be distinguished from vomiting by painless and purposeful movements observable in some infants who induce it. The food is then ejected from the mouth or swallowed. A characteristic position of straining and arching of the back, with the head held back, is observed. The infant makes sucking movements with the tongue and gives the impression of gaining considerable satisfaction from the activity. Usually, the infant is irritable and hungry between episodes of rumination.

Initially, rumination may be difficult to distinguish from the regurgitation that frequently occurs in normal infants. In infants with persistent and frequent rumination behaviors, however, the differences are obvious. Although spontaneous remissions are common, secondary complications can develop, such as progressive malnutrition, dehydration, and lowered resistance to disease. Failure to thrive, with absence of growth and developmental delays in all areas, can occur in the most severe cases. Additional complications may occur if the mother of a given infant with rumination becomes discouraged by the persistent symptoms, viewing it as her feeding failure, as this may lead to more tension and more rumination after feedings.

Luca was 9-months-old when he was referred by his pediatrician to a gastroenterologist, and by his gastroenterologist for a psychiatric evaluation due to persistent and frequent rumination. Luca was born full-term and had developed typically until 6 weeks of age, when he began to regurgitate large amounts of milk just after feedings. He was evaluated and diagnosed with gastroesophageal reflux, for which it was recommended to thicken his feedings. Luca responded well to the treatment; his regurgitation was markedly diminished, and he gained weight adequately. Luca continued to do well, and his mother decided to go back to work when Luca was 8-months-old. Luca's mother transitioned his care to a young nanny who cared for Luca while she worked. Luca and the nanny seemed to have a warm relationship; however, he started again to regurgitate his meals soon after his mother left the house. The regurgitation seemed to increase in frequency and intensity within 2 weeks of the mother's return to work. At this point, Luca regurgitated after almost every meal, and he was losing weight. Luca was evaluated by a gastroenterologist, and during the barium swallow, his doctor noted that Luca put his hand in his mouth, which seemed to induce the regurgitation. Luca was administered some medication for gastroesophageal reflux; however, he continued to induce regurgitation after meals with increasing frequency, prompting the psychiatric consultation.

Observation of mother and infant during feeding at home revealed that as soon as Luca finished feeding, he purposefully placed his hand in his mouth and induced the regurgitation. When his mother restricted his hand, Luca moved his tongue back and forth in a rhythmic manner until he regurgitated again. Luca engaged in this rhythmic tongue movement repeatedly, even when he could not bring up any more milk, and appeared to be enjoying this behavior.

Due to Luca's poor nutritional state and moderate dehydration, he was admitted to the hospital, and a nasojejunal tube was inserted for feedings. When Luca was awake during feedings, a special duty nurse or his parents played with him and distracted him during attempts to put his hand in his mouth or thrust his tongue rhythmically. Luca became increasingly engaged in this playful activity,
and his ruminatory activity decreased accordingly. After 1 week in the hospital, small feedings were started; however, Luca again successfully was able to bring up his food by his ruminating activity, and the oral feedings had to be temporarily stopped. At this point, Luca’s mother decided to stop working and take Luca home to continue an intensive behavioral “distracting” intervention in order to interrupt his ruminating during meals. Luca’s mother started small feedings while playing with him during and after feedings, and was able to interest him in other activities, so that he would not ruminate. After 4 weeks of slow increments in his feedings, Luca was able to take all his feedings by mouth without ruminating, and the nasojugal tube could be removed. Luca and his mother continued to use simulating and distracting activities during and just after meals, which over time became more interesting to Luca than his previous ruminating behavior.

PATHOLOGY AND LABORATORY EXAMINATION

No specific laboratory examination is pathognomonic of rumination disorder; however, rumination disorder is not uncommonly associated with gastrointestinal abnormalities. Clinicians are recommended to evaluate other physical causes of vomiting, such as pyloric stenosis and hiatal hernia, before making the diagnosis of rumination disorder. Ruminating disorder can lead to states of malnutrition and dehydration. In very severe cases, laboratory measures of endocrinological function, serum electrolytes, and a hematological workup may determine the need for medical intervention.

DIFFERENTIAL DIAGNOSIS

To make the diagnosis of rumination disorder, clinicians must rule out primary gastrointestinal congenital anomalies, infections, and other medical illnesses that could account for frequent regurgitation. Pyloric stenosis is usually associated with projectile vomiting and is generally evident before 3 months of age, when ruminating has its onset. Ruminating has been associated with both autism spectrum disorder and intellectual disability in which stereotypic behaviors and eating disturbances are not uncommon. Ruminating behavior may occur comorbidly in youth with severe anxiety disorders as well. Ruminating disorder may also occur in patients with other eating disorders, such as anorexia nervosa and bulimia nervosa.

Predictable of the mother–child relationship reveals deficits that can be influenced by offering guidance to the mother. Behavioral interventions, such as habit-reversal are aimed at reinforcing an alternate behavior that becomes more compelling than the behaviors leading to regurgitation. Aversive behavioral interventions, such as squirting lemon juice into the infant’s mouth whenever ruminating occurs, have been used in the past to diminish ruminating behavior. Although aversive behavioral interventions have been reported anecdotally to be effective in some cases, current recommendations support the use of habit-reversal techniques.

When features of child maltreatment of neglect may have contributed to ruminating behaviors in an infant, treatments include improvement of the child’s psychosocial environment, increased tender loving care from the mother or caretakers, and psychotherapy for the mother or both parents. Anatomical abnormalities, such as hiatal hernia, are not uncommon, and must be evaluated, in some cases leading to surgical repair. In severe cases in which malnutrition and weight loss have occurred, placement of a jejunal tube may need to be inserted before other treatments can be utilized.

Medication is not a standard part of the treatment of rumination. Case reports, however, cite a variety of medications that have been tried, including metoclopramide (Reglan), cimetidine (Tagamet), and even antipsychotics such as haloperidol (Haldol) have been cited to be helpful according to anecdotal reports. The treatment of adolescents with ruminating disorder is often complex and includes a multidisciplinary approach consisting of individual psychotherapy, nutritional intervention, and pharmacologic treatment for frequent comorbid anxiety and depressive symptoms.

31.9c Avoidant/Restrictive Food Intake Disorder

Avoidant/restrictive food intake disorder, formerly known as feeding disorder of infancy or early childhood, is characterized by a lack of interest in food, or its avoidance based on the sensory features of the food or the perceived consequences of eating. This newly included DSM-5 disorder adds more detail about the nature of the eating problems, and has also been expanded to include adolescents and adults. The disorder is manifested by a persistent failure to meet nutritional or energy needs as evidenced by one or more of the following: significant weight loss or failure to achieve expected weight, nutritional deficiency, dependence on enteral feedings or nutritional supplements, or marked interference with psychosocial functioning. It may take the form of outright food refusal, food selectivity, eating too little, food avoidance, and delayed self-feeding. The diagnosis should not be made in the context of anorexia nervosa or bulimia nervosa, or if caused by a medical condition, by another mental disorder, or by a true lack of available food.

Infants and children with the disorder may be withdrawn, irritable, apathetic, or anxious. Because of the avoidant behavior during feeding, touching and holding between mothers and infants are diminished during the entire feeding process compared with other children. Some reports suggest that food avoidance or
restriction may be relatively long-standing; however, in many cases, normal adult functioning is eventually achieved.

**Epidemiology**

It is estimated that between 15 percent and 35 percent of infants and young children have transient feeding difficulties. A study of restrictive eating difficulties in Swedish 9-year-olds and 12-year-olds found that restrictive eating problems were present in 0.6 percent of their sample. However, another study of avoidant eating patterns in young children in Germany, found that some degree of avoidance was present in up to 53 percent of children. Thus, avoidant eating behaviors without impairment of nutritional state or psychosocial functioning must be separated from restricted eating disturbances leading to significant functional impairment. A survey of feeding problems in nursery school children revealed a prevalence of 4.8 percent with equal gender distribution. In that study, children with feeding problems exhibited more somatic complaints and mothers of affected infants exhibited increased risk of anxiety symptoms. Data from community samples estimate a prevalence of failure to thrive syndromes in approximately 3 percent of infants, with approximately half of those infants exhibiting feeding disorders.

**Differential Diagnosis**

The disorder must be differentiated from structural problems with the infants’ gastrointestinal tract that may be contributing to discomfort during the feeding process. Because feeding disorders and organic causes of swallowing difficulties often coexist, it is important to rule out medical reasons for feeding difficulties. A study of videofluoroscopic evaluation of children with feeding and swallowing problems revealed that clinical evaluation was 92 percent accurate in identifying those children at increased risk of aspiration. This type of evaluation is necessary before psychotherapeutic interventions in cases where a medical contribution to feeding problems is suspected.

**Course and Prognosis**

Most infants with feeding disorder who are identified within the first year of life and who receive treatment do not go on to develop malnutrition, growth delay, or failure to thrive. When feeding disorders have their onset later, in children 2 to 3 years of age, growth and development can be affected when the disorder lasts for several months. In older children, or adolescents, the feeding disorder typically interferes with social functioning, until treated. It is estimated that about 70 percent of infants who persistently refuse food in the first year of life continue to have some eating problems during childhood.

Jennifer was 6 months old when she was referred for a psychiatric evaluation because of feeding difficulties, irritability, and poor weight gain since birth. She was small and slight, but she did not appear to be lethargic or malnourished. Her parents were college-educated, and both had pursued their professional careers until Jennifer was born. Although Jennifer was full-term and weighed 7 pounds at birth, she had been unable to be breast fed due to turning away and not ingesting enough milk. When she was 4-weeks-old, Jennifer’s mother had reluctantly switched her to bottle feedings because Jennifer was losing weight. Although her intake improved somewhat on bottle feedings, she gained weight very slowly and was still less than 8 pounds at 3 months of age. Since then, she had gained a minimal amount each month to maintain a low but adequate weight. Jennifer’s mother appeared tired and described that Jennifer would drink only up to about 6 ounces at a time, or two bites of baby food, and then wiggle and cry; and refuse to continue with the feeding. But after a few hours, she might cry again as if she were hungry. However, she could not settle her into a good rhythm of feeding, and continued attempts to feed her would lead her to cry inconsolably. Jennifer’s mother described approximately 10 to 15 attempts at feeding her both liquids and solids in a 24-hour period. Jennifer was reported to be an irritable and fussy infant, who cried multiple times during the day and at night, and woke her family often during the night with her crying. Jennifer’s developmental milestones such as sitting up, tracking, and making sounds were within normal limits.

The observation of mother–infant interactions during feeding and play revealed that Jennifer was a very active and fussy baby who had difficulty sitting still. While drinking from the bottle she would kick her feet and move around, and if the bottle slipped out of her mouth, she did not try to recapture it. When eating baby foods, she was not interested and her mother had to coax her to open her mouth. This upset Jennifer, and she would start crying. Jennifer’s mother reported that she was always anxious during meals, and would try to convince Jennifer to take spoonfuls of baby food while sitting in her high chair. After repeated unsuccessful attempts of adequate feeding, Jennifer and her mother both appeared exhausted and took a break.

The history and examination revealed that Jennifer was a very active and exciting baby who had difficulty keeping calm during feedings. After reviewing the videotape with the mother, the therapist explored ways in which the mother could better facilitate calming Jennifer before and during meals. Using a quiet corner in the house, and singing to Jennifer before meals resulted in Jennifer remaining more calm during meals, and she was able to drink larger amounts of milk, eat more solid foods, and waited longer between meals. This, in turn, relieved her mother’s anxiety and helped both to have calmer interactions.

(Adapted by Caroly Pataki, M.D.)

**Treatment**

Most interventions for feeding disorders are aimed at optimizing the interaction between the mother and infant during feedings and identifying any factors that can be changed to promote greater ingestion. The mother is helped to become more aware of the infant’s stamina for length of individual feedings, the infant’s biological regulation patterns, and the infant’s fatigue level with a goal of increasing the level of engagement between mother and infant during feeding.

A transactional model of intervention has been proposed for infants who exhibit the “difficult” temperamental traits of emotional intensity, stubbornness, lack of hunger cues, and irregular eating and sleeping patterns. The treatment includes education for the parents regarding the temperament traits of the infant, exploration of the parents’ anxieties about the infant’s nutrition, and training for the parents regarding changing their behaviors to promote internal regulation of eating in the infant. Parents are encouraged to feed the infant on a regular basis at 3- to 4-hour
intervals, and offer only water between meals. The parents are trained to deliver praise to the infant for any self-feeding efforts, regardless of the amount of food ingested. Furthermore, parents are guided to limit any distracting stimulation during meals and give attention and praise to positive eating behaviors rather than intense negative attention to inappropriate behavior during meals. This training process for parents is done in an intense manner within a short period of time. Many parents are able to facilitate improved eating patterns in the infant as a result. If the mother or caregiver is unable to participate in the intervention, it may be necessary to include additional caregivers to contribute to feeding the infant. In rare cases, an infant may require hospitalization until adequate nutrition on a daily basis is accomplished. If an infant tires before ingesting an adequate amount of nutrition, it may be necessary to begin treatment with the placement of a nasogastric tube for supplemental oral feedings.

For older children with failure-to-thrive syndromes, hospitalization and nutritional supplementation may be necessary. Medication is not a standard component of treatment for feeding disorders; however, there are anecdotal reports of preadolescents with failure-to-thrive and feeding disorders who were comorbid for anxiety and mood symptoms and who received enteral nutritional interventions in addition to risperidone (Risperdal), and who were observed to have an increase in oral intake and accelerated weight gain.

### 31.10 Elimination Disorders

The developmental milestones of mastering control over bowel and bladder function are complex processes that involve motor and sensory functions, coordinated through frontal lobe activities, and regulated by neurons in the pons and midbrain area. Mastery of bowel and bladder function is achieved over a period of months for the typical toddler. Infants generally void small volumes of urine approximately every hour, commonly stimulated by feeding, and may have incomplete emptying of the bladder. As the infant matures to be a toddler, bladder capacity increases, and between 1 and 3 years of age, cortical inhibitory pathways develop that allow the child to have voluntary control over reflexes that control the bladder muscles. The ability to have muscular control over the bowel occurs even before bladder control for most toddlers, and the assessment of fecal soiling includes determining whether the clinical presentation occurs with or without chronic constipation and overflow soiling. The normal sequence of developing control over bowel and bladder functions is the development of nocturnal fecal continence, diurnal fecal continence, diurnal bladder control, and nocturnal bladder control. Bowel and bladder control develops gradually over time. Toilet training is affected by many factors, such as a child’s intellectual capacity and social maturity, cultural determinants, and the psychological interactions between child and parents. The ability to control bowel and bladder functions depends on the maturation of neurobiological systems, so that children with developmental delays may also display delayed continence of bowel and bladder. When children exhibit incontinence of urine or feces on a regular basis, it is troubling to the child and family, and often misunderstood as voluntary misbehavior.

Encopresis (repeated passage of feces into inappropriate places) and enuresis (repeated urination into bed or clothes) are the two elimination disorders described in the Fifth Edition of the American Psychiatric Association’s *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5). These diagnoses are not made until after age 4 years, for encopresis, and after age 5 years for enuresis, the ages at which a typically developing child is expected to master these skills. Normal development encompasses a range of time in which a given child is able to devote the attention, motivation, and physiological skills
to exhibit competency in elimination processes. Encopresis is characterized by a pattern of passing feces in inappropriate places, such as in clothing or other places, at least once per month for 3 consecutive months, whether the passage is involuntary or intentional. Up to about 80 percent of children with fecal incontinence have associated constipation. A child with encopresis typically exhibits dysregulated bowel function; for example, with infrequent bowel movements, constipation, or recurrent abdominal pain and sometimes pain on defecations. Enuresis is characterized by repeated voiding of urine into clothes or bed, whether the voiding is involuntary or intentional. The behavior must occur twice weekly for at least 3 months or must cause clinically significant distress or impairment socially or academically. The child's chronological or developmental age must be at least 5 years.

### 31.10a Encopresis

#### EPIDEMIOLOGY

Encopresis has been estimated to affect 3 percent of 4-year-olds and 1.6 percent of 10-year-old children. Incidence rates for encopretic behavior decrease drastically with increasing age. Between the ages of 10 years and 12 years, it is estimated to affect 0.75 percent of typically developing children. Globally, community prevalence of encopresis ranges from 0.8 to 7.8 percent. In Western cultures, bowel control is established in more than 95 percent of children by their fourth birthday and in 99 percent by the fifth birthday. Encopresis is virtually absent in children with bowel control and intentionally deposit feces in normal places at the age of 16 years. Males are found to from three to six times more likely to have encopresis than females. A significant relation exists between encopresis and enuresis.

#### ETIOLOGY

Ninety percent of chronic childhood encopresis is considered to be functional. Children with this disorder typically withhold feces by contracting their gluteal muscles, holding their legs together, and tightening their external anal sphincter. In some cases, this is an entrenched behavioral response to previously painful bowel movements due to hard stool, which leads to fear of defecation and withholding behaviors. Encopresis involves an often-complicated interplay between physiological and psychological factors leading to an avoidance of defecation. However, when children chronically hold in bowel movements, the result is often fecal impaction and eventual overflow soiling. This pattern is observed in more than 75 percent of children with encopretic behavior. This common set of circumstances in most children with encopresis supports a behavioral intervention with a focus on ameliorating constipation while increasing appropriate toileting behavior. Inadequate training or the lack of appropriate toilet training may delay a child's attainment of continence.

Evidence indicates that some encopretic children have lifelong inefficient and ineffective sphincter control. Other children may soil involuntarily, either because of an inability to control the sphincter adequately or because of excessive fluid caused by a retentive overflow.

In about 5 to 10 percent of cases, fecal incontinence is caused by medical conditions including abnormal innervation of the anorectal region, ultrashort segment Hirschsprung disease, neuronal intestinal dysplasia, or spinal cord damage. One study found encopresis to occur with significantly greater frequency among children with known sexual abuse, and other psychiatric disorders, compared with a sample of healthy children. Encopresis, however, is not a specific indicator of sexual abuse.

It is evident that once a child has developed a pattern of withholding bowel movements, and attempts to defecate have become painful, a child's fear and resistance to changing the pattern are high. Battles with parents who insist that their children attempt to defece before they are adequately treated may aggravate the condition and cause secondary behavioral difficulties. Children with encopresis who are not promptly treated, however, frequently end up being socially ostracized and rejected. The social consequences of soiling can lead to the development of emotional problems. On the other hand, children with encopresis who clearly can control their bowel function adequately but chronically deposit feces of relatively normal consistency in abnormal places are likely to have preexisting neurodevelopmental problems. Occasionally, a child has a specific fear of using the toilet, leading to a phobia.

Encopresis, in some cases can be considered secondary, that is, emerging after a period of normal bowel habits in conjunction with a disruptive life event, such as the birth of a sibling or a move to a new home. When encopresis manifests after a long period of fecal continence, it may reflect a developmental regressive behavior based on a severe stressor, such as a parental separation, loss of a best friend, or an unexpected academic failure.

### Megacolon

Most children with encopresis retain feces and become constipated, either voluntarily or secondary to painful defecation. In some cases a subclinical preexisting anorectal dysfunction exists that contributes to the constipation. In either case, resulting chronic rectal distention from large, hard fecal masses can cause loss of tone in the rectal wall and desensitization to pressure. Thus, children in this situation become even less aware of the need to defecate, and overflow encopresis occurs, usually with relatively small amounts of liquid or soft stool leaking out.

#### DIAGNOSIS AND CLINICAL FEATURES

According to DSM-5, encopresis is diagnosed when feces are passed into inappropriate places on a regular basis (at least once a month) for 3 months. Encopresis may be present in children who have bowel control and intentionally deposit feces in their clothes or other places for a variety of emotional reasons. Anecdotal reports have suggested that occasionally encopresis is attributable to an expression of anger or rage in a child whose parents have been punitive or of hostility at a parent. In a case such as this, once a child develops this inappropriate repetitive behavior eliciting negative attention, it is difficult to break the cycle of continuous negative attention. In other children, sporadic episodes of encopresis can occur during times of stress—for example, proximal to the birth of a new sibling—but...
in such cases, the behavior is usually transient and does not fulfill the diagnostic criteria for the disorder.

Encopresis can also be present on an involuntary basis in the absence of physiological abnormalities. In these cases, a child may not exhibit adequate control over the sphincter muscles, either because the child is absorbed in another activity or because he or she is unaware of the process. The feces may be of normal, near-normal, or liquid consistency. Some involuntary soiling occurs from chronic retaining of stool, which may result in liquid overflow. In rare cases, the involuntary overflow of stool results from psychological causes of diarrhea or anxiety disorder symptoms.

The DSM-5 includes two specifiers to encopresis: with constipation and overflow incontinence and without constipation and overflow incontinence. To receive a diagnosis of encopresis, a child must have a developmental or chronological level of at least 4 years. If the fecal incontinence is directly related to a medical condition, encopresis is not diagnosed.

Studies have indicated that children with encopresis who do not have gastrointestinal illnesses have high rates of abnormal anal sphincter contractions. This finding is particularly prevalent among children with encopresis with constipation and overflow incontinence who have difficulty relaxing their anal sphincter muscles when trying to defecate. Children with constipation who have difficulties with sphincter relaxation are not likely to respond well to laxatives in the treatment of their encopresis. Children with encopresis without abnormal sphincter tone are likely to improve over a short period.

Jack was a 7-year-old boy with daily encopresis, enuresis, and a history of hoarding behaviors, along with hiding the feces around the house. He lived with his adoptive parents, having been removed from his biological parents at age 3 years because of neglect and physical abuse. He was reported to be cocaine addicted at birth, but was otherwise healthy. Jack’s biological mother was a known methamphetamine and alcohol user, and his father had spent time in jail for drug dealing. Jack had always been enuretic at night, and until this year, he had a history of daytime enuresis as well. Jack had a short attention span, was highly impulsive, and had great difficulty staying in his seat at school and remaining on task. He had reading difficulties and was placed in a contained special education classroom because of his disruptive behavior as well as his academic difficulties. Despite experiencing physical abuse, he has not experienced flashbacks or other symptoms that would indicate the presence of posttraumatic stress disorder. Jack was treated for attention-deficit/hyperactivity disorder (ADHD) with good response to methylphenidate (Concerta 36 mg per day).

Jack’s adoptive family sought help at a university hospital’s outpatient program that had expertise in the behavioral treatments of many psychiatric disorders including encopresis. The treatment program combined use of regular laxatives and a bowel training method with cognitive-behavioral therapy for Jack and for his family. Jack was started on a regimen of daily polyethylene glycol (PEG) solution and was seen by a pediatrician who was able to perform a manual evacuation under sedation. Following that, Jack was continued on daily PEG solution combined with therapy. He learned to empty his bowel while sitting on the toilet for 10 minutes after each meal, whether or not he felt like he had to go. He soon was eager to stay on this regular bathroom schedule, and felt proud when he was able to have a bowel movement in the toilet. Over a period of 3 months, Jack was noticeably improved, and at 6 months, he was almost completely better. (Courtesy of Edwin J. Mikkelsen, M.D. and Caroly Pataki, M.D.)

**PATHOLOGY AND LABORATORY EXAMINATION**

Although no specific test indicates a diagnosis of encopresis, clinicians must rule out medical illnesses, such as Hirschsprung’s disease, before making a diagnosis. It must be determined whether fecal retention is responsible for encopresis with constipation and overflow incontinence; a physical examination of the abdomen is indicated, and an abdominal X-ray can help determine the degree of constipation present. Tests to determine whether sphincter tone is abnormal are generally not conducted in simple cases of encopresis.

**DIFFERENTIAL DIAGNOSIS**

In encopresis with constipation and overflow incontinence, constipation can begin as early as the child’s first year and can peak between the second and fourth years. Soiling usually begins by age 4. Frequent liquid stools and hard fecal masses are found in the colon and the rectum on abdominal palpation and rectal examination. Complications include impaction, megacolon, and anal fissures.

Encopresis with constipation and overflow incontinence is rarely caused by faulty nutrition; structural disease of the anus, rectum, and colon; medicinal adverse effects; or nongastrointestinal medical (endocrine or neurological) disorders. The chief differential medical problem is aganglionic megacolon or Hirschsprung’s disease, in which a patient may have an empty rectum and no desire to defecate, but may still have an overflow of feces. The disorder occurs in 1 in 5,000 children; signs appear shortly after birth.

**COURSE AND PROGNOSIS**

The outcome of encopresis depends on the etiology, the chronicity of the symptoms, and coexisting behavioral problems. In some cases, encopresis is self-limiting, and it rarely continues beyond middle adolescence. Encopresis in children who have contributing physiological factors, such as poor gastric motility and an inability to relax the anal sphincter muscles, is more difficult to treat than that in those with constipation but normal sphincter tone.

Encopresis is a particularly objectionable disorder to family members, who may assume that the behavior is due to “laziness,” and family tensions are often high. Peers are intolerant of the developmentally inappropriate behavior and typically taunt and reject a child with encopresis. Many affected children have abysmally low self-esteem and are plagued by constant social rejection. Psychologically, a child may appear blunted toward the symptoms or less frequently, may be entrenched in a pattern of encopresis as a mode of expressing anger. The outcome of encopresis is influenced by a family’s willingness and ability to participate in treatment without being overly punitive and by the child’s ability and motivation to engage in treatment.

**TREATMENT**

A typical treatment plan for a child with encopresis includes daily oral administration of laxatives such as PEG at 1 g/kg
per day, and often a surgical disimpaction under general anesthesia before maintenance laxatives can be administered. In addition, an ongoing cognitive-behavioral intervention to begin regular attempts to have bowel movements in the toilet, and to diminish anxiety related to bowel movement. By the time a child is brought for treatment, considerable family discord and distress are common. Family tensions about the symptom must be reduced, and a nonpunitive atmosphere established. Similar efforts should be made to reduce the child’s embarrassment at school. Many changes of underwear with a minimum of embarrassment should be arranged. Education of the family and correction of misperceptions that a family may have about soiling must occur before treatment. Laxatives are not necessary for children who are not constipated and do have good bowel control, but regular, timed intervals on the toilet may be useful with these children as well.

A report confirms the success of an interactive parent–child family guidance intervention for young children with encopresis based on psychological and behavioral interventions for children younger than age 9 years. Supportive psychotherapy and relaxation techniques may be useful in treating the anxieties and other sequelae of children with encopresis, such as low self-esteem and social isolation. Family interventions can be helpful for children who have bowel control but who continue to deposit their feces in inappropriate locations. An optimal outcome occurs when a child achieves a feeling of control over his or her bowel function.

REFERENCES
factors often play a role in the development of enuresis, and behavioral patterns are likely to maintain the maladaptive urination. Normal bladder control, which is acquired gradually, is influenced by neuromuscular and cognitive development, socioemotional factors, toilet training, and genetic factors. Difficulties in one or more of these areas can delay urinary continence.

Genetic factors are believed to play a role in the expression of enuresis, given that the emergence of enuresis has been found to be significantly greater in first-degree relatives. A longitudinal study of child development found that children with enuresis were about twice as likely to have concomitant developmental delays as those who did not have enuresis. About 75 percent of children with enuresis have a first-degree relative who has or has had enuresis. A child's risk for enuresis has been found to be more than seven times greater if the father was enuretic. The concordance rate is higher in monozygotic twins than in dizygotic twins. A strong genetic component is suggested, and much can be accounted for by tolerance for enuresis in some families and by other psychosocial factors.

Studies indicate that children with enuresis with a normal anatomical bladder capacity report urge to void with less urine in the bladder than children without enuresis. Other studies report that nocturnal enuresis occurs when the bladder is full because of lower than expected levels of nighttime antidiuretic hormone. This could lead to a higher-than-usual urine output. Enuresis does not appear to be related to a specific stage of sleep or time of night; rather, bed-wetting appears randomly. In most cases, the quality of sleep is normal. Little evidence indicates that children with enuresis sleep more soundly than other children.

Psychosocial stressors appear to precipitate enuresis in a subgroup of children with the disorder. In young children, the disorder has been particularly associated with the birth of a sibling, hospitalization between the ages of 2 and 4 years, the start of school, separation of a family due to divorce, or a move to a new environment.

**DIAGNOSIS AND CLINICAL FEATURES**

Enuresis is the repeated voiding of urine into a child's clothes or bed; the voiding may be involuntary or intentional. For the diagnosis to be made, a child must exhibit a developmental or chronological age of at least 5 years. According to DSM-5, the behavior must occur twice weekly for a period of at least 3 months or must cause distress and impairment in functioning to meet the diagnostic criteria. Enuresis is diagnosed only if the behavior is not caused by a medical condition. Children with enuresis are at higher risk for ADHD compared with the general population. They are also more likely to have comorbid encopresis. DSM-5 and the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) break down the disorder into three types: nocturnal only, diurnal only, and nocturnal and diurnal.

**PATHOLOGY AND LABORATORY EXAMINATION**

No single laboratory finding is pathognomonic of enuresis; but clinicians must rule out organic factors, such as the presence of urinary tract infections, which may predispose a child to enuresis. Structural obstructive abnormalities may be present in up to 3 percent of children with apparent enuresis. Sophisticated radiographic studies are usually deferred in simple cases of enuresis with no signs of repeated infections or other medical problems.

**DIFFERENTIAL DIAGNOSIS**

To make the diagnosis of enuresis, organic causes of bladder dysfunction must be investigated and ruled out. Organic syndromes, such as urinary tract infections, obstructions, or anatomical conditions are found most often in children who experience both nocturnal and diurnal enuresis combined with urinary frequency and urgency. The organic features include genitourinary pathology—structural, neurological, and infectious—such as obstructive uropathy, spina bifida occulta, and cystitis; other organic disorders that can cause polyuria and enuresis, such as diabetes mellitus and diabetes insipidus; disturbances of consciousness and sleep, such as seizures, intoxication, and sleepwalking disorder, during which a child urinates; and adverse effects from treatment with antipsychotic agents.

**COURSE AND PROGNOSIS**

Enuresis is often self-limited, and a child with enuresis may have a spontaneous remission. Most children who master the task of control over their bladder gain self-esteem and improved social confidence when they become continent. About 80 percent of affected children have never achieved a year-long period of dryness. Enuresis after at least one dry year usually begins between the ages of 5 and 8 years; if it occurs much later, especially during adulthood, organic causes must be investigated. Some evidence indicates that late onset of enuresis in children is more frequently associated with a concomitant psychiatric difficulty than is enuresis without at least one dry year. Relapses occur in children with enuresis who are becoming dry spontaneously and in those who are being treated. The significant emotional and social difficulties of these children usually include poor self-image, decreased self-esteem, social embarrassment and restriction, and intrafamilial conflict. The course of children with enuresis may be influenced by whether they receive appropriate evaluation and treatment for common comorbid disorders such as ADHD.

**TREATMENT**

A relatively high rate of spontaneous remission of enuresis occurs over time in childhood; however, in many cases, interventions are necessary because enuresis is causing functional impairment. The first step in any treatment plan is to review appropriate toilet training. If toilet training was not attempted, the parents and the patient should be guided in this undertaking. Record-keeping is helpful in determining a baseline and following the child's progress, and may itself be a reinforcer. A star chart may be particularly helpful. Other useful techniques include restricting fluids before bed and night lifting to toilet train the child. Interventions with alarm therapy, which is triggered by wet underwear, has been a mainstay of treatment for enuresis. Alarm therapy works by alerting a child to respond when voiding begins during sleep. The alarm is a battery-operated device that can be attached to a child's underwear or a mat. The alarm is triggered
as soon as voiding begins by emitting a loud noise that awakens the child. The success of this method is based on the child's ability to awaken promptly and respond to the alarm by getting up and voiding in the toilet. A child who can respond optimally is at least 6 or 7 years old. Pharmacological interventions including desmopressin therapy in managing nocturnal enuresis have been shown to be effective in some patients. Desmopressin is a “synthetic analogue” of vasopressin, which can be administered as a pill, a sublingual melt, or a nasal spray. Its effect can last up to 8 hours, and it works by reducing urine production at night. This method is optimal when no fluids are ingested in the evening.

Another basic intervention for those children with enuresis and bowel dysfunction is to assess whether chronic constipation is contributing to urinary dysfunction, and to consider increasing dietary fiber to diminish constipation.

Behavioral Therapy

Classic conditioning with the bell (or buzzer) and pad (alarm) apparatus is generally the most effective treatment for enuresis, with dryness resulting in more than 50 percent of cases. Bladder training—encouragement or reward for delaying micturition for increasing times during waking hours—has also been used. Although sometimes effective, this method is decidedly inferior to the bell and pad.

Pharmacotherapy

Medication is considered when enuresis is causing impairment in social, family, and school function and behavioral, dietary, and fluid restriction have not been efficacious. When the problem interferes significantly with a child's functioning, several medications can be considered, although the problem often recurs as soon as medications are withdrawn.

Desmopressin (DDAVP), an antidiuretic compound that is available as an intranasal spray, has shown success in reducing enuresis. Reduction of enuresis has varied from 10 to 90 percent with the use of desmopressin. In most studies, enuresis recurred shortly after discontinuation of this medication. Adverse effects that can occur with desmopressin include headache, nasal congestion, epistaxis, and stomachache. The most serious adverse effect reported with the use of desmopressin to treat enuresis was a hyponatremic seizure experienced by a child.

Reboxetine (Edronax, Vestra), a norepinephrine reuptake inhibitor with a noncardiototoxic side effect profile has recently been investigated as a safer alternative to imipramine in the treatment of childhood enuresis. A trial in which 22 children with enuresis causing social impairment, who had not responded to an enuresis alarm, desmopressin, or anticholinergics were administered 4 to 8 mg of reboxetine at bedtime. Of the 22 children, 13 (59 percent) in this open trial achieved complete dryness with reboxetine alone, or in combination with desmopressin. Side effects were minimal and did not lead to discontinuation of the medication in this trial.

Psychotherapy

Psychotherapy may be useful in dealing with the coexisting psychiatric problems and the emotional and family difficulties that arise secondary to chronic enuresis.

31.11a Reactive Attachment Disorder and Disinhibited Social Engagement Disorder

Reactive attachment disorder and disinhibited social engagement disorder are clinical disorders characterized by aberrant social behaviors in a young child that reflect grossly negligent parenting and maltreatment that disrupted the development of normal attachment behavior. A diagnosis of either reactive attachment disorder or disinhibited social engagement disorder is based on the presumption that the etiology is directly linked to the caregiving deprivation experienced by the child. The diagnosis of reactive attachment disorder was first defined in the DSM, Third Edition (DSM-III) in 1980. The formation of this diagnosis is based on the building blocks of attachment theory, which describes the quality of a child's affective relationship with primary caregivers, usually parents. This basic relationship is the product of a young child's need for protection, nurturance, and comfort and the interaction of the parents and child in fulfilling these needs.

Based on observations of a young child and parents during a brief separation and reunion, designated the "strange situation procedure," pioneered by Mary Ainsworth and colleagues, researchers have designated a child's basic pattern of attachment to be characterized as secure, insecure, or disorganized. Children who exhibit secure attachment behavior are believed to experience their caregivers as emotionally available and appear to be more exploratory and well adjusted than children who exhibit insecure or disorganized attachment behavior. Insecure attachment is believed to result from a young child's perception that the caregiver is not consistently available, whereas disorganized attachment behavior in a child is believed to result from experiencing both the need for proximity to the caregiver and apprehension in approaching the caregiver. These early patterns of attachment are believed to influence a child's future capacities for affect regulation, self-soothing, and relationship building. According to the DSM-5, reactive attachment disorder is characterized by a consistent pattern of emotionally withdrawn responses toward adult caregivers, limited positive affect, sadness, and minimal social responsiveness to others, and concomitant neglect, deprivation, and lack of appropriate nurturance from caregivers. It is presumed that reactive attachment disorder is due to grossly pathological caregiving received by the child. The pattern of care may exhibit disregard for a child's emotional or physical needs or repeated changes of caregivers, as when a child is frequently relocated during foster care. Reactive attachment disorder is not accounted for by autism spectrum disorder, and the child must have a developmental age of at least 9 months.

Pathological caretaking can result in two distinct disorders: reactive attachment disorder, in which the disturbance takes the form of the child's constantly failing to initiate and respond to most social interactions in a developmentally normal way; and disinhibited social engagement disorder, in which the disturbance takes the form of undifferentiated, unselective, and inappropriate social relatedness, with familiar and unfamiliar adults.

In disinhibited social engagement disorder, according to DSM-5, a child actively approaches and interacts with unfamiliar adults in an overly familiar way, either verbally or physically. There is diminished checking with or seeking of a known caregiver, and a willingness to go with unfamiliar adults without hesitation. These behaviors in disinhibited social engagement disorder are not accounted for by impulsivity, although socially disinhibited behavior is predominant. These patterns of disinhibited, developmentally inappropriate behaviors are presumed to be caused by pathogenic caregiving. Thus, for both reactive attachment disorder and disinhibited social engagement disorder, aberrant caretaking is presumed to be the predominant cause of the child's inappropriate behaviors. However, there have been cases of less severe disturbances in parenting that may also be associated with young children who exhibit some characteristics of reactive attachment disorder or disinhibited social engagement disorder. The DSM-5 criteria for reactive attachment disorder are described in Table 31.11a-1 and those for disinhibited social engagement disorder are described in Table 31.11a-2.

These disorders may also result in a picture of failure to thrive, in which an infant shows physical signs of malnourishment and does not exhibit the expected developmental motor and verbal milestones.

**Epidemiology**

Few data exist on the prevalence, sex ratio, or familial pattern of reactive attachment disorder and disinhibited social engagement disorder. It has been estimated for either one to occur in less than 1 percent of the population. A study of 1,646 children aged 6- to 8-years-old living in a deprived sector of urban United Kingdom, found that the prevalence of reactive attachment disorder in this population was 1.4 percent. However, other studies of selected high-risk populations have estimated that about 10 percent of young children with documented neglectful and grossly pathological caregiving exhibit reactive attachment disorder, and up to 20 percent of children in this situation exhibit disinhibited social engagement disorder. In a retrospective report of children in one county of the United States who were removed from their homes because of neglect or abuse before the age of 4 years, 38 percent exhibited signs of either reactive attachment disorder or disinhibited social engagement disorder. Another study established the reliability of the diagnosis by reviewing videotaped assessments of at-risk children interacting with caregivers, along with a structured interview with caregivers. Given that pathogenic care, including maltreatment, occurs more frequently in the presence of general psychosocial risk factors, such as poverty, disrupted families, and mental illness among caregivers, these circumstances are likely to increase the risk of reactive attachment disorder and disinhibited social engagement disorder.

**Etiology**

The core features of reactive attachment disorder and disinhibited social engagement disorder are disturbances of normal attachment behaviors. The inability of a young child to develop normative social interactions that culminate in aberrant attachment behaviors in reactive attachment disorder is inherent in the disorder's
Chapter 31: Child Psychiatry

### DSM-5 Diagnostic Criteria for Reactive Attachment Disorder

**A.** A consistent pattern of inhibited, emotionally withdrawn behavior toward adult caregivers, manifested by both of the following:
   1. The child rarely or minimally seeks comfort when distressed.
   2. The child rarely or minimally responds to comfort when distressed.

**B.** A persistent social and emotional disturbance characterized by at least two of the following:
   1. Minimal social and emotional responsiveness to others.
   2. Limited positive affect.
   3. Episodes of unexplained irritability, sadness, or fearfulness that are evident even during nonthreatening interactions with adult caregivers.

**C.** The child has experienced a pattern of extremes of insufficient care as evidenced by at least one of the following:
   1. Social neglect or deprivation in the form of persistent lack of having basic emotional needs for comfort, stimulation, and affection met by caregiving adults.
   2. Repeated changes of primary caregivers that limit opportunities to form stable attachments (e.g., frequent changes in foster care).
   3. Rearing in unusual settings that severely limit opportunities to form selective attachments (e.g., institutions with high child-to-caregiver ratios).

**D.** The care in Criterion C is presumed to be responsible for the disturbed behavior in Criterion A (e.g., the disturbances in Criterion A began following the lack of adequate care in Criterion C).

**E.** The criteria are not met for autism spectrum disorder.

**F.** The disturbance is evident before age 5 years.

**G.** The child has a developmental age of at least 9 months.

Specify if:
- **Persistent:** The disorder has been present for more than 12 months.

Specify current severity:
- Reactive attachment disorder is specified as severe when a child exhibits all symptoms of the disorder, with each symptom manifesting at relatively high levels.

definition. Reactive attachment disorder and disinhibited social engagement disorder are presumed to be linked to maltreatment of the child, including emotional neglect, physical abuse, or both. Grossly pathogenic care of an infant or young child by the caregiver presumably causes the markedly disturbed social relatedness that is evident. The emphasis is on the unidirectional cause; that is, the caregiver does something inimical or neglects to do something essential for the infant or child. In evaluating a patient for whom such a diagnosis is appropriate, however, clinicians should consider the contributions of each member of the caregiver–child

### DSM-5 Diagnostic Criteria for Disinhibited Social Engagement Disorder

**A.** A pattern of behavior in which a child actively approaches and interacts with unfamiliar adults and exhibits at least two of the following:
   1. Reduced or absent reticence in approaching and interacting with unfamiliar adults.
   2. Overly familiar verbal or physical behavior (that is not consistent with culturally sanctioned and with age-appropriate social boundaries).
   3. Diminished or absent checking back with adult caregiver after venturing away, even in unfamiliar settings.
   4. Willingness to go off with an unfamiliar adult with minimal or no hesitation.

**B.** The behaviors in Criterion A are not limited to impulsivity (as in attention-deficit/hyperactivity disorder) but include socially disinhibited behavior.

**C.** The child has experienced a pattern of extremes of insufficient care as evidenced by at least one of the following:
   1. Social neglect or deprivation in the form of persistent lack of having basic emotional needs for comfort, stimulation, and affection met by caregiving adults.
   2. Repeated changes of primary caregivers that limit opportunities to form stable attachments (e.g., frequent changes in foster care).
   3. Rearing in unusual settings that severely limit opportunities to form selective attachments (e.g., institutions with high child-to-caregiver ratios).

**D.** The care in Criterion C is presumed to be responsible for the disturbed behavior in Criterion A (e.g., the disturbances in Criterion A began following the pathogenic care in Criterion C).

**E.** The child has a developmental age of at least 9 months.

Specify if:
- **Persistent:** The disorder has been present for more than 12 months.

Specify current severity:
- Disinhibited social engagement disorder is specified as severe when the child exhibits all symptoms of the disorder, with each symptom manifesting at relatively high levels.

dyad and their interactions. Clinicians should weigh such things as infant or child temperament, deficient or defective bonding, a developmentally disabled child, and a particular caregiver–child mismatch. The likelihood of neglect increases with parental psychiatric disorder, substance abuse, intellectual disability, the parent's own harsh upbringing, social isolation, deprivation, and premature parenthood (i.e., adolescent). These factors compromise parental ability to attend to the needs of the child, as they focus primarily on their own existence rather than on their child. Frequent changes of the primary caregivers, for example, from multiple foster care placements or repeated lengthy hospitalizations, may also lead to impaired attachment. In the general population, a study of 1,600 children found that those children with reactive attachment disorder/disinhibited social engagement disorder showed a constellation of symptoms characterized by early emergence of symptoms eliciting neurodevelopmental examination (ESSENCE). Some of the associated symptoms in children with reactive attachment disorder/disinhibited social engagement disorder include higher risk of failure to gain weight as neonates, feeding difficulty, and poor impulse control. These traits are likely to emerge because of both genetic and environmental factors. The authors found that children with reactive attachment disorder/disinhibited social engagement disorder were more likely to have multiple psychiatric comorbidities, lower intelligence quotients (IQs) compared to the general population, and more behavioral problems. Thus, a broad assessment may be necessary to identify symptoms and disorders associated with reactive attachment disorder/disinhibited social engagement disorder.

**DIAGNOSIS AND CLINICAL FEATURES**

Children with reactive attachment disorder and disinhibited social engagement disorder may initially be identified by a preschool teacher or by a pediatrician based on direct observation of the child's inappropriate social responses. The DSM-5 diagnostic criteria for reactive attachment disorder and disinhibited social engagement disorder are described in Tables 31.11a-1 and 31.11a-2, respectively. The diagnoses of reactive attachment disorder and disinhibited social engagement disorder are based partially on documented evidence of pervasive disturbance of attachment leading to inappropriate social behaviors present before the age of 5 years. The clinical picture varies greatly, depending on a child's chronological and mental ages, but expected social interaction and liveliness are not present. Often, the child is not progressing developmentally or is frankly malnourished. Perhaps the most common clinical picture of an infant with reactive attachment disorder is the nonorganic failure to thrive. Such infants usually exhibit hypokinesis, dullness, listlessness, and apathy, with a poverty of spontaneous activity. Infants look sad, joyless, and miserable. Some infants also appear frightened and watchful, with a radar-like gaze. Nevertheless, they may exhibit delayed responsiveness to a stimulus that would elicit fear or withdrawal from a normal infant. Infants with failure to thrive and reactive attachment disorder appear significantly malnourished, and many have protruding abdomens. Occasionally, foul-smelling, celiac-like stools are reported. In unusually severe cases, a clinical picture of marasmus appears.

The infant's weight is often below the third percentile and markedly below the appropriate weight for his or her height. If serial weights are available, the weight percentiles may have decreased progressively because of an actual weight loss or a failure to gain weight as height increases. Head circumference is usually normal for the infant's age. Muscle tone may be poor. The skin may be colder and paler or more mottled than skin of a normal child. Laboratory findings may indicate coincident malnutrition, dehydration, or concurrent illness. Bone age is usually retarded. Growth hormone levels are usually normal or elevated, a finding suggesting that growth failure in these children is secondary to caloric deprivation and malnutrition. Cortisol secretion in children with reactive attachment disorder or disinhibited social engagement disorder is lower than in typical developing children. For children with failure to thrive, improvement physically and weight gain generally occur rapidly after they are hospitalized.

Socially, the infants with reactive attachment disorder usually show little spontaneous activity and a marked diminution of both initiative toward others and reciprocity in response to the caregiving adult or examiner. Both mother and infant may be indifferent to separation on hospitalization or to termination of subsequent hospital visits. The infants frequently show none of the normal upset, fretting, or protest about hospitalization. Older infants usually show little interest in their environment. They may not play with toys, even if encouraged; however, they rapidly or gradually take an interest in, and relate to, their caregivers in the hospital.

**Psychosocial Dwarfism.** Classic psychosocial dwarfism or psychosocially determined short stature is a syndrome that usually is first manifest in children 2 to 3 years of age. The children are typically unusually short and have frequent growth hormone abnormalities and severe behavioral disturbances. All of these symptoms result from an inimical caregiver–child relationship. The affectionless character may appear when there is a failure, or lack of opportunity, to form attachments before the age of 2 to 3 years. Children cannot form lasting relationships, and their inability is sometimes accompanied by an inability to obey rules, a lack of guilt, and a need for attention and affection. Children with disinhibited social engagement disorder appear to be overly friendly and familiar with little fear.

A 7-year-old boy was referred by his adoptive parents because of hyperactivity and inappropriate social behavior at school. He had been adopted at 4 years of age, after living most of his life in a Chinese orphanage in which he received care from a rotating shift of caregivers. Although he had been below the 5th percentile for height and weight on arrival, he quickly approached the 15th percentile in his new home. However, his adoptive parents were frustrated by his inability to bond with them. They had initially worried about an intellectual problem, although testing and his capacity to engage almost any adult and many children verbally suggested otherwise. He appeared to be too friendly, talking to anyone and often following strangers willingly. He showed little empathy when others were hurt and yet he would sit on the laps of teachers and students without asking. He was frequently injured because of seemingly reckless behavior, although he had an extremely high tolerance for pain. His parents focused on problem behaviors at home to decrease his impulsive behavior, which improved with much prompting; however, he remained oddly overfriendly at home and in school. The child was diagnosed with disinhibited social engagement disorder. (Adapted from Neil W. Boris, M.D. and Charles H. Zeanah, Jr., M.D.)
PATHOLOGY AND LABORATORY EXAMINATION

Although no single specific laboratory test is used to make a diagnosis, many children with reactive attachment disorder have disturbances of growth and development. Thus, establishing a growth curve and examining the progression of developmental milestones may be helpful in determining whether associated phenomena, such as failure to thrive, are present.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of reactive attachment disorder and disinhibited social engagement disorder must take into account that many other psychiatric disorders may arise in conjunction with maltreatment, including depressive disorders, anxiety disorders, and posttraumatic stress disorders. Psychiatric disorders to consider in the differential diagnosis include language disorders, autism spectrum disorder, intellectual disability, and metabolic syndromes. Children with autism spectrum disorders are typically well nourished and of age-appropriate size and weight, and are generally alert and active, despite their impairments in reciprocal social interactions. Significant intellectual disability is often present in children with autism spectrum disorder, whereas when intellectual disability occurs with reactive attachment disorder or disinhibited social engagement disorder, it is generally relatively mild. Children with disinhibited social engagement disorder often show comorbid attention-deficit/hyperactivity disorder, posttraumatic stress disorder, and language disorder or delay. Furthermore, children with disinhibited social engagement disorder symptoms may have complex neuropsychiatric problems.

COURSE AND PROGNOSIS

Most of the data available on the natural course of children with reactive attachment disorder and disinhibited social engagement disorder come from follow-up studies of children in residential facilities with histories of serious neglect. Findings from these studies suggest that children with reactive attachment disorder, who are later adopted into caring environments, improve in their attachment behaviors and may normalize over time. Children with disinhibited social engagement disorder, however, appear to have more difficulty developing attachments to new caregivers. Children with disinhibited social engagement disorder who exhibit indiscriminate social behavior also tend to have poor peer relationships. The prognosis for children with reactive attachment disorder and disinhibited social engagement disorder is influenced by the duration and severity of the neglect and the degree of impairment that results. Constitutional and nutritional factors interact in children, who may either respond resiliently to treatment or continue to fail to thrive. After a pathological caregiving situation has been recognized, the amount of treatment and rehabilitation that the family receives affects the child. Children who have multiple problems stemming from pathogenic caregiving may recover physically faster and more completely than they do emotionally.

TREATMENT

The first consideration in treating reactive attachment disorder or disinhibited social engagement disorder is a child's safety. Thus, the management of these disorders must begin with a comprehensive assessment of the current level of safety and adequate caregiving. When there is suspicion of maltreatment persisting in the home, the first decision is often whether to hospitalize the child or to attempt treatment while the child remains in the home. If neglect, or emotional, physical, or sexual abuse is suspected, legally, such must be reported to the appropriate law enforcement and child protective services in the area. The child's physical and emotional state and the level of pathological caregiving determine the therapeutic strategy. A determination must be made regarding the nutritional status of the child and the presence of ongoing physical abuse or threat. Hospitalization is necessary for children with malnourishment. Along with an assessment of the child's physical well-being, an evaluation of the child's emotional condition is important. Immediate intervention must address the parents' awareness and capacity to participate in altering the injurious patterns that have heretofore ensued. The treatment team must begin to improve the unsatisfactory relationship between caregiver and child. This usually requires extensive and intensive intervention and education with the mother or with both parents when possible.

In one study, parents of 120 children between 11.7 months and 31.9 months, identified as being at risk for neglect, were randomly assigned to an intervention for at-risk parents called Attachment and Biobehavioral Catch-up (ABC) or to a control intervention. The ABC intervention was designed to decrease frightening behavior toward the infant by parents, and to increase sensitive and nurturing interactions between parents and infant. The intervention was manualized so that parents were specifically guided in how to provide those interactions with their infants. Children were evaluated after 10 sessions, and the 60 children who received the ABC intervention showed significantly lower rates of disorganized attachment (32%), and higher rates of secure attachment (52%) compared to those who received the control intervention (disorganized attachment 57%; secure attachment 33%). The authors concluded that parental nurturance and sensitivity can be enhanced by a comprehensive and explicit intervention such as the ABC intervention, and significant improvements in attachment behaviors can be measured in young children after 10 sessions.

The caregiver–child relationship is the basis of the assessment of reactive attachment disorder and disinhibited social engagement disorder symptoms, and the substrate from which to modify attachment behaviors. Structured observations allow a clinician to determine the range of attachment behaviors established with various family members. The clinician may work closely with the caregiver and the child to facilitate greater sensitivity in their interactions. Three basic psychotherapeutic modalities are helpful in promoting positive bonds between children and caregiver. First, a clinician can target the caregiver to promote positive interaction with a child who does not yet have the repertoire to respond positively. Second, a clinician can work with the child and the caregiver together as a dyad to advocate for practicing appropriate positive reinforcement for each other. Through the use of videotapes, parent–child interactions...
can then be viewed and modifications can be suggested to increase positive engagement. The third modality for clinical intervention is through individual work with the child. Working with the child and caregiver together is often more effective in producing more emotionally meaningful exchanges than working with parent or child individually.

Psychosocial interventions for families in which a child has reactive attachment disorder or dishibited social engagement disorder include (1) psychosocial support services, including hiring a homemaker, improving the physical condition of the apartment, or obtaining more adequate housing; improving the family’s financial status; and decreasing the family’s isolation; (2) psychotherapeutic interventions, including individual psychotherapy, psychotropic medications, and family or marital therapy; (3) educational counseling services, including mother-infant or mother–toddler groups, and counseling to increase awareness and understanding of the child’s needs and to develop parenting skills; and (4) provisions for close monitoring of the progression of the patient’s emotional and physical well-being. Sometimes, separating a child from the stressful home environment temporarily, as in hospitalization, allows the child to break out of the accustomed pattern. A neutral setting, such as the hospital, is the best place to start with families who are genuinely available emotionally and physically for intervention. If interventions are unfeasible or inadequate or if they fail, placement with relatives or in foster care, adoption, or a group home or residential treatment facility must be considered.

that reenact the traumatic situation, along with agitation, fear, or disorganization.

**EPIDEMIOLOGY**

In the United States, it is estimated that approximately 80 percent of individuals have been exposed to at least one traumatic event; however, less than 10 percent of trauma victims develop posttraumatic stress disorder. The rates of traumatic events, including assaultive violence, exposure to unexpected deaths, being a witness of trauma to others, and bodily injury, all peak sharply between the ages of 16 to 20 years. PTSD is more common in females than in males throughout the life span mainly due to their increased risk for exposure to traumatic events. In situations of natural disaster, the rates of PTSD in males and females are similar. Lifetime risk for PTSD in the United States ranges from 6.8 percent to 12.2 percent. A consistent epidemiologic finding in the United States and in other countries is that PTSD is more prevalent in women than in men. Epidemiologic studies of children 9 to 17 years of age have found 3-month prevalence rates of PTSD ranging from 0.5 to 4 percent. An epidemiologic survey of preschoolers aged 4 to 5 years found a rate of 1.3 percent of PTSD.

Among trauma-exposed samples of persons not referred for treatment, a wide range of 25 percent to 90 percent have been reported to exhibit the full diagnosis of PTSD. Children exposed chronically to trauma, such as child abuse, or traumas resulting in a broader disruption of entire communities, such as war, have the greatest risk of developing PTSD. In addition to the staggering rate of the full-blown disorder of PTSD among youth, several studies indicate that most children exposed to severe or chronic trauma develop PTSD symptoms sufficiently severe to disrupt functioning, even in the absence of the full diagnosis.

**ETIOLOGY**

**Biological Factors**

Risk factors in children for developing PTSD include preexisting anxiety disorders and depressive disorders. A prospective study found that among children exposed to traumatic events, those with anxiety disorders and teacher ratings of externalizing behavior problems by the age of 6 years were at increased risk for PTSD. Furthermore, children with an IQ greater than 115 at age 6 years were at lower risk for developing PTSD. In addition, among children exposed to trauma, those who developed PTSD were also at higher risk of developing comorbid disorders such as depression. This suggests that a genetic predisposition for anxiety disorders, as well as a family history indicating increased risk of depressive disorders, may predispose a trauma-exposed child to develop PTSD. Children with PTSD have been found to exhibit increased excretion of adrenergic and dopaminergic metabolites, smaller intracranial volume and corpus callosum, memory deficits, and lower intelligence quotients (IQs) compared with age-matched controls. Adults with PTSD have been found to have an overactive amygdala and decreased hippocampal volume. Whether the above findings are sequelae of PTSD or markers of vulnerability to the disorder remains a focus of investigation.

**Psychological Factors**

Although the exposure to trauma is the initial etiological factor in the development of PTSD, the enduring symptoms typical of PTSD, such as avoidance of the place where the trauma occurred, can be conceptualized, in part, as the result of both classic and operant conditioning. Extreme physiological responses may accompany fear of a given traumatic event, such as an adolescent who was terrorized by an attack by a group of students near school, who then develops an extreme negative physiological reaction each time he or she is near the school. This is an example of classic conditioning in that a neutral cue (the school) has become paired with an intensely fearful past event. Operant conditioning occurs when a child learns to avoid traumatic reminders to prevent distressing feelings from arising. For example, if a child was in a motor vehicle accident, the child may then refuse to ride in cars altogether to prevent negative physiological reactions and fear from occurring.

Another mechanism in developing and maintaining symptoms of PTSD is through modeling, which is a form of learning. For example, when parents and children are exposed to traumatic events, such as natural disasters, children may emulate parental responses, such as avoidance, withdrawal, or extreme expressions of fear, and “learn” to respond to their own memories of the traumatic event in the same manner.

**Social Factors**

Family support and reactions to traumatic events in children may play a significant role in the development of PTSD, in that adverse parental emotional reactions to a child’s abuse may increase that child’s risk of developing PTSD. Lack of parental support and psychopathology among parents—especially maternal depression—have been identified as risk factors in the development of PTSD after a child has been exposed to a traumatic event.

**DIAGNOSIS AND CLINICAL FEATURES**

For PTSD to ensue, exposure to a traumatic event consisting of either a direct personal experience or witnessing an event involving the threat of death, serious injury, or serious harm must occur. Most common traumatic exposures for children and adolescents include physical or sexual abuse; domestic, school or community violence; being kidnapped; terrorist attacks; motor vehicle or household accidents; or disasters, such as floods, hurricanes, tornadoes, fires, explosions, or airline crashes. A child with PTSD experiences either intrusive memories of the event, recurrent frightening dreams, dissociative reactions including flashbacks in which the child feels as if the traumatic event is recurring, or intense psychological distress when exposed to reminders of the trauma (Fig. 31.11b-1).

Symptoms of PTSD include *reexperiencing* the traumatic event in at least one of the following ways. Children may have intrusive thoughts, memories, or images that spontaneously recur, or body sensations that remind them of the event. In very young children, it is common to observe play that includes elements of the traumatic event, or behaviors, such as sexual behaviors that are not developmentally expected. Children may experience periods during which they either act or feel as
It is not uncommon for children and adolescents with PTSD to experience feelings of guilt, especially if they have survived the trauma and others in the situation did not. They may blame themselves for the demise of the others and may go on to develop a comorbid depressive episode. Childhood PTSD is also associated with increased rates of other anxiety disorders, depressive episodes, substance use disorders, and attentional difficulties. DSM-5 includes a specifier With dissociative symptoms, which can present as either Depersonalization, in which there are recurrent experiences of feeling detached, as if outside of one's own body; or Derealization, in which the world feels unreal, dreamlike, and distant. A final specifier, With delayed expression, indicates that the full diagnostic criteria were not met until 6 months after the traumatic event, although some symptoms may present earlier.

**PATHOLOGY AND LABORATORY EXAMINATION**

Although reports indicate some alterations in both neurophysiological and neuroimaging studies of children and adolescents with PTSD, no current laboratory tests can help in making this diagnosis.

**DIFFERENTIAL DIAGNOSIS**

A number of overlapping symptoms are seen between childhood PTSD and presentations of childhood anxiety disorders, such as separation anxiety disorder, obsessive-compulsive disorder (OCD) or social phobia, in which recurrent intrusive thoughts or avoidant behaviors occur. Children with depressive disorders often exhibit withdrawal and a sense of isolation from peers as well as guilt about life events over which they realistically have no control. Irritability, poor concentration, sleep disturbance, and decreased interest in usual activities can also be observed in both PTSD and major depressive disorder.

Children who have lost a loved one in a traumatic event may go on to experience both PTSD and a major depressive disorder when bereavement persists beyond its expected course. Children with PTSD may also be confused with children who have disruptive behavior disorders, because they often show poor concentration, inattention, and irritability. It is critical to elicit a history of traumatic exposure and evaluate the chronology of the trauma and the onset of the symptoms to make an accurate diagnosis of PTSD.

**COURSE AND PROGNOSIS**

For some children and adolescents with milder forms of PTSD, symptoms may persist for one to two years, after which they diminish and attenuate. In more severe circumstances, however, PTSD syndromes persist for many years or decades in children and adolescents, with spontaneous remission in only a portion of them.

The prognosis of untreated PTSD has become an issue of growing concern for researchers and clinicians who have documented a variety of serious comorbidities and psychobiological abnormalities associated with PTSD. In one study, children and adolescents with severe PTSD were at risk for decreased intracranial volume, diminished corpus callosum area, and lower IQs.
compared to children without PTSD. Children and adolescents with histories of physical and sexual abuse have been found to exhibit higher rates of depression and suicidality themselves and in their offspring as well. This highlights the importance of early recognition and treatment of PTSD that may significantly improve the long-term outcome among youth.

**TREATMENT**

**Trauma-Focused Cognitive-Behavior Therapy**

Randomized clinical trials have provided evidence for the efficacy of trauma-focused cognitive-behavior therapy (CBT) in the treatment of PTSD in children and adolescents. This treatment is generally administered over 10 to 16 treatment sessions, including nine components itemized in the acronym PRAC-TICE. Trauma-focused CBT as detailed by Cohen, Mannarino, and Deblinger in their text *Treating Trauma and Traumatic Grief in Children and Adolescents* entails the inclusion of gradual exposure to feared stimuli as a critical element. Such stimuli encompass places, people, sounds, and situations. The first component of trauma-focused CBT is *psychoeducation* regarding the nature of typical emotional and physiological reactions to traumatic events and PTSD. Next, *Parenting Skills* involve sessions focused on guiding parents in understanding how to deal with past or current situations. As with SPARCS treatment, gradual exposure to traumatic memories through a narrative, in vivo exposure, and affect modulation, cognitive restructuring, and social problem solving. In one randomized controlled trial, 86% of students in the CBITS group reported significantly decreased PTSD symptoms compared to the waitlist controls. Students who received CBITS also reported lower depression scores. Among parents whose children received CBITS treatment, 78% reported decreased psychosocial problems in their children. After CBITS treatment, the improvements in both the PTSD and depression symptoms were sustained at 6 months.

**Structured Psychotherapy for Adolescents Responding to Chronic Stress (SPARCS)**

SPARCS consists of a group intervention, generally administered in 16 sessions, with a focus on the needs of adolescents between the ages of 12 and 19 years who have lived with chronic trauma and may also carry a diagnosis of PTSD. SPARCS was tested in a trial of multicultural teens and young adults with moderate or severe trauma exposure. Most of the participants were female, and comprised multiple ethnic groups: 67% African American; 12% Latino; 21% Caucasian. SPARCS demonstrated efficacy in reducing traumatic stress symptoms, mainly in the largest group, the African American group. SPARCS utilizes cognitive behavioral techniques, and also incorporates many of the components of TF-CBT. In addition, SPARCS includes mindfulness techniques and relaxation.

**Trauma Affect Regulation: Guide for Education and Therapy (TARGET)**

TARGET, an affect regulation therapy, combines CBT components, such as cognitive processing, with affect modulation. It is administered to adolescents between the ages of 13 and 19 who have been exposed to maltreatment and/or chronic traumatic exposure to such things as community violence or domestic violence. It is generally administered in 12 sessions, which focus on past or current situations. As with SPARCS treatment, gradual exposure may occur in the context of recounting past trauma but is not a core component of the treatment. A randomized trial with 59 delinquent girls aged 13 to 17 years who met full or partial criteria for PTSD found that TARGET reduced anxiety, anger, depression, and PTSD cognitions. TARGET is a promising treatment for girls with histories of delinquency, especially to reduce anger and to enhance optimism and self-efficacy.

**Crisis Intervention/Psychological Debriefing**

Crisis intervention/psychological debriefing typically consists of several sessions immediately after an exposure to a traumatic...
event in which a traumatized child or adolescent is encouraged to describe the traumatic event in the context of a supportive environment. Psychoeducation is provided and guidance about the management of initial emotional reactions may be provided. Ancedotal reports suggest that this intervention may be helpful, but no controlled studies have yet provided evidence that this intervention leads to a more positive outcome.

**Psychopharmacological Treatment**

Several pharmacologic agents have been utilized to treat children and adolescents with PTSD, often focused on diminishing intrusive thoughts, hyperarousal, and avoidance, with some success and mixed results. Given the frequent comorbidity of depressive disorder, anxiety disorders, and behavioral problems associated with PTSD, a multitude of psychopharmacological agents have been utilized to ameliorate symptoms associated with PTSD in youth. Antidepressant agents have been used as adjuncts to psychosocial treatments in youth with PTSD. Despite the fact that sertraline and paroxetine are approved by the Food and Drug Administration (FDA) in the treatment of PTSD in adults, there is scant evidence to support its use for the core symptoms of PTSD in youth. A randomized controlled trial of TF-CBT plus sertraline compared to TF-CBT plus placebo in 24 children with PTSD found that both groups had significant reduction in PTSD symptoms, with no significant difference between the groups. A multicenter study of 131 children aged 6 to 17 years with PTSD were treated with 10 weeks of sertraline or placebo. Results showed sertraline to be a safe treatment; however, it was not demonstrated to have efficacy compared to placebo. A randomized controlled trial using citalopram did not show superiority of citalopram over placebo in treatment of core PTSD symptoms. There is, however, evidence suggesting that the use of selective serotonin reuptake inhibitors (SSRIs) in traumatized children with burns may be preventive regarding the development of PTSD. Published literature demonstrates that up to 50 percent of children with moderate to severe burns develop PTSD, thus preventive strategies are important. A randomized controlled study of sertraline to prevent PTSD found that children who received sertraline, flexibly dosed between 25 mg and 150 mg per day, had a decrease in parent-reported symptoms of PTSD over 8 weeks compared to a placebo group. Among the child-reported symptoms, however, there was no significant difference between the two groups.

Antiadrenergic agents have been tried to treat dysregulation of the noradrenergic system in adults and youth with PTSD. α-2-agonists such as clonidine and guanfacine, for example, have been used to decrease norepinephrine release, whereas centrally acting β-agonists such as propranolol, and α-1-agonists such as prazosin, are hypothesized to improve hyperarousal and intrusive thoughts through attenuation of norepinephrine postsynaptically. In adults, clonidine (Catapres) and propranolol (Inderal) have been used to treat PTSD, especially nightmares and exaggerated startle response, with evidence of improvement. Although there are some data in adults with PTSD to support the use of these agents, data in youth are limited largely to case reports. There is a suggestion that guanfacine may reduce nightmares in children with PTSD and that clonidine may diminish symptoms of reenactment of traumatic events in children. One report of propranolol treatment in 11 pediatric patients with PTSD from sexual or physical abuse with a mean age of 8.5 years, who exhibited agitation and hyperarousal, indicated some decrease in symptoms in 8 of the 11 children studied. Another open study of transdermal clonidine treatment of preschoolers with PTSD suggests that clonidine may be efficacious in this population in decreasing activation and hyperarousal. An additional open trial of oral clonidine with dosage ranges of 0.05 to 0.1 mg twice daily similarly suggests that this medication may provide some relief for the symptoms of hyperarousal, impulsivity, and agitation in young children with PTSD.

Second-generation antipsychotics such as risperidone, olanzapine, quetiapine, ziprasidone, and aripiprazole have been studied in adults with PTSD with mixed results. Risperidone and aripiprazole have both been given FDA approval for use in children and adolescents with aggression, severe behavioral dyscontrol, and severe psychiatric disorders, however, controlled trials have not been done with children with PTSD. A report of three preschool-aged children who exhibited symptoms of acute stress disorder and who had severe thermal burns were reported to improve after being treated with risperidone.

Mood-stabilizing agents including divalproex, carbamazepine, topiramate, and gabapentin have been utilized for adults with PTSD with modest improvement. In children and adolescents with PTSD, one open-label trial of carbamazepine and one trial of divalproex have been undertaken. In the carbamazepine trial, all 28 patients were reported to be either asymptomatic or improved at blood levels of the agent of 10 to 11.5 micrograms/mL. In the divalproex trial, 12 males who carried diagnoses of conduct disorder comorbid with PTSD were randomly assigned to high- or low-dose divalproex with reported improvement in those receiving the higher doses. Benzodiazepines are often prescribed to treat anxiety symptoms in patients with PTSD, although there are no controlled trials to support their use in youth with PTSD at this time.

Given that many children and adolescents with PTSD have comorbid depressive and anxiety disorders, SSRIs are recommended in the treatment of these coexisting disorders.

**References**

Mood disorders in children and adolescents have been studied increasingly over the last two decades, culminating in large sample multisite randomized controlled trials such as the Treatment of Adolescent Depression (TADS) study, which provides evidence of the efficacy of both cognitive-behavioral therapy as well as selective serotonin reuptake inhibitors (SSRIs). Furthermore, when the preceding modalities are combined, the greatest efficacy is achieved. Increased recognition of depressive disorders in preschool populations has sparked clinicians and researchers to develop psychosocial interventions such as the Parent-Child Interaction Therapy Emotion Development (PCIT-ED), which target treatment specifically for this age group. The expression of disturbed and depressed mood appears to vary with developmental stage. Very young children with major depression are often observed to be sad, listless, or apathetic, even though they may not articulate these feelings verbally. Perhaps surprisingly, mood-congruent auditory hallucinations are not infrequently observed in young children with major depression. Somatic complaints such as headaches and stomachaches, withdrawn and sad appearance, and poor self-esteem are more universal symptoms. Patients in late adolescence with more severe forms of depression often display pervasive anhedonia, severe psychomotor retardation, delusions, and a sense of hopelessness. Symptoms that appear with the same frequency, regardless of age and developmental status, include suicidal ideation, depressed or irritable mood, insomnia, and diminished ability to concentrate.

Developmental issues, however, influence the expression of depressive symptoms. For example, unhappy young children who exhibit recurrent suicidal ideation are rarely able to propose a realistic suicide plan or to carry out such a plan. Children’s moods are especially vulnerable to the influences of severe social stressors, such as chronic family discord, abuse and neglect, and academic failure. Many young children with major depressive disorder have histories of abuse, neglect, and families with significant psychosocial burdens such as parental mental illness, substance abuse, or poverty. Children who develop depressive disorders in the midst of acute toxic family stressors may have remission of depressive symptoms when the stressors diminish or when a more nurturing family environment is introduced. Depressive disorders are generally episodic, albeit typically lasting close to a year; however, their onset may be insidious and remain unidentified until significant impairment in peer relationships, deterioration in academic function, or withdrawal from activities emerges. Attention-deficit/hyperactivity disorder (ADHD), oppositional defiant disorder, and conduct disorder are not infrequently comorbid with a major depressive episode. In some cases, conduct disturbances or disorders occur in the context of a major depressive episode and resolve with the resolution of the depressive episode. Clinicians must clarify the chronology of the symptoms to determine whether a given behavior (e.g., poor concentration, defiance, or temper tantrums) was present before the depressive episode and is unrelated to it or whether the behavior is occurring for the first time and is related to the depressive episode.

# 31.12 Mood Disorders and Suicide in Children and Adolescents

## 31.12a Depressive Disorders and Suicide in Children and Adolescents

Depressive disorders in youth represent a significant public health concern, in that they are prevalent and result in long-term adverse effects on the individual’s cognitive, social, and psychological development. These disorders affect approximately 2 to 3 percent of children and up to 8 percent of adolescents, so the need for early identification and access to evidence-based interventions such as cognitive-behavioral therapies (CBTs) and antidepressant agents, is essential. Although major depression runs in families, with the highest risk in children whose parents experienced early onset depression, twin studies have demonstrated that major depression is only moderately heritable, approximately 40 to 50%, highlighting environmental stressors and adverse events as major contributors to major depressive disorder in youth. The core features of major depression in children, adolescents, and adults bear a striking resemblance; however, clinical presentation is strongly influenced by the developmental level of the child or adolescent. The American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) utilizes the same criteria for major depressive disorder in youth as in adults, except that for children and adolescents, irritable mood may replace a depressed mood in the diagnostic criteria.

Most children and adolescents with depressive disorders neither attempt nor complete suicide; however, severely depressed youth often have suicidal ideation, and suicide remains the most serious risk of major depression. Nevertheless, many depressed youth do not ever have suicidal ideation, and many children and adolescents who engage in suicidal behavior do not have a depressive disorder. There is epidemiological evidence to suggest that depressed youth with recurrent active suicidal ideation, including a plan, and who have made prior attempts, are at higher risk to complete suicide, compared to youth who express only passive suicidal ideation.

Epidemiology

Depressive disorders increase in frequency with increasing age in the general population. Mood disorders among preschool-age
children are estimated to occur in about 0.3 percent of community samples, and 0.9 percent in clinic settings. The prevalence of major depression in school-age children is 2 to 3 percent. Depression in referred samples of school-age children is found to be the same frequency in boys as in girls, with some surveys indicating a slightly increased rate among boys. In adolescents, prevalence rate of major depression is from 4 to 8 percent and two to three times more likely in females than males. By age 18 years, the cumulative incidence of major depression is 20 percent. Children with a family history of major depression in a first-degree relative are about three times more likely to develop the disorder than in those without family histories of affective disorders. The prevalence of persistent depressive disorder in children ranges from 0.6 to 4.6 percent and in adolescence increases to 1.6 to 8 percent. Children and adolescents with persistent depressive disorder have a high likelihood of developing major depressive disorder at some point after 1 year of the persistent depressive disorder. The rate of developing a major depression on top of persistent depressive disorder (double depression) within a 6-month period of persistent depressive disorder is estimated to be about 9.9 percent.

Among psychiatrically hospitalized children and adolescents, the rates of major depressive disorder have been estimated to be close to 20 percent for children and 40 percent for adolescents.

ETIOLOGY

Considerable evidence indicates that major depression in youth is the same fundamental disorder experienced by adults, and that its neurobiology is likely to be an interaction of genetic vulnerability and environmental stressors.

Genetic Studies

Converging evidence suggests that an interaction between genetic susceptibility and environmental stressors contributes to an emerging major depression and is associated with brain volume, especially in the hippocampal region. The serotonin transporter gene and, in particular, the serotonin transporter polymorphism (5-HTTLPR) have become a focus of investigation. Patients with the short S-allele of the serotonin polymorphism who also experienced a significant environmental adverse event such as neglect, developed smaller hippocampal volumes compared to patients with only one of the above risk factors. The S-allele of the polymorphism leads to decreased serotonin (5-HT) reuptake and thus potentially to decreased uptake of serotonin into the brain. A large longitudinal study in New Zealand found that the S-allele of the serotonin transporter gene was associated with early environmental stress and subsequent depression. This study demonstrated a relationship between early environmental stress and subsequent depression in children with one or two short alleles, but not in children with two long alleles. Because the short alleles are less efficient in transcription, this finding suggests that the availability of the transporter gene may provide a marker for vulnerability to depression. The findings that the combination of a decreased volume in the hippocampus is associated with the S-allele of the serotonin transporter gene polymorphism and early adverse events in depression, may represent a mechanism by which the risk of major depression is mediated by both genetics and environmental stressors.

Familiality

Twin studies have demonstrated that major depression is approximately 40 to 50 percent heritable. There is an increased risk of depression in the children of parents with the disorder, and this risk is further increased for the child when the parents developed depressive disorders at an early age. Studies suggest age-related differences in the heritability of major depression such that in younger children, environmental influences appear to be more dominant and in first episodes in adolescence, heritability may play a larger role. Family studies suggest that for children with a parent with a history of major depressive disorder, the risk of developing an episode of major depressive disorder is doubled, whereas with two depressed parents, the risk of an episode of major depressive disorder quadruples in the offspring before age 18 years. Similarly, children with the largest number of severe episodes starting at younger ages exhibit the densest family histories of major depressive disorder.

Neurobiology

Neuroendocrine studies have examined the hypothalamic-pituitary-adrenal axis, the hypothalamic growth hormone, the hypothalamic-pituitary-thyroid, and the hypothalamic-pituitary-gonadal axes, seeking to demonstrate consistent markers in depressed youth. These studies have yielded inconsistent results. For example, depressed prepubertal children secrete significantly more growth hormone during sleep than nondepressed children or youth with other psychiatric disorders. In addition, depressed children secrete significantly less growth hormone in response to insulin-induced hypoglycemia than do nondepressed patients. Both findings appear to persist for months after partial or full remission. Thyroid hormone studies have found lower free total thyroxine (FT₄) levels in depressed adolescents than in a matched control group. These values were associated with normal thyroid-stimulating hormone (TSH). This finding suggests that, although values of thyroid function remain in the normative range, FT₃ levels have shifted downward. These downward shifts in thyroid hormone possibly contribute to the clinical manifestations of depression.

Sleep studies are also inconclusive in depressed children and adolescents. Polysomnography in depressed children have only occasionally shown characteristic sleep markers of adults with major depressive disorder: reduced rapid eye movement (REM) latency and an increased number of REM periods.

Magnetic Resonance Imaging

Neuroimaging studies of depressed youth demonstrate smaller frontal white matter volumes, larger frontal gray matter volumes, and larger lateral ventricle volumes. Depressed youth have been found to have a blunted amygdala response to fearful faces compared to non-depressed children and depressed children have been found to have smaller amygdala volumes compared to healthy controls.

Because twin studies and adoption studies have demonstrated that depression appears to be only 40 to 50 percent
heritable, with environmental contributions more predominant in younger children, family and environmental contributions must be examined. Adverse events during childhood such as maltreatment, abuse or neglect, parental death, parental psychiatric illness, substance abuse, parent–child conflict, and lack of family cohesion are all risk factors for childhood depression. Data from twin and genetic studies support the conclusion that the interaction of genetic and environmental factors plays a critical role in depressive disorders, since correlation of adverse life events and depression is stronger in children and adolescents with known genetic susceptibility. Once a child or adolescent has experienced one major depressive episode, the psychosocial “scars” increase his or her vulnerability for a subsequent episode. The psychosocial impairments in depressed children remain far after recovery from the episode. Among depressed preschoolers, the sooner that adverse life events promoting the depression are identified, the more rapidly interventions may be administered to treat the depression.

**DIAGNOSIS AND CLINICAL FEATURES**

**Major Depressive Disorder**

Major depressive disorder in children is diagnosed most easily when it is acute and occurs in a child without previous psychiatric symptoms. Often, however, the onset is insidious, and the disorder occurs in a child who has had several years of difficulties with hyperactivity, separation anxiety disorder, or intermittent depressive symptoms.

According to the DSM-5, diagnostic criteria for a major depressive episode consist of at least five symptoms, for a period of 2 weeks, including either (1) depressed or irritable mood, or (2) a loss of interest or pleasure. Additional symptoms may include failure to make expected weight gains, daily insomnia or hypersomnia, psychomotor agitation or retardation, daily fatigue or loss of energy, feelings of worthlessness or inappropriate guilt, diminished ability to think or concentrate, and recurrent thoughts of death. These symptoms must produce social or academic impairment. To meet the diagnostic criteria for major depressive disorder, the symptoms cannot be due to the direct effects of a substance (e.g., alcohol) or a general medical condition. In contrast to the **Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)**, in which a diagnosis of major depressive disorder was not made within 2 months of the loss of a loved one, except when marked functional impairment, morbid preoccupation with worthlessness, suicidal ideation, psychotic symptoms, or psychomotor retardation was present, in DSM-5, a diagnosis of major depressive disorder can be made at any time following a loss, even without the preceding symptoms. This change reflects the understanding that grief typically lasts 1 to 2 years, rather than 2 months, and that major depressive disorder may occur in the presence of grief at any time after a loss.

A major depressive episode in a prepubertal child is likely to be manifest by somatic complaints, psychomotor agitation, and mood-congruent hallucinations. Anhedonia is also frequent, but anhedonia, as well as hopelessness, psychomotor retardation, and delusions, are more common in adolescent and adult major depressive episodes than in those of young children. Adults have more problems than depressed children and adolescents with sleep and appetite. In adolescence, negativistic or frankly antisocial behavior and the use of alcohol or illicit substances can occur and may justify the additional diagnoses of oppositional defiant disorder, conduct disorder, and substance abuse or dependence. Feelings of restlessness, irritability, aggression, reluctance to cooperate in family ventures, withdrawal from social activities, and isolation from peers often occur in adolescents. School difficulties are likely. Depressed adolescents may become less attentive to personal appearance and show increased sensitivity to rejection by peers, and in romantic relationships.

Children can be reliable reporters about their emotions, relationships, and difficulties in psychosocial functions. They may, however, refer to depressive feelings in terms of anger, or feeling "mad" rather than sad. Clinicians should assess the duration and periodicity of the depressive mood to differentiate relatively universal, short-lived, and sometimes frequent periods of sadness, usually after a frustrating event, from a true, persistent depressive mood. The younger the child, the more imprecise his or her time estimates are likely to be.

Mood disorders tend to be chronic if they begin early. Childhood onset may be the most severe form of mood disorder and tends to appear in families with a high incidence of mood disorders and alcohol abuse. The children are likely to have such secondary complications as conduct disorder, alcohol and other substance abuse, and antisocial behavior. Functional impairment associated with a depressive disorder in childhood extends to practically all areas of a child's psychosocial world; school performance and behavior, peer relationships, and family relationships all suffer. Only highly intelligent and academically oriented children with no more than a moderate depression can compensate for their difficulties in learning by substantially increasing their time and effort. Otherwise, school performance is invariably affected by a combination of difficulty concentrating, slowed thinking, lack of interest and motivation, fatigue, sleepiness, depressive ruminations, and preoccupations. Depression in a child may be misdiagnosed as a learning disorder. Learning problems secondary to depression, even when long-standing, are corrected rapidly after a child's recovery from the depressive episode.

Children and adolescents with severe forms of major depressive disorder may have hallucinations and/or delusions. Usually, these psychotic symptoms are thematically consistent with the depressed mood, occur with the depressive episode (usually at its worst), and do not include certain types of hallucinations (such as conversing voices and a commenting voice, which are specific to schizophrenia). Depressive hallucinations usually consist of a single voice speaking to the person from outside his or her head, with derogatory or suicidal content. Depressive delusions center on themes of guilt, physical disease, death, nihilism, deserved punishment, personal inadequacy, and (sometimes) persecution. These delusions are rare in prepuberty, probably because of cognitive immaturity, but are present in about half of psychotically depressed adolescents.

Adolescent onset of a mood disorder can be complicated by use of alcohol or drugs. One study found that up to 17 percent of adolescents with depressive disorder received an initial evaluation due to substance abuse.
Persistent Depressive Disorder (Dysthymia)

Persistent depressive disorder, in DSM-5, represents a consolidation of chronic major depressive disorder and what DSM-IV-TR termed dysthymic disorder. In children and adolescents it consists of a depressed or irritable mood for most of the day, for more days than not, over a period of at least 1 year. DSM-5 notes that in children and adolescents, irritable mood can replace the depressed mood criterion for adults and that the duration criterion is not 2 years but 1 year for children and adolescents. According to the DSM-5 diagnostic criteria, two or more of the following symptoms must accompany the depressed or irritable mood: low self-esteem, hopelessness, poor appetite or overeating, insomnia or hypersomnia, low energy or fatigue, or poor concentration or difficulty making decisions. During the year of the disturbance, these symptoms do not resolve for more than 2 months at a time. In addition, the diagnostic criteria for dysthymic disorder specify that during the first year, no major depressive episode emerges. To meet the DSM-5 diagnostic criteria for persistent depressive disorder, a child must not have a history of a manic or hypomanic episode. Persistent depressive disorder is also not diagnosed if the symptoms occur exclusively during a chronic psychotic disorder or if they are the direct effects of a substance or a general medical condition. DSM-5 provides specifiers for early onset (before 21 years of age) or late onset (after 21 years of age).

A child or adolescent with persistent depressive disorder may have had a major depressive episode before developing persistent depressive disorder; however, it is much more common for a child with persistent depressive disorder for more than 1 year to develop a concurrent episode of major depressive disorder. In this case, both depressive diagnoses apply (double depression). Persistent depressive disorder in youth is known to have an average age of onset that is several years earlier than the typical onset of major depressive disorder. Occasionally, youth fulfill the criteria for persistent depressive disorder, except that their episode does not last for a whole year, or they experience remission from symptoms for more than a 2-month period. These mood presentations in youth may predict additional mood disorder episodes in the future. Current knowledge suggests that the longer, more recurrent, and less directly related to social stress these episodes are, the greater the likelihood of future severe mood disorder. When minor depressive episodes follow a significant stressful life event by less than 3 months, it may be classified as an adjustment disorder.

Cyclothymic Disorder

Cyclothymia is a chronic and fluctuating mood disturbance of hypomanic symptoms and periods of depressive symptoms that do not meet diagnostic criteria for major depressive disorder. The difference in the DSM-5 diagnostic criteria for youth with cyclothymic disorder compared to adults is that a period of 1 year, rather than 2 years, of numerous mood swings is applied. Bipolar II disorder is distinguished from cyclothymia by a history of episodes of major depressive disorder. When an episode of major depressive disorder occurs after a diagnosis of cyclothymia has been present for at least 2 years, a concurrent diagnosis of Bipolar II disorder is made.

Bereavement

Bereavement is a state of grief related to the death of a loved one, which presents with an overlap of symptoms characteristic of a major depressive episode. Typical depressive symptoms associated with bereavement include feelings of sadness, insomnia, diminished appetite, and, in some cases, weight loss. Grieving children may become withdrawn and appear sad, and they are not easily drawn into even favorite activities.

In DSM-5, bereavement is not a mental disorder; however, uncomplicated bereavement is included as a category documented with a v code, indicating that a normal grief reaction to the loss of a loved one has become a focus of clinical attention. Children in the midst of a typical bereavement period may also meet the criteria for major depressive disorder. Symptoms indicating major depressive disorder exceeding typical bereavement include intense guilt related to issues beyond those surrounding the death of the loved one, preoccupation with death other than thoughts about being dead to be with the deceased person, morbid preoccupation with worthlessness, marked psychomotor retardation, prolonged serious functional impairment, and hallucinations other than transient perceptions of the voice of the deceased person.

The duration of bereavement varies; in children, the duration may depend partly on the support system in place. For example, a child who must be removed from home because of the death of the only parent in the home may feel devastated and abandoned for a long period. Children who lose loved ones may feel a sense of guilt, that the death may have occurred because they were “bad” or did not perform as expected.

Ryan was a 12-year-old 7th grader in middle school who was brought to the emergency room in handcuffs by police after walking into oncoming traffic right after school. Ryan walked in front of a city bus; the driver began honking at the boy who kept walking slowly into the traffic. Two police stationed in their car across the street from the school heard the bus honking and noticed Ryan and confronted him. The police were about to issue the boy a citation for crossing against the red light; however, when they inquired as to why he had crossed against the traffic light he informed them that he was trying to kill himself. The police handcuffed Ryan, placed him in the police car without a struggle and brought him to the local hospital’s emergency room. Ryan’s mother was contacted and met her son in the emergency room. Ryan was found to be physically intact, without injury, by the emergency room doctors, and psychiatric evaluation was initiated by a team of child psychiatrists including an attending child psychiatrist and two child and adolescent psychiatry residents. Ryan became tearful when asked what had happened, and reported that he had purposefully walked in front of the bus in the hope of being hit by the bus in order to die. Ryan reported that he has been bullied by numerous peers over the last 2 years and is picked on because he is short and overweight. Ryan reported that on this day, a girl in his class had pushed him down and started hitting him and laughing at him. Ryan reported that he had been teased and physically assaulted repeatedly by peers in his grade and that they call him stupid and fat. Ryan has some friends, who usually defend him, but on this day, his friends were not close by and he became desperate. Ryan disclosed, however, that even before this day, he has been consistently sad in school for the past year, and that he has thought about suicide recurrently over the last year, mainly due to feeling ostracized and worthless after being picked on and
bullied. Ryan continues to be actively suicidal, disclosing his strong feeling that for him, life is not worth living. Ryan is a relatively good student, earning good grades, especially in math, although he is currently failing history. Upon separate interview with Ryan's mother, she reports that she has no knowledge of any problems that Ryan has been struggling with, and that she feels that Ryan is not depressed, not severely bullied, or seriously unhappy in school, and reports that this must have been a mistake and that she is ready to take him home. Ryan reported that he had previously seen a counselor in school a few times last year when he was bullied, but that he has received no intervention for his depression or his suicidality and that he has not shared these feeling with his family and that he is generally content at home. Ryan has an older brother and a younger brother who are well adjusted. When Ryan and his mother were interviewed together, Ryan was able with some encouragement to let his mother know how depressed, hopeless, and suicidal he feels, and why. Ryan's mother burst into tears and Ryan tried to comfort his mother, although he was crying as well. Ryan was placed on a 72-hour hold for "danger to self," and referred to a children's psychiatric inpatient unit for further evaluation and treatment. A trial of an SSRI antidepressant was recommended as well as psychoeducation and family sessions so that Ryan and his family would reach an understanding about his current psychiatric disorder, and that together they could work on a safe and productive plan for Ryan. Ongoing psychosocial intervention was recommended for Ryan and his family after hospitalization.

PATHOLOGY AND LABORATORY EXAMINATION

No laboratory test is useful in making a diagnosis of a major depression. If a child or adolescent also complains of symptoms of hypothyroidism, that is, dry skin, coldness, lethargy, and so on, then a screening test for thyroid function may be indicated.

Rating scales for depressive symptoms administered by the clinician to the child and parent may be helpful in the evaluation. The Children's Depression Rating Scale-Revised (CDRS-R) is a 17-item instrument administered by the clinician separately to the parent and child or adolescent. The clinician scores a rating for each item using the information from both the parent and the child. The scale assesses affective, somatic, cognitive, and psychomotor symptoms. A cumulative score of 40 is a marker for moderate depression and a score of 45 or greater for significant depression.

DIFFERENTIAL DIAGNOSIS

Substance-induced mood disorder may be difficult to differentiate from other mood disorders until detoxification occurs. Anxiety symptoms and disorders often coexist with depressive disorders. Of particular importance in the differential diagnosis is the distinction between agitated depressive or manic episodes and ADHD, in which the persistent excessive activity and restlessness can cause confusion. Prepubertal children generally do not show classic forms of agitated depression, such as hand-wringing and pacing. Instead, an inability to sit still, irritability, and frequent temper tantrums are the most common symptoms. Sometimes, the correct diagnosis becomes evident only after remission of the depressive episode.

COURSE AND PROGNOSIS

The course and prognosis of major depression in children and adolescents depends on the severity of illness, the rapidity of interventions, and the degree of response to the interventions. In general, 90 percent of youth recover from a first episode of moderate to severe major depressive disorder within 1 to 2 years. The age of onset, episode severity, and the presence of comorbid disorders also influence course and prognosis. In general, the younger the age of onset, the greater the recurrence of multiple episodes, and the presence of comorbid disorders predict a poorer prognosis. The mean length of an untreated episode of major depression in children and adolescents is about 8 to 12 months; the cumulative probability of recurrence is 20 to 60 percent within 2 years and 70 percent by 5 years. The greatest risk for relapse is in the 6 months to 1 year after treatment is discontinued. Depressed children who live in families with high levels of chronic conflict are more likely to have relapses. The relapse rates for childhood major depression into adulthood are also high. In a community sample, 45 percent of adolescents with a history of major depression developed another episode of major depression in early adulthood.

Youth with major depression are at higher risk for the development of future bipolar disorder, compared to adults. Overall estimates of children with an episode of major depression developing bipolar disorder are about 20 to 40 percent. Clinical characteristics of a depressive episode in youth, suggesting the highest risk of developing bipolar I disorder include hallucinations and delusions, psychomotor retardation, and a family history of bipolar illness. In a longitudinal study of prepubertal children with major depression, 33 percent developed bipolar I disorder, whereas 48 percent went on to develop bipolar II or bipolar disorder not otherwise specified by early adulthood.

Depressive disorders are associated with short-term and long-term peer relationship difficulties and complications, compromised academic achievement, and persistently low self-esteem. Persistent depressive disorder has an even more protracted recovery than major depressive disorder; the mean episode length is about 4 years. Early onset persistent depressive disorder is associated with significant risks of comorbidity with major depressive disorder (70 percent), bipolar disorder (13 percent), and future substance abuse (15 percent). The risk of suicide, which accounts for about 12 percent of adolescent mortalities, is significant among adolescents with depressive disorders.

TREATMENT

The American Academy of Child and Adolescent Psychiatry practice parameters, as well as a consensus of experts who developed the Texas Children's Medication Algorithm Project (TMAP) made evidence-based recommendations for the treatment of children and adolescents with depressive disorders. These include psychoeducation and supportive interventions for youth with mild forms of depression. For youth with moderate to severe depression or recurrent episodes of major depression, with significant impairment and with active suicidal thoughts or behaviors, or psychosis, optimal intervention includes both psychopharmacological and CBT. CBT or interpersonal therapy (IPT) alone may be effective for moderate depression, especially when treatment is continued for 6 months or longer.
Psychiatric Hospitalization

Assessment of suicidal thoughts, behaviors, and past history of suicidal behavior is indicated in evaluating every child or adolescent with major depression. Safety is the most immediate consideration in assessing depression in youth, that is, a determination as to whether immediate psychiatric hospitalization is necessary. Depressed children and adolescents who express suicidal thoughts or behaviors most often require some extended evaluation in the safety of the psychiatric hospital to provide maximal protection from self-destructive impulses and behaviors.

EVIDENCE-BASED TREATMENT STUDIES

The Treatment for Adolescents with Depression Study (TADS) divided 439 adolescents between 12 years and 17 years of age into three treatment groups of 12 weeks, composed of either fluoxetine (Prozac) alone (10 to 40 mg per day), fluoxetine with the same dose range in combination with CBT, or CBT alone. Based on ratings of the Children's Depression Rating Scale-Revised (CDRS-R) combination treatment had significantly superior response rates compared with either treatment alone. Based on CGI scores, at 12 weeks, rates of much or very much improved were 71 percent for the combined treatment group, 60.6 percent for the fluoxetine group, and 43.2 percent for the CBT alone group; and 34.4 percent for the placebo group. At 12 weeks, combination treatment was rated the optimal strategy in the treatment of adolescent depression. By the end of 9 months of treatment, however, response rates for each group had converged so that response for the combination group was 86 percent, fluoxetine group response was about 81 percent, and CBT-alone group response rate was 81 percent. The long-term effectiveness of treatments for adolescent depression demonstrates that for moderately ill adolescents, fluoxetine, CBT, or the combination is efficacious. However, the addition of CBT to fluoxetine decreased persistent suicidal ideation and potential treatment-related emergence of suicidal ideation.

A second large multicenter randomized placebo controlled trial, Treatment of SSRI-Resistant Depression in Adolescents (TORDIA), included adolescents with major depression, who had not responded to a 2-month trial with an SSRI antidepressant. In this study, 334 adolescents between 12 and 18 years of age were randomly assigned to a different SSRI agent (either citalopram, paroxetine, citalopram, or another antidepressant class, venlafaxine) with or without concurrent CBT. The SSRI plus CBT group and the venlafaxine plus CBT group had higher response rates of improvement (54.8 percent) than the group on medications alone (40.5 percent). There were no differences found in the response rates between antidepressant agents.

Psychosocial Interventions

CBT is widely recognized as an efficacious intervention for the treatment of moderately severe depression in children and adolescents. CBT aims to challenge maladaptive beliefs and enhance problem-solving abilities and social competence. A review of controlled cognitive-behavioral studies in children and adolescents revealed that, as with adults, both children and adolescents showed consistent improvement with these methods. Other "active" treatments, including relaxation techniques, were also shown to be helpful as adjunctive treatment for mild to moderate depression. Findings from one large controlled study comparing cognitive-behavioral interventions with non-directive supportive psychotherapy and systemic behavioral family therapy showed that 70 percent of adolescents had some improvement with each of the interventions; cognitive-behavioral intervention had the most rapid effect. Another controlled study comparing a brief course of CBT with relaxation therapy favored the cognitive-behavioral intervention. At a 3- to 6-month follow-up, however, no significant differences existed between the two treatment groups. This effect resulted from relapse in the cognitive-behavioral group, along with continued recovery in some patients in the relaxation group. Factors that seem to interfere with treatment responsiveness include the presence of comorbid anxiety disorder that probably was present before the depressive episode. It has been shown, however, that longer term CBT is efficacious in the treatment of depression, and has the advantage of mitigating suicidal ideation.

Interpersonal psychotherapy (IPT) focuses on improving depression through a focus on ways in which depression interferes with interpersonal relationships and overcoming these challenges. The four main areas of focus with interpersonal psychotherapy include loss, interpersonal disputes, role transition, and interpersonal deficits. A modification of interpersonal therapy to more specifically address depression for adolescents (IPT-A) includes a focus on separation from parents, authority figures, peer pressures, and dyadic relationships. IPT-A has been studied on an outpatient basis as well as in a school-based clinic setting. A 12-week study of 48 adolescents with major depression randomly assigned to IPT-A or clinical monitoring found that the group receiving IPT-A showed decreased depressive symptoms, increased social functioning, and improved problem solving compared to the other group. In the school-based health clinic, depressed adolescents were randomly assigned to IPT-A or treatment as usual for a period of 16 weeks. Clinic staff were trained and administered the treatment. At the end of 16 weeks, those adolescents receiving IPT-A had greater symptom reduction and improved overall functioning; especially older and more severely depressed adolescents seemed to benefit most significantly.

Parent-Child Interaction Therapy Emotion Development (PCIT-ED) for preschool depression, a modification of Parent-Child Interaction Therapy (PCIT) historically used in the treatment of disruptive disorders for children, was piloted in a randomized controlled trial for 54 depressed preschoolers. Fifty-four depressed young children from age 3 to 7 years were randomly assigned to either PCIT-ED or psych-education with their caregivers. PCIT-ED was manualized and consists of three modules conducted over 14 sessions in 12 weeks. The core modules of PCIT—Child-Directed Interaction (CDI) and Parent-Directed Interaction (PDI)—were utilized and limited to four sessions each. The focus of these modules is to strengthen the parent–child relationship by coaching parents in positive play techniques, giving effective directives to the child, and responding to disruptive behavior in firm but not punitive ways. The novel portion of the treatment targeting the preschool depression consisted of a 6-week Emotion Development (ED) module, which focused on helping the parent to be a more effective emotion guide and affect regulator for the child. As part of the
ED module, the parent learned to accurately recognize his or her own emotions as well as the child's and serves to help regulate the child's emotions. A psychoeducation control condition, Developmental Education and Parenting Intervention (DEPI) was developed and administered to parents in small group sessions. The DEPI condition was designed to educate parents about child development and emphasized emotional and social development without individual coaching or practice with behavioral techniques as provided in the PCIT-ED group. Primary outcome measures included parent's report of the child's symptoms of depression using a structured instrument, the Preschool Age Psychiatric Assessment (PAPA), and depression severity was measured pretreatment and posttreatment using parent ratings on the Preschool Reelings Checklist Scale Version (PFC-S) a 20-item checklist. Results revealed that both groups showed significant improvement with particular improvement in the PCIT-ED group with respect to emotion recognition, child executive functioning, and parenting stress. This pilot study indicates that PCIT-ED is a promising novel intervention for preschool depression that deserves further investigation.

Pharmacotherapy

Fluoxetine (Prozac) and escitalopram (Lexapro) have Food and Drug Administration (FDA) approval in the treatment of major depression in adolescents. Three randomized controlled trials (RCTs) using fluoxetine with depressed children and adolescents demonstrate its efficacy. Common side effects observed with fluoxetine include headache, gastrointestinal symptoms, sedation, and insomnia.

Short-term randomized clinical trials have demonstrated efficacy of citalopram (Celexa), and sertraline (Zoloft) compared with placebo in the treatment of major depression in children and adolescents.

Citalopram has been demonstrated in one RCT in the United States to be efficacious in 174 children and adolescents treated with citalopram at doses of 20 to 40 mg a day or placebo for 8 weeks. Significantly more of the group on citalopram showed improvement compared with placebo on the depression rating scale (CDRS-R). A significantly increased response rate (response defined as less than 28 on CDRS-R) of 35 percent was found in the citalopram group, compared with 24 percent of the placebo group. Common side effects that emerged included headache, nausea, insomnia, rhinitis, abdominal pain, dizziness, fatigue, and flu-like symptoms.

Sertraline has been shown to provide efficacy in two multicenter, double-blind, placebo-controlled trials of 376 children and adolescents who were treated with sertraline at doses ranging from 50 mg to 200 mg a day, or placebo. Greater than 40 percent decrease in depression rating scale scores were found in nearly 70 percent of the patients treated with sertraline, compared with 56 percent in the placebo group. Most common side effects are anorexia, vomiting, diarrhea, and agitation.

Citalopram has been demonstrated in one RCT in the United States to be efficacious in 174 children and adolescents treated with citalopram at doses of 20 to 40 mg a day or placebo for 8 weeks. Significantly more of the group on citalopram showed improvement compared with placebo on the depression rating scale (CDRS-R). A significantly increased response rate (response defined as less than 28 on CDRS-R) of 35 percent was found in the citalopram group, compared with 24 percent of the placebo group. Common side effects that emerged included headache, nausea, insomnia, rhinitis, abdominal pain, dizziness, fatigue, and flu-like symptoms.

Similar to the literature for adult depression, as many negative as positive study findings have emerged in RCTs of the treatment of childhood and adolescent depression. RCTs to date that have not shown efficacy on primary outcome measures include those using mirtazapine (Remeron), and tricyclic antidepressants. A meta-analysis of SSRI trials in depressed children and adolescents found efficacy of SSRIs compared to placebo with an average response rate of 60 percent for the SSRI compared to 49 percent for placebo.

Starting doses of SSRIs for prepubertal children are lower than doses recommended for adults, and adolescents are generally treated at the same doses recommended for adults.

Venlafaxine (Effexor), which blocks both serotonin and norepinephrine uptake, has been found to be effective in the TORDIA study; however, adverse effects including increased blood pressure have made this agent a second-line choice compared to the SSRIs. Tricyclic antidepressants are not generally recommended for the treatment of depression in children and adolescents due to a lack of proved efficacy along with the potential risk of cardiac arrhythmia associated with their use.

A potential side effect of selective serotonin reuptake inhibitors (SSRIs) in depressed children is behavioral activation, or induction of hypomanic symptoms. In such situations, the medication should be discontinued to determine whether the activation resolves with discontinuation of the medication, or evolves into a hypomanic or manic episode. Activation due to SSRIs, however, do not necessarily predict a diagnosis of bipolar disorder.

FDA Warning and Suicidality

In September 2004, the FDA received information from their Psychopharmacologic Drug and Pediatric Advisory Committee indicating, based on their review of reported suicidal thoughts and behavior among depressed children and adolescents who participated in randomized clinical trials with nine different antidepressants, an increased risk of suicidality in those children who were on active antidepressant medications. Although no suicides were reported, the rates of suicidal thinking and behaviors were 2 percent for patients on placebo, versus 4 percent among patients on antidepressant medications. The FDA, in accordance with the recommendation of their advisory committees, instituted a “black-box” warning to the health professional label of all antidepressant medications indicating the increased risk of suicidal thoughts and behaviors in children and adolescents being treated with antidepressant medications, and the need for close monitoring for these symptoms. Several reviews since 2004, however, concluded that the data do not indicate a significant increase in the risk of suicide or serious suicide attempts after starting treatment with antidepressant drugs.

Duration of Treatment

Based on available longitudinal data and the natural history of major depression in children and adolescents, current recommendations include maintaining antidepressant treatment for 1 year in a depressed child who has achieved a good response, and to then discontinue the medication at a time of relatively low stress for a medication-free period.

Pharmacologic Treatment Strategies for Resistant Depression

Pharmacological recommendations, in accordance with an expert consensus panel that developed the Texas Children’s Medication Algorithm Project (TMAP), as well as the Treatment of SSRI-resistant Adolescents with Depression study (TORDIA) in the treatment of children or adolescents who...
have not responded to treatment with an SSRI agent is to change to another SSRI medication. If a child is not responsive to the second SSRI medication, then either a combination of antidepressants or augmentation strategies may be reasonable choices as well as an antidepressant from another class of medications.

**Electroconvulsive Therapy**

Electroconvulsive therapy (ECT) has been used for a variety of psychiatric illnesses in adults, primarily severe depressive and manic mood disorders and catatonia. ECT is used rarely for adolescents, although published case reports indicate its efficacy in adolescents with depression and mania. Currently case reports suggest that ECT may be a relatively safe and useful treatment for adolescents who have persistent severe affective disorders, particularly with psychotic features, catatonic symptoms, or persistent suicidality.

**SUICIDE**

In the United States, suicide is the third leading cause of death among adolescents, after accidental death and homicide. Throughout the world, suicide rarely occurs in children who have not reached puberty. In the last 15 years, the rates of both completed suicide and suicidal ideation rates have decreased among adolescents. This decrease appears to coincide with the increase in SSRI medications prescribed to adolescents with mood and behavioral disturbance.

**Suicidal Ideation and Behavior**

Suicidal ideation, gestures, and attempts are frequently, but not always, associated with depressive disorders. Reports indicate that as many as half of suicidal individuals express suicidal intentions to a friend or a relative within 24 hours before enacting suicidal behavior.

Suicidal ideation occurs in all age groups and with greatest frequency in children and adolescents with severe mood disorders. More than 12,000 children and adolescents are hospitalized in the United States each year because of suicidal threats or behavior, but completed suicide is rare in children younger than 12 years of age. A young child is hardly capable of designing and carrying out a realistic suicide plan. Cognitive immaturity seems to play a protective role in preventing even children who wish they were dead from committing suicide. Completed suicide occurs about five times more often in adolescent boys than in girls, although the rate of suicide attempts is at least three times higher among adolescent girls than among boys. Suicidal ideation is not a static phenomenon; it can wax and wane with time. The decision to engage in suicidal behavior may be made impulsively without much forethought, or the decision may be the culmination of prolonged rumination.

The method of the suicide attempt influences the morbidity and completion rates, independent of the severity of the intent to die at the time of the suicidal behavior. The most common method of completed suicide in children and adolescents is the use of firearms, which accounts for about two thirds of all suicides in boys and almost one half of suicides in girls. The second most common method of suicide in boys, occurring in about one fourth of all cases, is hanging; in girls, about one fourth commit suicide through ingestion of toxic substances. Carbon monoxide poisoning is the next most common method of suicide in boys, but it occurs in less than 10 percent; suicide by hanging and carbon monoxide poisoning are equally frequent among girls and account for about 10 percent each. Additional risk factors in suicide include a family history of suicidal behavior, exposure to family violence, impulsivity, substance abuse, and availability of lethal methods. Gender differences in nonfatal suicidal behavior among 9th grade adolescents in a recent survey of students in 100 high schools found that serious suicidal thoughts were reported in 19.8 percent of female students and 10.8 percent of females had made an attempt. In male students, 9.3 percent had a history of suicidal thoughts and 4.9 percent had made an attempt. In this study, female students showed evidence of higher levels of mood and anxiety problems, whereas males had a slightly higher level of disruptive behavior problems. Female students reported higher levels of depression, anxiety, somatic complaints, and increased levels of emotional and behavioral problems than males. In young adolescents, even without meeting full criteria for psychiatric disorders, females report more psychopathology along with higher likelihood of nonfatal suicidal behavior.

**Epidemiology**

In a study of 9- to 16-year-olds in a 3-month period, passive suicidal thoughts were approximately 1 percent, suicidal ideation with a plan was 0.3 percent, and suicide attempt was 0.25 percent. In adolescents 14 to 18 years, the current rate of suicidal ideation was found to be 2.7 percent and annual incidence was 4.3 percent. Among this population of adolescents, lifetime prevalence of suicide attempt was 7.1 percent with a much higher rate of suicidal behavior for girls than for boys: 10.1 percent compared to 3.8 percent. Completed suicide rates in youth are much less common in children and younger teens 10 to 14 years, with a slightly lower rate of 0.95 per 100,000 for females compared to 1.71 per 100,000 for males. In older adolescents 15 to 19 years of age, completed suicide is considerably lower for females, 3.52 per 100,000 compared to males, 12.65 per 100,000 in the United States in 2004.

**Etiology**

Universal features in adolescents who resort to suicidal behaviors are the inability to synthesize viable solutions to ongoing problems and the lack of coping strategies to deal with immediate crises. Therefore, a narrow view of the options available to deal with recurrent family discord, rejection, or failure contributes to a decision to commit suicide.

**Genetic Factors.** Completed suicide and suicidal behavior is two to four times more likely to occur in individuals with a first-degree family member with similar behavior. Evidence of a genetic contribution to suicidal behavior is based on family suicide risk studies and the higher concordance for suicide among monozygotic twins compared to dizygotic twins. Recent studies have investigated the possible contributions of the short allele of the serotonin transporter promoter polymorphism (5-HTTLPT)
to suicidal behaviors, although to date, the evidence has not been consistent. Current studies are seeking to investigate correlations between genetic vulnerability and environment and timing interactions as multiple variables that may interact to increase the risk of suicidal behavior.

**Biological Factors.** A relationship between altered central serotonin with suicide as well as impulsive aggression has been found in children and adolescents, and has been demonstrated in adults. Studies have documented a reduction in the density of serotonin transporter receptors in the prefrontal cortex, and serotonin receptors among individuals with suicidal behaviors. Postmortem studies in adolescents who have completed suicide show the most significant alterations in the prefrontal cortex and hippocampus, brain regions that are also associated with emotion regulation and problem solving. These studies have found altered serotonin metabolites, alteration in 5-HT2a binding and decreased activity of protein kinase A and C. Decreased levels of serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) have also been found in the cerebrospinal fluid of depressed adults who attempted suicide by violent methods. Meta-analyses suggest an association between the short S-allele of the serotonin transporter promoter gene and depression as well as suicidal behavior, particularly when combined with adverse life events.

**Psychosocial Factors.** Although severe major depressive illness is the most significant risk factor for suicide, increasing its risk by 20 percent, many severely depressed individuals are not suicidal. A sense of hopelessness, impulsivity, current substance use, and a history of aggressive behavior, have been associated with an increased risk of suicide. A wide range of psychopathological symptoms are associated with exposure to violent and abusive homes. Aggressive, self-destructive, and suicidal behaviors seem to occur with greatest frequency among youth who have endured chronically stressful family lives. The most significant family risk factor for suicidal behavior is maltreatment, including physical and sexual abuse and neglect. The single largest association is between sexual abuse and suicidal behavior. Large community studies have provided data suggesting that youth at risk for suicidal behavior include those who feel disconnected, isolated, or alienated from peers. Sexual orientation is a risk factor, with increased rates of suicidal behavior of two to six times among youth who identify themselves as gay, lesbian, or bisexual. Protective factors mitigating the risk of suicidal behavior are youth who have a strong connection to school and peers even in the face of other risk factors.

**Diagnosis and Clinical Features**

The characteristics of adolescents who attempt suicide and those who complete suicide are similar and up to 40 percent of suicidal persons have made a previous attempt. Direct questioning of children and adolescents about suicidal thoughts is necessary, because studies have consistently shown that caregivers are frequently unaware of these ideas in their children. Suicidal thoughts (i.e., children talking about wanting to harm themselves) and suicidal threats (e.g., children stating that they want to jump in front of a car) are more common than suicide completion.

Most older adolescents with suicidal behavior meet criteria for one or more psychiatric disorders, often including major depressive disorder, bipolar disorder, and psychotic disorders. Youth with mood disorders in combination with substance abuse and a history of aggressive behavior are at particularly high risk for suicide. The most common precipitating factors in younger adolescent suicide completers appear to be impending disciplinary actions, impulsive behavioral histories, and access to loaded guns, particularly in the home. Adolescents without mood disorders with histories of disruptive and violent, aggressive, and impulsive behavior may be susceptible to suicide during family or peer conflicts. High levels of hopelessness, poor problem-solving skills, and a history of aggressive behavior are risk factors for suicide. A less common profile of an adolescent who completes suicide is one of high achievement and perfectionistic character traits facing a perceived failure, such an academically proficient adolescent humiliated by a poor grade on an exam.

Findings from a World Health Organization mental health survey reveals that a range of psychiatric disorders increase the risk of suicidal ideation across the lifespan. Youth with psychiatric disorders characterized by severe anxiety and poor impulse control are at higher risk to act on suicidal ideation. In psychiatrically disturbed and vulnerable adolescents, suicide behavior may represent impulsive responses to recent stressors. Typical precipitants of suicidal behavior include conflicts and arguments with family members and boyfriends or girlfriends. Alcohol and other substance use can further predispose an already vulnerable adolescent to suicidal behavior. In other cases, an adolescent attempts suicide in anticipation of punishment after being caught by the police or other authority figures for a forbidden behavior.

About 40 percent of youth who complete suicide had previous psychiatric treatment, and about 40 percent had made a previous suicide attempt. A child who has lost a parent by any means before age 13 is at higher risk for mood disorders and suicide. The precipitating factors include loss of face with peers, a broken romance, school difficulties, unemployment, bereavement, separation, and rejection. Clusters of suicides among adolescents who know one another and go to the same school have been reported. Suicidal behavior can precipitate other such attempts within a peer group through identification—so-called copycat suicides. Some studies have found a transient increase in adolescent suicides after television programs in which the main theme was the suicide of a teenager.

The tendency of disturbed young persons to imitate highly publicized suicides has been referred to as *Werther syndrome*, after the protagonist in Johann Wolfgang von Goethe's novel, *The Sorrows of Young Werther*. The novel, in which the hero kills himself, was banned in some European countries after its publication more than 200 years ago because of a rash of suicides by young men who read it; some dressed like Werther before killing themselves or left the book open at the passage describing his death. In general, although imitation may play a role in the timing of suicide attempts by vulnerable adolescents, the overall suicide rate does not seem to increase when media exposure increases. In contrast, direct exposure to peer suicide is associated with increased risk of depression and posttraumatic stress disorder rather than suicide.
Treatment

The prognostic significance of suicidal ideation and behaviors in adolescents ranges from relatively low lethality, to high risk for completion. One of the challenges in addressing suicide is to identify children and adolescents with suicidal ideation, and particularly to treat those who have untreated psychiatric disorders, as the risk of completed suicide increases with age, as does the onset of an untreated psychiatric disorder. Adolescents who come to medical attention because of suicidal attempts must be evaluated before determining whether hospitalization is necessary. Pediatric patients who present to the emergency room with suicidal ideation benefit from an intervention that occurs in the emergency room to ensure that the patient is transitioned to outpatient care when hospitalization is not necessary. Those who fall into high-risk groups should be hospitalized until the acute suicidality is no longer present. Adolescents at higher risk include those who have made previous suicide attempts, especially with a lethal method, males older than 12 years of age, histories of aggressive behavior or substance abuse, use of a lethal method, and severe major depressive disorder with social withdrawal, hopelessness, and persistent suicidal ideation.

Relatively few adolescents evaluated for suicidal behavior in a hospital emergency room subsequently receive ongoing psychiatric treatment. Factors that may increase the probability of psychiatric treatment include psychomedication for the family in the emergency room, diffusing acute family conflict, and setting up an outpatient follow-up during the emergency room visit. Emergency room discharge plans often include providing an alternative if suicidal ideation reoccurs, and a telephone hotline number provided to the adolescent and the family in case suicidal ideation reappears.

Scant data exist to evaluate the efficacy of various interventions in reducing suicidal behavior among adolescents. CBT alone and in combination with SSRIs have been shown to decrease suicidal ideation in depressed adolescents over time in the Treatment of Adolescent Depression (TADS) study, a large multisite study; however, these interventions do not work immediately, so safety precautions must be taken for high-risk situations. Dialectical behavior therapy (DBT), a long-term behavioral intervention that can be applied to individuals or groups of patients, has been shown to reduce suicidal behavior in adults, but has yet to be investigated in adolescents. Components of DBT include mindfulness training to improve self-acceptance, assertiveness training, instruction on avoiding situations that may trigger self-destructive behavior, and increasing the ability to tolerate psychological distress. This approach warrants investigation among adolescents.

Given the reduction in completed suicide among adolescents over the last decade, during the same period in which SSRI treatment in the adolescent population has markedly risen, it is possible that SSRIs have been instrumental in this effect. Given the risk of increased rate of suicidal thoughts and behaviors among depressed children and adolescents (indicated in randomized clinical trials with antidepressant medications and leading to the “black-box” warning for all antidepressants for depressed youth), close monitoring for suicidality is mandatory for any child or adolescent being treated with antidepressants.

Hall WD. How have the SSRI antidepressants affected suicide risk? Lancet. 2006;367(9527):1959.

Early onset bipolar disorder has been recognized in children as a rare disorder with greater continuity with its adult counterpart when it occurs in adolescents than in prepubertal children. Over the last decade there has been a significant increase in the diagnosis of bipolar I disorder made in youth referred to psychiatric outpatient clinics and inpatient units. Questions have arisen regarding the phenotype of bipolar disorder in youth, particularly in view of the continuous irritability and mood dysregulation and lack of discrete mood episodes in most prepubertal children who have received the diagnosis. The “atypical” bipolar symptoms among prepubertal children often include extreme mood dysregulation, severe temper tantrums, intermittently aggressive or explosive behavior, and high levels of distractibility and inattention. This constellation of mood and behavior disturbance in the majority of prepubertal children with a current diagnosis of bipolar disorder is nonepisodic, although some fluctuation in mood may occur. The high frequency of the above symptoms in combination with chronic irritability has led to the inclusion of a new mood disorder in youth in the Fifth Edition of the American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders (DSM-5) called Disruptive Mood Dysregulation Disorder, which is discussed in the next section (31.12c).

Many children with nonepisodic mood disorders often have past histories of severe attention-deficit/hyperactivity disorder (ADHD), making the diagnosis of bipolar disorder even more complicated. Family studies of children with ADHD have not revealed an increased rate of bipolar I disorder. Children with “atypical” bipolar disorders, however, are frequently seriously impaired, are difficult to manage in school and at home, and often require psychiatric hospitalization. Longitudinal follow-up studies are under way with groups of children diagnosed with subthreshold bipolar disorders and nonepisodic mood disorders, to determine how many will develop classic bipolar disorder. In one recent study of 140 children with bipolar disorder not otherwise specified (that is, the presence of distinct manic symptoms but subthreshold for manic episodes), 45 percent developed bipolar I or bipolar II illness over a follow-up period of 5 years. In another study, 84 children who were labeled with “severe mood dysregulation” (that is, a persistent nonepisodic negative mood along with severe anger outbursts) who also exhibited at least three manic symptoms (either pressured speech, agitation, insomnia, or flight of ideas) plus distractibility (also common to ADHD), followed for approximately 2 years, found that only one child experienced a hypomanic or mixed episode. Although childhood severe mood dysregulation has been found to be common in community samples—one study reported a lifetime prevalence of 3.3 percent in youth 9 to 19 years of age—its relationship to future bipolar disorder remains questionable. A longitudinal community-based study that followed children and adolescents with nonepisodic irritability over a 20-year period, found that these children were at higher risk to develop depressive disorders and generalized anxiety disorder, rather than bipolar disorders over time.

Among adults and older adolescents with bipolar disorder who present with classic manic episodes, a major depressive episode typically precedes a manic episode. A classic manic episode in an adolescent, similar to in a young adult, may emerge as a distinct departure from a preexisting state often characterized by grandiose and paranoid delusions and hallucinatory phenomena. According to DSM-5, the diagnostic criteria for a manic episode are the same for children and adolescents as for adults (see Table 8.1-6). The diagnostic criteria for a manic episode include a distinct period of an abnormally elevated, expansive, or irritable mood that lasts at least 1 week or for any duration if hospitalization is necessary. In addition, during periods of mood disturbance, at least three of the following significant and persistent symptoms must be present: inflated self-esteem or grandiosity, decreased need for sleep, pressure to talk, flight of ideas or racing thoughts, distractibility, an increase in goal-directed activity, and excessive involvement in pleasurable activities that may result in painful consequences.

According to the DSM-5, in contrast to DSM-IV-TR, diagnostic criteria for bipolar disorder now include changes in both mood and activity or energy level. Furthermore, whereas previously, full criteria for both mania or hypomania and major depressive disorder were required to make a diagnosis of a mixed episode, in DSM-5, this requirement no longer applies; instead a specifier, “with mixed features,” has been added. This specifier can be applied to a current manic episode, hypomanic episode, or depressive episode. Thus, for example, in order to add the “mixed features” specifier to a manic or hypomanic episode, three of the following symptoms must be present during the majority of days in the current or most recent episode of mania or hypomania: prominent depressed mood, diminished interest in most activities, psychomotor retardation nearly every day, fatigue or loss of energy, feelings of excessive guilt or worthlessness, or recurrent thoughts of death. To apply the “with mixed features” specifier to a full major depressive episode, three of the following hypomanic/manic symptoms must be present: elevated or expansive mood, grandiosity, pressured speech or increased speech, flight of ideas, increased energy, or decreased need for sleep.

When mania appears in an adolescent, there is a high incidence of psychotic features including both delusions and hallucinations, which most typically involve grandiose notions about their power, worth, and relationships. Persecutory delusions and flight of ideas are also common. Overall, gross impairment of reality testing is common in adolescent manic episodes. In adolescents with major depressive disorder destined for bipolar I disorder, those at highest risk have family histories of bipolar I disorder and exhibit acute, severe depressive episodes with psychosis, hypersomnia, and psychomotor retardation.

**Epidemiology**

The prevalence rates of bipolar disorder among youth vary depending on the age group studied, and on whether the diagnostic criteria are applied narrowly, restricting it to discrete mood episodes or more broadly, to include nonepisodic mood and behavioral states. In younger children, bipolar disorder is extremely rare, with no cases of bipolar I disorder identified in children between the ages of 9 years and 13 years by the Great Smokey Mountain Study. However, severe mood dysregulation, often a prominent feature in prepubertal children receiving a diagnosis of bipolar disorder, was found in 3.3 percent of an epidemiological sample. In adolescents, bipolar disorder is more frequent, found to range from 0.06 to 0.1 percent of the general population of 16-year-olds in studies using a narrow definition.
of bipolar I disorder. Prevalence of subthreshold symptoms of bipolar illness was found to be 5.7 percent in one study to at least 10 percent in another. Follow-up studies into adulthood revealed that the subthreshold manic symptoms predicted high levels of impairment with progression to depression and anxiety disorders, not bipolar I or II disorders.

Community use of the diagnosis of bipolar disorder in youth has increased markedly over the last 15 years in both outpatient and inpatient psychiatric settings. A recent survey indicated a 40-fold increase in the diagnosis of bipolar disorder in youth being treated at outpatient clinics from the mid-1990s to the mid-2000s. Furthermore, from 2000 through 2006, the rate of youth hospitalized with a primary diagnosis of bipolar disorder increased from 3.3 per 10,000 to 5.7 per 10,000.

ETIOLOGY

Genetic Factors

Estimates of the heritability of bipolar disorder based on adult twin studies range from approximately 60 to 90 percent, with shared environmental variables accounting for 30 to 40 percent and the nonshared environmental factors accounting for approximately 10 to 20 percent. High rates of bipolar disorder have been reported in the relatives of the narrow phenotype of early onset bipolar disorder compared to young adult-onset of bipolar disorder. The high rates of comorbid ADHD among children with early onset bipolar disorder has led to questions regarding the co-transmission of these disorders in family members. However, children with the broader phenotype of bipolar disorder, that is, severe mood dysregulation without episodes of mania, have not been found to have higher rates of bipolar disorder in family members, which suggests that the narrow and broad phenotypes of bipolar disorder may be distinct and separate entities. Nearly 25 percent of adolescent offspring of families with probands with bipolar disorder experienced a mood disorder by the age of 17 years old, compared to 4 percent of controls, with approximately 8 percent representing bipolar I, bipolar II, or bipolar disorder not otherwise specified. Most of the risk in the offspring, therefore, is for unipolar major depressive disorder. Disruptive behavior disorders were not found to be increased, in a longitudinal study, in the offspring of families with a bipolar proband, compared to controls. The combination of ADHD and bipolar disorder is not found as frequently in relatives of children with only ADHD compared with first-degree relatives of children with the combination.

Although bipolar disorder appears to have a significant heritable component, its mode of inheritance remains unknown. A number of research groups have concluded that early onset bipolar disorder is a more severe form of the illness, characterized by more mixed episodes, greater psychiatric comorbidity, more lifetime psychotic symptoms, poorer response to prophylactic lithium treatment, and a greater heritability. The European collaborative study of early-onset bipolar disorder (France, Germany, Ireland, Scotland, Switzerland, England, and Slovenia) carried out a genome-wide linkage analysis of both the narrow and the broad early onset bipolar disorder. This group concluded that a genetic factor located in the 2q14 region is either specifically involved in the etiology of early onset bipolar disorder, or that a gene in this region exerts influence as a modifier of other genes in the development of bipolar disorder in this age group. Other linkage regions that were found by this collaborative did not find specific genome regions that pertained only to the early onset group of bipolar disorder, suggesting that there may be some genetic factors common to early-onset and adult-onset bipolar disorder. This is consistent with the increased incidence of adult-onset bipolar disorder among siblings of early onset disease. Further genome-wide studies are needed to elucidate the genetic etiology of early onset bipolar disorder.

Neurobiological Factors

Converging data suggest that early-onset bipolar disorder is associated with both structural and functional brain alterations in prefrontal cortical and subcortical regions associated with the processing and regulation of emotional stimuli. Structural magnetic resonance imaging (MRI) studies suggest that altered development of white matter and a decreased amygdalar volume are found more frequently in this population than in the general population. Functional MRI (fMRI) studies are important in that they can identify altered brain function in vulnerable populations such as youth with early-onset bipolar disorder at baseline, and can also be utilized to elucidate functional changes toward normalization in brain functioning after various treatments, and potentially identify pretreatment neural predictors of good response to various treatments.

A recent fMRI study of pediatric bipolar patients documented pretreatment brain activity and posttreatment effects of a trial of risperidone versus divalproex. This double-blind study included 24 unmedicated manic patients with a mean age of 13 years, randomized to either risperidone or divalproex treatment, and 14 healthy controls examined over a 6-week period. Prior to treatment, the patient group showed increased amygdala activity compared to healthy controls, which was poorly controlled by the higher ventrolateral prefrontal cortex (VLPFC) and the dorsolateral prefrontal cortex (DLPFC), which are believed to exert influence on the amygdala to control emotional regulation and processing. Increased amygdala activity at baseline predicted a poorer treatment response to both the risperidone and the divalproex in the patient group. Patients were given an affective color-matching word task involving matching positive words (i.e., happiness, achievement, success), negative words (i.e., disappointment, depression, or rejection), or neutral words, with one of two colored circles displayed on a screen while fMRI was administered. Greater pretreatment right amygdala activity during a word task with positive and negative words in the risperidone group, and greater pretreatment left amygdala activity with a positive word task in the divalproex group, predicted poor response on the Young Mania Rating Scale. Increased amygdala activity in early-onset bipolar patients is hypothesized to be a potential biomarker predicting resistance and poor treatment response to both risperidone and divalproex.

Neuropsychological Studies

Impairments in verbal memory, processing speed, executive function, working memory, and attention are commonly found in early-onset bipolar disorder. Data suggest that on tasks of working memory, processing speed, and attention, children and adolescents with comorbid bipolar disorder and ADHD demonstrate more pronounced impairments compared with those without ADHD. Other studies found that children with bipolar disorder make a greater number of emotion recognition errors compared with controls. They more frequently identified faces
as “angry” when presented with adult faces; however, these errors did not occur when children’s faces were shown. Impaired perception of facial expression has also been reported in studies of adults with bipolar disorder.

**DIAGNOSIS AND CLINICAL FEATURES**

Early onset bipolar disorder is often characterized by extreme irritability that is severe and persistent, and may include aggressive outbursts and violent behavior. In between outbursts, children with the broad diagnosis may continue to be angry or dysphoric. It is rare for a prepubertal child to exhibit grandiose thoughts or euphoric mood; for the most part, children diagnosed with early onset bipolar disorder are intensely emotional with a fluctuating but overriding negative mood. Current diagnostic criteria for bipolar disorders in children and adolescents in DSM-5 are the same as those used in adults (see Tables 8.1-6 and 31.12b-1). The clinical picture of early-onset bipolar disorder, however, is complicated by the prevalence of comorbid psychiatric disorders.

**Comorbidity with ADHD**

ADHD is the most common comorbid condition among youth with early onset bipolar disorder and has been reported in up to 90 percent of prepubertal children and up to 50 percent of adolescents diagnosed with bipolar disorder. One of the main sources of diagnostic confusion regarding children with early onset bipolar disorder is the comorbid ADHD, since the two disorders share many diagnostic criteria, including distractibility, hyperactivity, and talkativeness. Even when the overlapping symptoms are removed from the diagnostic count, a significant percentage of children with bipolar disorder continued to meet the full criteria for ADHD. This implies that both disorders with their own distinct features are present in many cases.

**Comorbidity with Anxiety Disorders**

Children and adolescents with bipolar disorder have been reported to have higher than expected rates of panic and other anxiety disorders. In youth with the narrow phenotype of bipolar disorders, up to 77 percent have been reported to exhibit an anxiety disorder. Lifetime prevalence of panic disorder was found to be 21 percent among subjects with the broader phenotype of bipolar disorder compared with 0.8 percent in those without mood disorders. Patients diagnosed with bipolar disorder who have comorbid high levels of anxiety symptoms are reported as adults to have higher risks of alcohol abuse and suicidal behavior. On the other hand, children who exhibit the broader phenotype of bipolar disorder are at higher risk to go on to have anxiety disorders as well as depressive disorders.

Jeannie is a 13-year-old adopted teen who was admitted to the hospital after assaulting her adoptive mother, causing bruises on her arms and legs from Jeanie’s kicks and punches. Jeanie has had a long history of excessively severe tantrums, which include assaultive and self-injurious behavior since before she was adopted at the age of 3 years. Jeanie had always been a child who was irritable and explosive, with a short fuse, who could blow up with very little provocation, even when things were going her way. Jeanie had become increasingly hard to manage at home, refused to go to school, yelled and screamed for hours on a daily basis, and often hit and kicked her adoptive parents by the time she was 10 years old. Jeanie had been placed in residential treatment for about a year and a half from age 11 and a half to almost 13, where she had been given a diagnosis of bipolar disorder and placed on lithium and citalopram. She was doing so well there after a year that Jeannie’s adoptive mother decided to take her home. After a few weeks at home, however, Jeanie began to decompensate, having daily explosive tantrums during which she became aggressive and out of control. On multiple occasions she had hurt herself and her adoptive mother and father. Upon arriving at the hospital, Jeanie was calm by the time she was brought to her hospital room; however, her adoptive mother refused to consider taking her home until she had received a full psychiatric evaluation and something new was done to control Jeannie’s unsafe behaviors. Jeanie was initially evaluated by the child and adolescent psychiatrist on-call, after which she was admitted to a pediatric inpatient unit, where she waited a bed on a psychiatric adolescent inpatient unit. The psychiatrist learned that Jeanie had been born prematurely to a teenage mother and placed in multiple foster homes until she was adopted. Jeanie was a small girl who appeared younger than her stated age, although her demeanor was bossy and pedantic. Jeanie’s biological family history was unknown, and although she had at least one stigmata of fetal alcohol syndrome, her IQ was in the average range and there was no other evidence to corroborate this possibility. On mental status examination in the hospital, Jeanie reported that things were fine, that she was not depressed, and that she did not get along with kids her own age but that she had a few friends. Jeanie admitted that she had a bad temper and that she did not remember what she did after she was in a rage. Jeanie’s affect was odd, and she seemed to like having the psychiatrist as her audience. Jeanie denied suicidal ideation or past attempts, and she denied having been a danger to herself or her adoptive parents. Jeanie seemed annoyed when she was asked about the reasons for her placement in a residential facility, and she became irritable when questioned about the reasons for her current admission. Jeanie was referred for admission to an adolescent psychiatric inpatient unit with the following recommendations: Jeanie was referred for a trial of an antipsychotic antipsychotic, such as risperidone or olanzapine, and a reconsideration of a return to a more structured school program, either a day program or residential facility. The diagnosis of bipolar disorder remained in question, as she did not meet the narrow phenotype for this disorder.

**PATHOLOGY AND LABORATORY EXAMINATION**

No specific laboratory indices are currently helpful in making the diagnosis of bipolar disorders among children and adolescents.

**DIFFERENTIAL DIAGNOSIS**

The most important clinical entities to distinguish from early onset bipolar disorder are also the disorders with which it is most frequently comorbid. Included are ADHD, oppositional defiant disorder, conduct disorder, anxiety disorders, and depressive disorders.

Although childhood ADHD tends to have its onset earlier than pediatric mania, current evidence from family studies supports the presence of ADHD and bipolar disorders as highly
Table 31.12b-1
DSM-5 Diagnostic Criteria for Bipolar II Disorder

For a diagnosis of bipolar II disorder, it is necessary to meet the following criteria for a current or past hypomanic episode and the following criteria for a current or past major depressive episode:

**Hypomanic Episode**
A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood and abnormally and persistently increased activity or energy, lasting at least 4 consecutive days and present most of the day, nearly every day.
B. During the period of mood disturbance and increased energy and activity, three (or more) of the following symptoms have persisted (four if the mood is only irritable), represent a noticeable change from usual behavior, and have been present to a significant degree:
   1. Inflated self-esteem or grandiosity.
   2. Decreased need for sleep (e.g., feels rested after only 3 hours of sleep).
   3. More talkative than usual or pressure to keep talking.
   4. Flight of ideas or subjective experience that thoughts are racing.
   5. Distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli), as reported or observed.
   6. Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation.
   7. Excessive involvement in activities that have a high potential for painful consequences (e.g., engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments).
C. The episode is associated with an unequivocal change in functioning that is uncharacteristic of the individual when not symptomatic.
D. The disturbance in mood and the change in functioning are observable by others.
E. The episode is not severe enough to cause marked impairment in social or occupational functioning or to necessitate hospitalization. If there are psychotic features, the episode is, by definition, manic.
F. The episode is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication or other treatment).

**Major Depressive Episode**
A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.

**Note:** Do not include symptoms that are clearly attributable to a medical condition.

1. Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad, empty, or hopeless) or observation made by others (e.g., appears tearful). *(Note: In children and adolescents, can be irritable mood.)*
2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation).
3. Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day. *(Note: In children, consider failure to make expected weight gain.)*
4. Significant psychomotor agitation or retardation nearly every day.
5. Psychomotor agitation or retardation nearly every day (observable by others; not merely subjective feelings of restlessness or being slowed down).
6. Fatigue or loss of energy nearly every day.
7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick).
8. Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others).
9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, a suicide attempt, or a specific plan for committing suicide.

**B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.**

C. The episode is not attributable to the physiological effects of a substance or another medical condition.

**Note:** Criteria A–C above constitute a major depressive episode.

**Note:** Responses to a significant loss (e.g., bereavement, financial ruin, losses from a natural disaster, a serious medical illness or disability) may include the feelings of intense sadness, rumination about the loss, insomnia, poor appetite, and weight loss noted in Criterion A, which may resemble a depressive episode. Although such symptoms may be understandable or considered appropriate to the loss, the presence of a major depressive episode in addition to the normal response to a significant loss should be carefully considered. This decision inevitably requires the exercise of clinical judgment based on the individual's history and the cultural norms for the expression of distress in the context of loss.

**Bipolar II Disorder**
A. Criteria have been met for at least one hypomanic episode (Criteria A–F under "Hypomanic Episode" above) and at least one major depressive episode (Criteria A–C under “Major Depressive Episode” above).
B. There has never been a manic episode.
C. The occurrence of the hypomanic episode(s) and major depressive episode(s) is not better explained by schizoaffective disorder, schizophrenia, schizoaffective disorder, delusional disorder, or other specified or unspecified schizophrenia spectrum and other psychotic disorder.
D. The symptoms of depression or the unpredictability caused by frequent alternation between periods of depression and hypomania causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
comorbid in children, and the concurrence is not because of the overlapping symptoms that the two disorders share. In a recent study of more than 300 children and adolescents who attended a psychopharmacology clinic and received a diagnosis of ADHD, bipolar disorder was also evident in almost one third of those children with ADHD who had combined-type and hyperactive-types, and occurred with much less frequency (i.e., in less than 10 percent) in children with ADHD, inattentive-type.

**COURSE AND PROGNOSIS**

There are several pathways regarding the course and prognosis of children diagnosed with early onset bipolar disorder. Those who present with severe mood dysregulation at an early age, without discrete mood cycles, are most likely to develop anxiety and depressive disorders as they mature. Youth who present in adolescence with a recognizable manic episode are most likely to continue to meet criteria for bipolar I disorder in adulthood. In both cases, the long-term impairment is considerable.

A longitudinal study of 263 child and adolescent inpatients and outpatients with bipolar disorder followed for an average of 2 years found that approximately 70 percent recovered from their index episode within that period. Half of these patients had at least one recurrence of a mood disorder during this time, more frequently a depressive episode than a mania. No differences were found in the rates of recovery for children and adolescents whose diagnosis was bipolar I disorder, bipolar II disorder, or bipolar disorder not otherwise specified; however, those youth whose diagnosis was bipolar disorder not otherwise specified had a significant longer duration of illness before recovery, with less frequent recurrences once they recovered. About 19 percent of patients changed polarity once per year or less, 61 percent shifted five or more times per year, about half cycled more than ten times per year, and about one third cycled more than 20 times per year. Predictors of more rapid cycling included lower socioeconomic status (SES), presence of lifetime psychosis, and bipolar disorder not otherwise specified diagnosis. Over the follow-up period, about 20 percent of subjects who were diagnosed with bipolar II disorder converted to bipolar I disorder, and 25 percent of the bipolar disorder not otherwise specified subjects developed bipolar I disorder or bipolar II disorder during the follow-up period.

Similar to the natural history of bipolar disorders in adults, children have a wide range of symptom severity in manic and depressed episodes. The more frequent diagnostic conversions from bipolar II disorder to bipolar I disorder among children and adolescents, compared with adults, highlight the lack of stability of the bipolar II disorder diagnosis in youth. This is also the case with respect to conversion from bipolar disorder not otherwise specified to other bipolar disorders. When bipolar disorder occurs in young children, recovery rates are lower. In addition,
a greater likelihood is seen of mixed states and rapid cycling, and higher rates of polarity changes compared with those who develop bipolar disorders in late adolescence or early adulthood.

**TREATMENT**

Treatment of early onset bipolar disorder incorporates multimodal interventions including pharmacotherapy, psychoeducation, psychosocial intervention with the family and the child, and school interventions to optimize a child’s school adjustment and achievement.

**Pharmacotherapy**

Two classes of medications—atypical antipsychotics and mood stabilizing agents—are the most well-studied agents that provide efficacy in the treatment of early-onset bipolar disorders.

Eight randomized controlled trials have shown efficacy of atypical antipsychotic agents in the treatment of bipolar disorder in youth between the ages of 10 and 17 years. These studies compared an atypical antipsychotic to placebo, or compared an atypical antipsychotic to a mood stabilizer, or added an antipsychotic to a mood-stabilizing agent. The atypical antipsychotics included olanzapine, quetiapine, risperidone, aripiprazole, and ziprasidone. All five of the atypical antipsychotic studies demonstrated significant efficacy in the treatment of early onset bipolar manic or mixed states. A recent trial comparing quetiapine and valproate found that both were efficacious, but the quetiapine was superior in the speed of its effect. In another trial comparing risperidone and divalproex treatment for bipolar disorder in youth, risperidone was found to have a more rapid improvement and a greater final reduction in manic symptoms compared to divalproex.

Mood-stabilizing agents have been used in open trials and anecdotally with early onset bipolar illness with little evidence of efficacy at this time. In trials using lithium or divalproex for treatment of early onset bipolar disorder, responses were less robust compared to results with atypical antipsychotics. Controlled trials have provided some evidence suggesting that lithium is efficacious in the management of aggression behavior disorders. Although lithium has been approved for use in adolescent mania, more research is needed to know if lithium is effective for more classic forms of mania in adolescents. The Collaborative Lithium Trials (CoLT) established a set of protocols to establish the safety and potential efficacy of lithium in youth, and to develop studies to provide evidence-based dosing of lithium for youth. A group of researchers recently studied the first-dose pharmacokinetics of lithium carbonate in youth and found that clearance and volume are correlated with total body weight in youth, and particularly with fat-free mass. Difference in body size was consistent with the pharmacokinetics of lithium metabolism in children and adults. An open-label trial of lamotrigine (Lamictal) in the treatment of bipolar depression among youth provides possible support for its use in children and adolescents.

Current evidence suggests a faster response and more robust effect with atypical antipsychotics compared to mood-stabilizing agents in the treatment of early-onset bipolar disorder. However, given the severity and impairment of bipolar disorder in youth, when only partial recovery is achieved, consideration of adding an additional agent may be necessary.

**Psychosocial Treatment**

Psychosocial treatment interventions for early onset bipolar illness have included a family-focused treatment. This treatment consists of several sessions of psychoeducation, then sessions focusing on current stressors and mood management plan, and then several sessions of communication enhancement training and problem-solving skills training. The use of this type of intervention for youth diagnosed with bipolar disorder as well as youth at risk for the disorder by virtue of their family history or subthreshold conditions has been of value. Adjunctive family-focused psychoeducational treatment modified for children and adolescents has been shown to reduce relapse rate. Children and adolescents treated with mood-stabilizing agents in addition to a psychosocial intervention showed improvement in depressive symptoms, manic symptoms, and behavioral disturbance over 1 year.

A year-long trial of a modified Family Focused Treatment-High Risk in youth with bipolar disorder showed significant improvement in mood disturbance, especially depressive mood and hypomania, and improved psychosocial functioning. Family-focused treatment for high-risk youth is a promising intervention that deserves further investigation as a longitudinal follow-up to determine the course of youth at risk to develop bipolar disorder.

**REFERENCES**

Disruptive mood dysregulation disorder, a new inclusion in the American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5), is characterized by severe, developmentally inappropriate, and recurrent temper outbursts at least three times per week, along with a persistently irritable or angry mood between temper outbursts. In order to meet diagnostic criteria, the symptoms must be present for at least a year, and the onset of symptoms must be present by the age of 10 years old. Children with these symptoms have typically been diagnosed with bipolar disorder, or a combination of oppositional defiant disorder, ADHD and intermittent explosive disorder. Recent longitudinal data suggest, however, that these children do not typically develop classic bipolar disorder in late adolescence or early adulthood. Instead, studies suggest that youth with chronic irritability and severe mood dysregulation are at higher risk for future unipolar depressive disorders and anxiety disorders. Although the initial studies of children and adolescents with severe mood dysregulation included several symptoms of hyperarousal (such as distractibility, physical restlessness, insomnia, racing thoughts, flight of ideas, pressured speech, or intrusiveness), the current DSM-5 diagnostic criteria for disruptive mood dysregulation do not include any hyperarousal criteria. Youths diagnosed with mood dysregulation disorder who also exhibit multiple symptoms of hyperarousal may be comorbid for ADHD.

**EPIDEMIOLOGY**

Most of the epidemiological data applied to disruptive mood dysregulation disorder was gathered from children and adolescents with severe mood dysregulation, which includes hyperarousal symptoms. Because disruptive mood dysregulation disorder differs from severe mood dysregulation disorder only in the absence of hyperarousal symptoms, the epidemiological data from the severe mood dysregulation disorder studies can be viewed as a useful proxy for disruptive mood dysregulation disorder. Severe mood dysregulation has a lifetime prevalence of 3 percent in children age 9 to 19 years. Within that percentage, males (78 percent) are more prevalent than females (22 percent). The mean age of onset is 5 to 11 years of age.

**COMORBIDITY**

Disruptive mood dysregulation disorder often co-occurs with other psychiatric disorders. The most common comorbidities are ADHD (94 percent), oppositional defiant disorder (84 percent), anxiety disorders (47 percent), and major depressive disorder (20 percent). The relationship of severe mood dysregulation and disruptive mood dysregulation disorder to bipolar disorder has been a topic of clinical investigation. Youth with severe mood dysregulation and hyperarousal symptoms have been conceptualized as a “broad phenotype” of pediatric bipolar disorder, however, the term “severe mood dysregulation” was utilized by researchers for these youth because it remains unclear whether these youth go on to meet criteria for a bipolar disorder. Disruptive mood dysregulation disorder is conceptualized as a disorder that is not episodic, and may coexist with ADHD. However, current evidence does not support its continuity with an emerging bipolar disorder.

**DIAGNOSIS AND CLINICAL FEATURES**

The DSM-5 diagnostic criteria for disruptive mood dysregulation disorder (Table. 31.12c-1) requires outbursts that are grossly out of proportion to the situation. These temper outbursts present with verbal rages and/or physical aggression toward people or property, and are inappropriate for the child’s developmental level. Temper outbursts occur, on average, three or more times per week, with variations in mood between outbursts. Symptoms must exhibit before age 10 years, be present for at least 12 months, and be present within at least two settings (i.e., home and school). The diagnosis is not made for the first time in youth younger than 6 years or older than 18 years. In between temper outbursts, the child’s mood is persistently irritable and angry, and this mood is observable by others such as parents, teachers, or peers. There has never been period lasting more than one day in which full criteria for a manic or hypomanic episode (except for duration) are fulfilled. The DSM-5 diagnostic criteria for disruptive mood dysregulation disorder are found in Table 31.12c-1.
The temper outbursts are inconsistent with developmental level.
C. The temper outbursts occur, on average, three or more times per week.
D. The mood between temper outbursts is persistently irritable or angry most of the day, nearly every day, and is observable by others (e.g., parents, teachers, peers).
E. Criteria A-D have been present for 12 or more months. Throughout that time, the individual has not had a period lasting 3 or more consecutive months without all of the symptoms in Criteria A–D.
F. Criteria A and D are present in at least two of three settings (i.e., at home, at school, with peers) are severe in at least one of these.
G. The diagnosis should not be made for the first time before age 6 years or after age 18 years.
H. By history or observation, the age at onset of Criteria A–E is before 10 years.
I. There has never been a distinct period lasting more than 1 day during which the full symptom criteria, except duration, for a manic or hypomanic episode have been met.

Note: Developmentally appropriate mood elevation, such as occurs in the context of a highly positive event or its anticipation, should not be considered as a symptom of mania or hypomania.
J. The behaviors do not occur exclusively during an episode of major depressive disorder and are not better explained by another mental disorder (e.g., autism spectrum disorder, posttraumatic stress disorder, separation anxiety disorder, persistent depressive disorder [dysthymia]).

Note: This diagnosis cannot coexist with oppositional defiant disorder, intermittent explosive disorder, or bipolar disorder, though it can coexist with others, including major depressive disorder, attention-deficit/hyperactivity disorder, conduct disorder, and substance use disorder. Individuals whose symptoms meet criteria for both disruptive mood dysregulation disorder and oppositional defiant disorder should only be given the diagnosis of disruptive mood dysregulation disorder. If an individual has ever experienced a manic or hypomanic episode, the diagnosis of disruptive mood dysregulation disorder should not be assigned.
K. The symptoms are not attributable to the physiological effects of a substance or to another medical or neurological condition.

Differential Diagnosis

Bipolar Disorder

Disruptive mood dysregulation disorder closely resembles the “broad phenotype” of bipolar disorder. Although not episodic, it has been theorized by some clinicians and researchers that the chronic and persistent symptoms of mood disturbance and irritability may be an early developmental presentation of bipolar disorder. Disruptive mood dysregulation, however, does not meet formal diagnostic criteria for mania in bipolar disorder, because irritability in disruptive mood dysregulation disorder is chronic and nonepisodic.

Oppositional Defiant Disorder

Disruptive mood dysregulation disorder is similar to oppositional defiant disorder in that they both include irritability, temper outbursts, and anger. Many patients with disruptive mood dysregulation disorder meet the criteria for oppositional defiant disorder; however, most patients with oppositional defiant disorder do not meet the criteria for disruptive mood dysregulation disorder. Oppositional defiant disorder includes symptoms of annoyance and defiance that are not found in disruptive mood dysregulation disorder. Disruptive mood dysregulation disorder requires that irritable outbursts be present in at least two settings, whereas oppositional defiant disorder requires that they be present in only one setting.

Course and Prognosis

Disruptive mood dysregulation disorder is a chronic disorder. Longitudinal studies thus far have shown that patients with disruptive mood dysregulation disorder in childhood have a high
risk of progressing to major depressive disorder, dysthymic disorder, and anxiety disorders over time.

**TREATMENT**

The current treatment of disruptive mood dysregulation is based on symptomatic interventions, in view of the fact that its etiology is not well understood at this time. If disruptive mood dysregulation disorder is confirmed to resemble unipolar depression and anxiety disorders in its pathophysiology, and it is often comorbid with ADHD, then SSRIs and stimulants would likely be the pharmacological agents of first choice. However, if the pathophysiology of disruptive mood dysregulation disorder is similar to that of bipolar disorder, then first-line treatments for youth would include atypical antipsychotic agents and mood stabilizers. There are scant treatment studies of disruptive mood dysregulation disorder in the current literature. One controlled trial of youths with symptoms of severe mood dysregulation and ADHD symptoms who did not respond to stimulants, responded to divalproex (Depakote) combined with behavioral psychotherapy compared to placebo and behavioral psychotherapy. There are treatment studies underway of youth who exhibit symptoms of severe mood dysregulation utilizing an SSRI plus a stimulant compared to a stimulant and placebo.

Psychosocial interventions such as cognitive-behavioral psychotherapy are likely to be an essential component of treatment for youth with disruptive mood dysregulation disorder, and psychosocial interventions targeting children diagnosed with bipolar disorder may be beneficial.

**REFERENCES**

Disruptive behaviors, especially oppositional patterns and aggressive behaviors, are among the most frequent reasons for children and adolescents to be referred for psychiatric evaluation. Demonstration of impulsive and oppositional behaviors are developmentally normative in young children; many youth who continue to display excessive patterns in middle childhood will find other forms of expression as they mature and will no longer demonstrate these behaviors in adolescence or adulthood. The origin of stable patterns of oppositional defiant behavior is widely accepted as a convergence of multiple contributing factors, including biological, temperamental, learned, and psychological conditions. Risk factors for the development of aggressive behavior in youth include childhood maltreatment such as physical or sexual abuse, neglect, emotional abuse, and overly harsh and punitive parenting. The American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5), has divided oppositional defiant disorder into three types: Angry/Irritable Mood, Argumentative/Defiant Behavior, and Vindictiveness. A child may meet diagnostic criteria for oppositional defiant disorder with a 6-month pattern of at least four symptoms from the three types above. Angry/Irritable children with oppositional defiant disorder often lose their tempers, are easily annoyed, and feel irritable much of the time. Argumentative/Defiant children display a pattern of arguing with authority figures, and adults such as parents, teachers, and relatives. Children with this type of oppositional defiant disorder actively refuse to comply with requests, deliberately break rules, and purposely annoy others. These children often do not take responsibility for their actions, and often blame others for their misbehavior. Children with the Vindictive type of oppositional defiant disorder are spiteful, and have shown vindictive or spiteful actions at least twice in 6 months to meet diagnostic criteria.

Oppositional defiant disorder is characterized by enduring patterns of negativistic, disobedient, and hostile behavior toward authority figures, as well as an inability to take responsibility for mistakes, leading to placing blame on others. Children with oppositional defiant disorder frequently argue with adults and become easily annoyed by others, leading to a state of anger and resentment. Children with oppositional defiant disorder may have difficulty in the classroom and with peer relationships, but generally do not resort to physical aggression or significantly destructive behavior.

In contrast, children with conduct disorder engage in severe repeated acts of aggression that can cause physical harm to themselves and others and frequently violate the rights of others. In oppositional defiant disorder, a child’s temper outbursts, active refusal to comply with rules, and annoying behaviors exceed expectations for these behaviors for children of the same age. The disorder is an enduring pattern of negativistic, hostile, and defiant behaviors in the absence of serious violations of the rights of others.

**EPIDEMIOLOGY**

Oppositional and negativistic behavior, in moderation, is developmentally normal in early childhood and adolescence.
Epidemiological studies of negativistic traits in nonclinical populations found such behavior in 16 to 22 percent of school-age children. Although oppositional defiant disorder can begin as early as 3 years of age, it typically is noted by 8 years of age and usually not later than early adolescence. Oppositional defiant disorder has been reported to occur at rates ranging from 2 to 16 percent with increased rates reported in boys before puberty, and an equal sex ratio reported after puberty. The prevalence of oppositional defiant behavior in males and females diminishes in youth older than 12 years of age.

ETIOLOGY

The most dramatic example of normal oppositional behavior peaks between 18 and 24 months, the “terrible twos,” when toddlers behave negativistically as an expression of growing autonomy. Pathology begins when this developmental phase persists abnormally, authority figures overreact, or oppositional behavior recurs considerably more frequently than in most children of the same mental age. Among the criteria included in oppositional defiant disorder, irritability appears to be the one most predictive of later psychiatric disorders, whereas the other elements may be considered components of temperament.

Children exhibit a range of temperamental predispositions to strong will, strong preferences, or great assertiveness. Parents who model more extreme ways of expressing and enforcing their own will may contribute to the development of chronic struggles with their children that are then reenacted with other authority figures. What begins for an infant as an effort to establish self-determination may become transformed into an exaggerated behavioral pattern. In late childhood, environmental trauma, illness, or chronic incapacity, such as mental retardation, can trigger oppositionality as a defense against helplessness, anxiety, and loss of self-esteem. Another normative oppositional stage occurs in adolescence as an expression of the need to separate from the parents and to establish an autonomous identity.

Classic psychoanalytic theory implicates unresolved conflicts as fueling defiant behaviors targeting authority figures. Behaviorists have observed that in children, oppositionality may be a reinforced, learned behavior through which a child exerts control over authority figures; for example, if having a temper tantrum when a request or demand is made of the child coerces the parents to withdraw their request, then tantrum behavior becomes strongly reinforced. In addition, increased parental attention during a tantrum can reinforce the behavior.

DIAGNOSIS AND CLINICAL FEATURES

Children with oppositional defiant disorder often argue with adults, lose their temper, and are angry, resentful, and easily annoyed by others at a level and frequency that is outside of the expected range for their age and developmental level. Frequently, youth with oppositional defiant disorder actively defy adults’ requests or rules and deliberately annoy other persons. They tend to blame others for their own mistakes and misbehavior, more often than is appropriate for their developmental age. Manifestations of the disorder are almost invariably present in the home, but they may not be present at school or with other adults or peers. In some cases, features of the disorder from the beginning of the disturbance are displayed outside the home; in other cases, the behavior starts in the home, but is later displayed outside. Typically, symptoms of the disorder are most evident in interactions with adults or peers whom the child knows well. Thus, a child with oppositional defiant disorder may not show signs of the disorder when examined clinically. Although children with oppositional defiant disorder may be aware that others disapprove of their behavior, they may still justify it as a response to unfair or unreasonable circumstances. The disorder appears to cause more distress to those around the child than to the child.

Chronic oppositional defiant disorder or irritability almost always interferes with interpersonal relationships and school performance. These children are often rejected by peers, and may become isolated and lonely. Despite adequate intelligence, they may do poorly or fail in school, due to their lack of cooperation, poor participation, and inability to accept help. Secondary to these difficulties are low self-esteem, poor frustration tolerance, depressed mood, and temper outbursts. Adolescents who are ostracized may turn to alcohol and illegal substances as a modality to fit in with peers. Children who are chronically irritable often develop mood disorders in adolescence or adulthood.

Pathology and Laboratory Examination

No specific laboratory tests or pathological findings help diagnose oppositional defiant disorder. Because some children with oppositional defiant disorder become physically aggressive and violate the rights of others as they get older, they may share some characteristics with people with high levels of aggression, such as low central nervous system serotonin.

DIFFERENTIAL DIAGNOSIS

Oppositional behaviors are both normal and adaptive within an expected range at specific developmental stages. Periods of normative negativism must be distinguished from oppositional defiant disorder. Developmentally appropriate oppositional behavior is neither considerably more frequent nor more intense than that seen in other children of the same mental age. Oppositional defiant disorder must be distinguished from Disruptive Mood Dysregulation Disorder in so far as they are both characterized by chronic irritability and inappropriate temper outbursts. According to the DSM-5, oppositional defiant disorder cannot be diagnosed in the presence of disruptive mood dysregulation disorder. (See Section 31.12c for a further discussion of disruptive mood dysregulation disorder.)

Oppositional defiant behavior occurring temporarily in reaction to a stressor should be diagnosed as an adjustment disorder. When features of oppositional defiant disorder appear during the course of conduct disorder, schizophrenia, or a mood disorder, the diagnosis of oppositional defiant disorder should not be made. Oppositional and negativistic behaviors can also be present in ADHD, cognitive disorders, and mental retardation. Whether a concomitant diagnosis of oppositional defiant disorder should be made depends on the severity, pervasiveness, and duration of such behavior. Some young children who receive a diagnosis of oppositional defiant disorder go on in several years to meet the criteria for conduct disorder. Some investigators believe that the two disorders may be developmental variants of each other, with conduct disorder being the natural progression of oppositional defiant behavior when a child matures. Most
children with oppositional defiant disorder, however, do not later meet the criteria for conduct disorder, and up to one fourth of children with oppositional defiant disorder may not meet the diagnosis several years later.

The subtype of oppositional defiant disorder that tends to progress to conduct disorder is one in which aggression is prominent, for example, the Angry/Irritable type and the Vindictive type. Many children who have ADHD and oppositional defiant disorder develop conduct disorder before the age of 12 years. Many children who develop conduct disorder have a history of oppositional defiant disorder. Overall, the current consensus is that two subtypes of oppositional defiant disorder may exist. One type, which is likely to progress to conduct disorder, includes certain symptoms of conduct disorder (e.g., fighting, bullying). The other type, which is characterized by less aggression and fewer antisocial traits, does not progress to conduct disorder. However, in either case, when both oppositional defiant disorder and conduct disorder are present, according to DSM-5, they may be diagnosed concurrently.

**CASE AND PROGNOSIS**

Jackson, age 8 years, was brought to the clinic for evaluation of irritability, negativity and defiant behavior by his mother. She complained that he had frequent prolonged tantrums, triggered by not “getting his way.” Jackson’s mother described the tantrums as consisting of shouting, cursing, crying, slamming doors, and sometimes throwing books or objects on the floor. Jackson had been having troubles in school as well and his teacher had reported to the family that he seemed to have a habit of provoking other students as well as the teacher by making noises, rocking in his seat, and whistling in class. Recently, at home, Jackson was kicking his foot against his mother’s chair and she asked him to stop. He looked at her and continued to kick her chair until she became angry and sent him to his room. He then started yelling and stated that he wasn’t doing anything and that his mother was just picking on him. Jackson’s mother reports that she has given up on asking him to help with chores, because it inevitably results in an argument. Jackson appears sullen and irritable on interview. He insists that his problems are all his mother’s fault and he is always nagging him unfairly. During the interview with his mother, he interrupted her several times, to say that she was lying and to contradict her story. Despite Jackson’s behavioral problem he has been able to succeed academically and scores highly on standardized tests. His mother reports that Jackson used to have some friends in kindergarten, but as he has gotten older, he has lost almost all of his friends because he has difficulty sharing his things and tends to be bossy. Jackson’s mother reports that ever since his sister was born when he was 2 years old, he has been aggressive and rivalrous toward her. Jackson’s parents separated and divorced when he was 3. He has had no contact with his father since then. Jackson’s mother was depressed for a year after the divorce until she sought treatment. She has always felt guilty that his father is not in his life, and Jackson blames her for not having his father around. She believes his behaviors have become worse since she recently started dating again.

**TREATMENT**

The primary treatment of oppositional defiant disorder is family intervention using both direct training of the parents in child management skills and careful assessment of family interactions. The goals of this intervention are to reinforce more prosocial behaviors and to diminish undesired behaviors at the same time. Cognitive behavioral therapists emphasize teaching parents how to alter their behavior to discourage the child’s oppositional behavior by diminishing attention to it, and encourage appropriate therapy focuses on selectively reinforcing and praising appropriate behavior and ignoring or not reinforcing undesired behavior.

Children with oppositional defiant behavior may also benefit from individual psychotherapy in which they role play and “practice” more adaptive responses. In the therapeutic relationship, the child can learn new strategies to develop a sense of mastery and success in social situations with peers and families. In the safety of a more “neutral” relationship, children may discover that they are capable of less provocative behavior. Often, self-esteem must be restored before a child with oppositional defiant disorder can make more positive responses to external control. Parent–child conflict strongly predicts conduct problems; patterns of harsh physical and verbal punishment particularly evoke the emergence of aggression in children. Replacing harsh, punitive parenting and increasing positive parent–child interactions may positively influence the course of oppositional and defiant behaviors.

**REFERENCES**

31.12e Conduct Disorder

Aggressive patterns of behavior are among the most frequent reasons for children and adolescents to be referred for psychiatric intervention. Although demonstration of impulsive behaviors is developmentally normative in children, many youth who continue to display excessive patterns of aggression in middle childhood generally require intervention. Children who develop enduring patterns of aggressive behaviors that begin in early childhood and violate the basic rights of peers and family mem- bers, however, may be destined for an entrenched maintenance of conduct disordered behaviors over time. Controversy remains as to whether a set of "voluntary" behaviors can constitute a valid psychiatric disorder, or may be better accounted for as maladaptive responses to adverse events, harsh or punitive par- enting, or a threatening environment. Longitudinal studies have demonstrated that, for some youth, early patterns of disruptive behavior may become a lifelong pervasive repertoire culmi- nating in adult antisocial personality disorder. The etiology of enduring patterns of aggressive behavior is widely accepted as a convergence of multiple contributing factors, including biologi- cal, temperamental, learned, and psychological conditions. Risk factors for the development of aggressive behavior in youth include childhood maltreatment such as physical or sexual abuse, neglect, emotional abuse, and overly harsh and punitive parenting. Chronic exposure to violence in the media including television, video games, and music videos has been shown to promote lower levels of empathy in children, which may add a risk factor for the development of aggressive behavior.

Conduct disorder is an enduring set of behaviors in a child or adolescent that evolves over time, usually characterized by aggression and violation of the rights of others. Youth with conduct disorder often demonstrate behaviors in the following four categories: physical aggression or threats of harm to people, destruction of the people's own property or that of others, theft or acts of deceit, and frequent violation of age-appropriate rules. Conduct disorder is associated with many other psychiatric dis- orderings including ADHD, depression, and learning disorders. It is also associated with certain psychosocial factors, including childhood maltreatment, harsh or punitive parenting, family discord, lack of appropriate parental supervision, lack of social competence, and low socioeconomic level. The American Psy- chiatric Association's DSM-5 criteria require three persistent specific behaviors of 15 conduct disorder symptoms listed, over the past 12 months, with at least one of them present in the past 6 months (Table 31.12e-1). Conduct disorder symptoms include bullying, threatening, or intimidating others, and staying out at night despite parental prohibition. DSM-5 also specifies that when truancy from school is a symptom, it begins before 13 years of age. The disorder may be diagnosed in a person older than 18 years only if the criteria for antisocial personality disorder are not met. DSM-5 includes specifiers denoting the severity of the disorder, including "mild" in which there are few conduct problems in excess of those needed to make the diagnosis and behaviors cause only minor harm to others. In "moderate" cases, symptoms exceed the minimum; however, there is less confronta- tion that may cause harm to individuals than in "severe" cases. According to DSM-5, the "severe" level shows many conduct problems in excess of the minimal diagnostic criteria or conduct problems that cause considerable harm to others. DSM-5 has also added the following specifier: "With limited prosocial emo- tions." To qualify for this specifier, the individual must show a persistent interpersonal and emotional pattern that can be charac- terized by at least two of the following: (1) Lack of remorse or guilt, (2) callous lack of empathy, (3) unconcerned about performance, (4) shallow or deficit affect. Individuals with conduct disorder who qualify for this specifier are more likely to have childhood-onset type and meet the criteria for a "severe" disor- der. Children with conduct disorder engage in severe repeated acts of aggression that can cause physical harm to themselves and others and frequently violate the rights of others. Children with conduct disorder usually have behaviors characterized by aggression to persons or animals, destruction of property, deceitfulness or theft, and multiple violations of rules, such as truancy from school. These behavior patterns cause distinct dif- ficulties in school life as well as in peer relationships. Conduct disorder has been divided into three subtypes, based on the age of onset of the disorder. Childhood-onset subtype, in which at least one symptom has emerged repeatedly before age 10 years; Adolescent-onset type, in which no characteristic persistent symptoms were seen until after age 10 years; and Unspecified- onset, in which age of onset is unknown. Although some young children show persistent patterns of behavior consistent with violating the rights of others or destroying property, the diagno- sis of conduct disorder in children appears to increase with age. Epidemiological surveys indicate that geographic locations repre- senting a broad range of different cultures are not associated
with significant variability in prevalence rates of either oppositional defiant disorder or conduct disorder. A longitudinal study of population density and antisocial behaviors in youth found no relationship in children 4 to 13 years of age between conduct problems and density of living area. However, higher rates of conduct problems were self-reported by youth 10 years to 17 years who lived in higher-density communities.

**EPIDEMIOLOGY**

Estimated prevalence rates of conduct disorder in the United States range from 6 to 16 percent for males, and from 2 to 9 percent for females. Ratio of conduct disorder in males compared to females ranges from 4:1 to as much as 12:1. Conduct disorder occurs with greater frequency in the children of parents with antisocial personality disorder and alcohol dependence than in the general population. The prevalence of conduct disorder and antisocial behavior is associated with socioeconomic factors, as well as parental psychopathology.

**Etiology**

A meta-analysis of longitudinal studies indicates that the most important risk factors that predict conduct disorder include impulsivity, physical or sexual abuse or neglect, poor parental supervision and harsh and punitive parental discipline, low intelligence quotient (IQ), and poor school achievement.

### Parental Factors

Harsh, punitive parenting characterized by severe physical and verbal aggression is associated with the development of children’s maladaptive aggressive behaviors. Chaotic home conditions are associated with conduct disorder and delinquency. Divorce itself is not necessarily a risk factor, but the persistence of hostility, resentment, and bitterness between divorced parents may be the more important contributor to maladaptive behavior. Parental psychopathology, child abuse, and negligence often contribute to conduct disorder. Sociopathy, alcohol dependence, and substance abuse in the parents are associated with conduct disorder in their children. Parents may be so negligent that a child’s care is shared by relatives or assumed by foster parents. Many such parents were scarred by their own upbringing and tend to be abusive, negligent, or engrossed in getting their own personal needs met.

Studies indicate that parents of children with conduct disorder have high rates of serious psychopathology, including psychotic disorders. Data shows that children who exhibit a pattern of aggressive behavior have frequently been exposed to physically or emotionally harsh parenting.

### Genetic Factors

A study of more than 6,000 male, female, and opposite sex twins found that genetic and environmental factors accounted for proportionally the same amount of variance in males and females. Genetic, and/or shared environmental factors exert different effects on males and females in childhood conduct disorder, but by adulthood, the gender-specific influences on antisocial behavior are no longer apparent. The sex-specific effects on antisocial behavior in youth along with the replicated finding of a potential role for the X-linked monoamine oxidase A gene in the etiology of antisocial behavior leads to the need for further genetic investigation of conduct disorder on the X chromosome and for analyses of these behaviors to be done separately by gender.

### Sociocultural Factors

Youth residing in geographic areas with greater population density report increased rates of aggression and delinquency. Unemployed parents, lack of a supportive social network, and lack of positive participation in community activities seem to predict conduct disorder. Associated findings that may influence the development of conduct disorder in urban areas are increased exposure to and prevalence of substance use. A survey of alcohol use and mental health in adolescents found that weekly alcohol use among adolescents is associated with increased delinquent and aggressive behavior. Significant interactions between frequent alcohol use and age indicated that those adolescents with weekly alcohol use at younger ages were most likely to exhibit aggressive behaviors and mood disorders. Although drug and alcohol use does not cause conduct disorder, it increases the risks associated with it. Drug intoxication itself can also aggravate the symptoms. Thus, all factors that increase the likelihood of regular substance use may, in fact, promote and expand the disorder.

### Psychological Factors

Poor emotion regulation among youth is associated with higher rates of aggression and conduct disorder. Emotion regulation is associated with social competence and can be observed even in children of preschool age. Those children with greater degrees of emotion dysregulation exhibit higher levels of aggression. Poor modeling of impulse control and the chronic lack of having their own needs met leads to a less well-developed sense of empathy.

### Neurobiological Factors

Neuroimaging studies utilizing MRI have used voxel-based morphometry methods to compare structural brain differences between children with conduct disorder compared to normal controls. Studies have reported that children with conduct disorder had decreased gray matter in limbic brain structures, and in the bilateral anterior insula and left amygdala compared to healthy controls. A study investigated structural brain differences in children comorbid for oppositional defiant disorder or conduct disorder and ADHD compared to those with ADHD alone, and normal controls. Findings included decreased gray matter in ADHD and ADHD comorbid for oppositional defiant disorder or conduct disorder compared to controls in regions including bilateral temporal and occipital cortices, and the left amygdala.

Neurotransmitter studies in children with conduct disorder suggest low level of plasma dopamine β-hydroxylase, an enzyme that converts dopamine to norepinephrine, leading to a hypothesis of decreased noradrenergic functioning in conduct disorder. Other studies of conduct-disordered juvenile offenders...
### A. Aggression to People and Animals
1. Often bullies, threatens, or intimidates others.
2. Often initiates physical fights.
3. Has used a weapon that can cause serious physical harm to others (e.g., a bat, brick, broken bottle, knife, gun).
4. Has been physically cruel to people.
5. Has been physically cruel to animals.
6. Has stolen while confronting a victim (e.g., mugging, purse snatching, extortion, armed robbery).
7. Has forced someone into sexual activity.

### B. Destruction of Property
8. Has deliberately engaged in fire setting with the intention of causing serious damage.
9. Has deliberately destroyed others’ property (other than by fire setting).

### C. Deceitfulness or Theft
10. Has broken into someone else’s house, building, or car.
11. Often lies to obtain goods or favors or to avoid obligations (i.e., “cons” others).
12. Has stolen items of nontrivial value without confronting a victim (e.g., shoplifting, but without breaking and entering: forgery).

### D. Serious Violations of Rules
13. Often stays out a night despite parental prohibitions, beginning before age 13 years.
14. Has run away from home overnight at least twice while living in the parental or parental surrogate home, or once without returning for a lengthy period.
15. Is often truant from school, beginning before age 13 years.

### E. The disturbance in behavior causes clinically significant impairment in social, academic, or occupational functioning.

### F. If the individual is age 18 years or older, criteria are not met for antisocial personality disorder.

#### Specify whether:

<table>
<thead>
<tr>
<th>Code</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>311.81 (F91.1)</td>
<td>Childhood-onset type: Individuals show at least one symptom characteristic of conduct disorder prior to age 10 years.</td>
</tr>
<tr>
<td>311.82 (F91.2)</td>
<td>Adolescent-onset type: Individuals show no symptom characteristic of conduct disorder prior to age 10 years.</td>
</tr>
<tr>
<td>311.89 (F91.9)</td>
<td>Unspecified onset: Criteria for a diagnosis of conduct disorder are met, but there is not enough information available to determine whether the onset of the first symptom was before or after age 10 years.</td>
</tr>
</tbody>
</table>

#### Specify if:

| With limited prosocial emotions: Qualify for this specifier, an individual must have displayed at least two of the following characteristics persistently over at least 12 months and in multiple relationships and settings. These characteristics reflect the individual’s typical pattern of interpersonal and emotional functioning over this period and not just occasional occurrences in some situations. Thus to assess the criteria for the specifier, multiple information sources are necessary. In addition to the individual’s self-report, is necessary to consider reports by others who have known the individual for extended periods of time (e.g., parents, teachers, co-workers, extended family members, peers). |
| Lack of remorse or guilt: Does not feel bad or guilty when he or she does something wrong (exclude remorse when expressed only when caught and/or facing punishment). The individual shows a general lack of concern about the negative consequences of his or her actions. For example, the individual is not remorseful after hurting someone or does not care about the consequences of breaking rules. |
| Callous – lack of empathy: Disregards and is unconcerned about the feelings of others. The individual is described as cold and uncaring. The person appears more concerned about the effects of his or her actions on himself or herself, rather than their effects on others, even when they result in substantial harm to others. |
| Unconcerned about performance: Does not show concern about poor/problematic performance at school, at work, or in other important activities. The individual does not put forth the effort necessary to perform well, even when expectations are clear, and typically blames others for his or her poor performance. |
| Shallow of deficient affect: Does not express feelings or show emotions to others, except in ways that seem shallow, insincere, or superficial (e.g., actions contradict the emotion displayed; can turn emotions “on” or “off” quickly) or when emotional expressions are used for gain (e.g., emotions displayed to manipulate or intimidate others). |

#### Specify current severity:

| Mild: Few if any conduct problems in excess of those required to make the diagnosis are present, and conduct problems cause relatively minor harm to others (e.g., lying, truancy, staying out after dark without permission, other rule breaking). |
| Moderate: The number of conduct problems and the effect on others are intermediate between those specified in “mild” and those in “severe” (e.g., stealing without confronting a victim, vandalism). |
| Severe: Many conduct problems in excess of those required to make the diagnosis are present, or conduct problems cause considerable harm to others (e.g., forced sex, physical cruelty, use of a weapon, stealing while confronting a victim, breaking and entering). |

have found high plasma serotonin levels in blood. Evidence indicates that blood serotonin levels correlate inversely with levels of 5-HIAA in the cerebrospinal fluid (CSF) and that low 5-HIAA levels in CSF correlate with aggression and violence.

**Neurologic Factors**

An electroencephalography (EEG) study investigating resting frontal brain electrical activity, emotional intelligence, aggression, and rule breaking in 10-year-old children found that aggressive children had significantly greater relative right frontal brain activity at rest compared with nonaggressive children. Frontal resting brain electrical activity has been hypothesized to reflect the ability to regulate emotion. Boys tended to show lower emotional intelligence than girls and greater aggressive behavior than girls. No relationship, however, was found between emotional intelligence and pattern of frontal EEG activation.

**Child Abuse and Maltreatment**

Evidence shows that children chronically exposed to violence, physical or sexual abuse, and neglect, particularly at a young age, are at high risk for demonstrating aggression. A study of female caregivers exposed to intimate partner violence revealed a strong association with offspring aggression and mood disturbance. Severely abused children and adolescents tend to be hypervigilant; in some cases, they misperceive benign situations as directly threatening and respond defensively with violence. Not all expressed aggressive behavior in adolescents is synonymous with conduct disorder; however, youth with a repetitive pattern of hypervigilance and violent responses are likely to violate the rights of others.

**Comorbid Factors**

ADHD and conduct disorder are often found to coexist, with ADHD often predating the development of conduct disorder, and not infrequently substance abuse. Central nervous system injury, dysfunction, or damage predispose a child to impulsivity and behavioral disturbances, which sometimes evolve into conduct disorder.

**DIAGNOSIS AND CLINICAL FEATURES**

Conduct disorder does not develop overnight, instead, many symptoms evolve over time until a consistent pattern develops that involves violating the rights of others. Very young children are unlikely to meet the criteria for the disorder, because they are not developmentally able to exhibit the symptoms typical of older children with conduct disorder. A 3-year-old does not break into someone's home, steal with confrontation, force someone into sexual activity, or deliberately use a weapon that can cause serious harm. School-age children, however, can become bullies, initiate physical fights, destroy property, or set fires. The DSM-5 diagnostic criteria for conduct disorder are given in Table 31.12e.

The average age of onset of conduct disorder is younger in boys than in girls. Boys most commonly meet the diagnostic criteria by 10 to 12 years of age, whereas girls often reach 14 to 16 years of age before the criteria are met.

Children who meet the criteria for conduct disorder express their overt aggressive behavior in various forms. Aggressive antisocial behavior can take the form of bullying, physical aggression, and cruel behavior toward peers. Children may be hostile, verbally abusive, impudent, defiant, and negativistic toward adults. Persistent lying, frequent truancy, and vandalism are common. In severe cases, destructiveness, stealing, and physical violence often occur. Some adolescents with conduct disorder make little attempt to conceal their antisocial behavior. Sexual behavior and regular use of tobacco, liquor, or illicit psychoactive substances begin unusually early for such children and adolescents. Suicidal thoughts, gestures, and acts are frequent in children and adolescents with conduct disorder who are in conflict with peers, family members, or the law and are unable to problem solve their difficulties.

Some children with aggressive behavioral patterns have impaired social attachments, as evinced by their difficulties with peer relationships. Some may befriend a much older or younger person or have superficial relationships with other antisocial youngsters. Many children with conduct problems have poor self-esteem, although they may project an image of toughness. They may lack the skills to communicate in socially acceptable ways and appear to have little regard for the feelings, wishes, and welfare of others. Children and adolescents with conduct disorders often feel guilt or remorse for some of their behaviors, but try to blame others to stay out of trouble.

Many children and adolescents with conduct disorder suffer from the deprivation of having few of their dependency needs met and may have had either overly harsh parenting or a lack of appropriate supervision. The deficient socialization of many children and adolescents with conduct disorder can be expressed in physical violation of others and, for some, in sexual violation of others. Severe punishments for behavior in children with conduct disorder almost invariably increases their maladaptive expression of rage and frustration rather than ameliorating the problem.

In evaluation interviews, children with aggressive conduct disorders are typically uncooperative, hostile, and provocative. Some have a superficial charm and compliance until they are urged to talk about their problem behaviors. Then, they often deny any problems. If the interviewer persists, the child may attempt to justify misbehavior or become suspicious and angry about the source of the examiner's information and perhaps bolt from the room. Most often, the child becomes angry with the examiner and expresses resentment of the examination with open belligerence or sullen withdrawal. Their hostility is not limited to adult authority figures, but is expressed with equal venom toward their age-mates and younger children. In fact, they often bully those who are smaller and weaker. By boasting, lying, and expressing little interest in a listener's responses, such children reveal their lack of trust in adults to understand their position.

Evaluation of the family situation often reveals severe marital disharmony, which initially may center on disagreements about management of the child. Because of a tendency toward family instability, parent surrogates are often in the picture. Children with conduct disorder are more likely to be unplanned or unwanted babies. The parents of children with conduct disorder, especially the father, have higher rates of antisocial personality disorder or alcohol dependence. Aggressive children
and their family show a stereotyped pattern of impulsive and unpredictable verbal and physical hostility. A child's aggressive behavior rarely seems directed toward any definable goal and offers little pleasure, success, or even sustained advantages with peers or authority figures.

In other cases, conduct disorder includes repeated truancy, vandalism, and serious physical aggression or assault against others by a gang, such as mugging, gang fighting, and beating. Children who become part of a gang usually have the skills for age-appropriate friendships. They are likely to show concern for the welfare of their friends or their own gang members and are unlikely to blame them or inform on them. In most cases, gang members have a history of adequate or even excessive conformity during early childhood that ended when the youngster became a member of the delinquent peer group, usually in preadolescence or during adolescence. Also present in the history is some evidence of early problems, such as marginal or poor school performance, mild behavior problems, anxiety, and depressive symptoms. Some family social or psychological pathology is usually evident. Patterns of paternal discipline are rarely ideal and can vary from harshness and excessive strictness to inconsistency or relative absence of supervision and control. The mother has often protected the child from the consequences of early mild misbehavior, but does not seem to encourage delinquency actively. Delinquency, also called juvenile delinquency, is most often associated with conduct disorder but can also result from other psychological or neurological disorders.

Violent Video Games and Violent Behavior

Longitudinal studies corroborate the contribution of media violence including video gaming in middle-school children with the expression of aggression in those adolescents. A review of the literature of the effect of violent video games on children and adolescents revealed that violent video game playing is related to aggressive affect, physiologic arousal, and aggressive behaviors. It stands to reason that the degree of exposure to violent games and the more restriction of activity would be related to a greater preoccupation with violent themes.

PATHOLOGY AND LABORATORY EXAMINATION

No specific laboratory test or neurological pathology helps make the diagnosis of conduct disorder. Some evidence indicates that amounts of certain neurotransmitters, such as serotonin in the CNS, are low in some persons with a history of violent or aggressive behavior toward others or themselves. Whether this association is related to the cause, or is the effect, of violence or is unrelated to the violence is not clear.

DIFFERENTIAL DIAGNOSIS

Disturbances of conduct, including impulsivity and aggression, may occur in many childhood psychiatric disorders, ranging from ADHD, to oppositional defiant disorder, to disruptive mood dysregulation disorder mood disorder, to major depression, to bipolar disorder, specific learning disorders, and psychotic disorders. Therefore, clinicians must obtain a comprehensive history of the chronology of the symptoms to determine whether the conduct disturbance is a transient or an enduring pattern. Isolated acts of aggressive behavior do not justify a diagnosis of conduct disorder; an entrenched pattern must be present. The relationship of conduct disorder to oppositional defiant disorder is still under debate. Historically, oppositional defiant disorder has been conceptualized as a mild precursor of conduct disorder, without the violation of rights, likely to be diagnosed in younger children who may be at risk for conduct disorder. Children who progress from oppositional defiant disorder to conduct disorder over time, maintain their oppositional characteristics, and some evidence indicates that the two disorders are independent. Currently, in the DSM-5, oppositional defiant disorder and conduct disorder are considered distinct, and they may be diagnosed comorbidly. Many children with oppositional defiant disorder do not develop conduct disorder, and conduct disorder emerging in adolescence is not necessarily preceded by oppositional defiant disorder. The main distinguishing clinical feature between these two disorders is that in conduct disorder, the basic rights of others are violated, whereas in oppositional defiant disorder, hostility and negativism fall short of seriously violating the rights of others.

Mood disorders are often present in children who exhibit irritability and aggressive behavior. Both major depressive disorder and bipolar disorders must be ruled out, but the full syndrome of conduct disorder can occur and be diagnosed during the onset of a mood disorder. Substantial comorbidity exists of conduct disorder and depressive disorders. A recent report concludes that the high correlation between the two disorders arises from shared risk factors for both disorders rather than a causal relation. Thus, a series of factors, including family conflict, negative life events, early history of conduct disturbance, level of parental involvement, and affiliation with delinquent peers, contribute to the development of affective disorders and conduct disorder. This is not the case with oppositional defiant disorder, which cannot be diagnosed if it occurs exclusively during a mood disorder.

ADHD and learning disorders are commonly associated with conduct disorder. Usually, the symptoms of these disorders predate the diagnosis of conduct disorder. Substance abuse disorders are also more common in adolescents with conduct disorder than in the general population. Evidence indicates an association between fighting behaviors as a child and substance use as an adolescent. Once a pattern of drug use is formed, this pattern may interfere with the development of positive mediators, such as social skills and problem-solving, which could enhance remission of the conduct disorder. Thus, once substance abuse develops, it may promote continuation of the conduct disorder. Obsessive-compulsive disorder also frequently seems to coexist with disruptive behavior disorders. All the disorders described here should be noted when they co-occur. Children with ADHD often exhibit impulsive and aggressive behaviors that may not meet the full criteria for conduct disorder.

Damien, age 12 years, was referred for psychiatric evaluation after being picked up by police for truancy, and running away from home. Damien explained that he just wanted to get out of his house and go see his friends. He doesn’t like to be at home because his mother tries to tell him what to do. Damien’s mother says that he...
left and stayed out overnight multiple times in the past year, but that he usually returns the next morning. She complains that he is constantly in trouble. He has shoplifted on several occasions that she knows of, the first time at age 8 years. She suspects that he also steals from neighbors or school. The police have been involved on many occasions including truancy, staying out all night, stealing from a neighborhood store, and smoking marijuana. Damien has a quick temper, and his mother knows he was involved in several fights over the past year in the neighborhood. Damien is particularly cruel to his younger brother, constantly taunting and teasing him. Damien’s mother stated that he lies constantly, sometimes for no apparent reason. When he was 6 years of age, he was fascinated with fire and set several small fires at home, fortunately with no serious injury or damage. Damien’s mother was fearful when she disclosed that Damien is just like his no-good father and that she wished she never had him. Damien initially refused to answer questions, and turned away scowling, but gradually began to talk. Damien presented a tough image with an indifferent attitude toward the interviewer. Damien denied any abuse at home, saying that he ran off because he was bored. However, upon further questioning, Damien admitted that his mother’s previous boyfriend who was in the home when Damien was between 6 and 8 years of age used to hit him with a belt when he got out of line. Damien justified his own behaviors as just having fun. He explained the fights as being provoked by the others and denied the use of any weapons, although he bragged about breaking the nose of another youth. Damien’s school records indicate that an Individualized Educational Plan (IEP) was required when he was in the 2nd grade, and he was evaluated for symptoms of ADHD when he was in 1st grade. Methylphenidate (Ritalin) was prescribed; however, the family did not continue with treatment, and he is currently on no medication. Damien is currently in 6th grade special education classes, having failed and repeated 5th grade. Damien’s grades are failing, and he may have to repeat 6th grade. Damien admits to truancy on several occasions this year in addition to his problems with completing schoolwork. His previous evaluation indicates that child protective services evaluated the family for possible neglect when he was 5 years of age after he and his brother were found barefoot on the street late one evening without his mother in sight. Apparently, Damien’s family was referred for counseling and never attended. Both of Damien’s parents have a history of drug and alcohol abuse. Damien’s birth was unplanned, and his mother used drugs during pregnancy. His parents separated soon after his birth, and his mother returned to live with her parents briefly. Damien and his mother moved to live with her boyfriend when Damien was 1 year of age after she became pregnant with his younger sister. Damien’s mother’s relationship ended within a year, and only Damien, his mother, and his sister live in their apartment. Damien’s mother has worked several different jobs, and Damien wonders if she has a drinking problem.

**COURSE AND PROGNOSIS**

The course and prognosis for children with conduct disorder is most guarded in those who have symptoms at a young age, exhibit the greatest number of symptoms, and the most severe, and express them most frequently. This finding is true partly because those with severe conduct disorder seem to be most vulnerable to comorbid disorders later in life, such as mood disorders and substance use disorders. A longitudinal study found that, although assaultive behavior in childhood and parental criminality predict a high risk for incarceration later in life, the diagnosis of conduct disorder per se was not correlated with imprisonment. The best prognosis is predicted for mild conduct disorder in the absence of coexisting psychopathology and the presence of normal intellectual functioning.

**TREATMENT**

**Psychosocial Interventions**

Early sustained preventive interventions can significantly alter the course and prognosis of aggressive behavior when it is administered starting at kindergarten age. A screening program used with kindergarteners predicted lifetime disruptive behavior disorder by age 18 years, with the highest risk group demonstrating an 82 percent chance of a disruptive behavior diagnosis without intervention. A prevention program, the Fast Track Preventive Intervention, randomized 891 kindergartners to either a 10-year prevention program or a control condition. The 10-year intervention included parent behavior management, child social cognitive skills, reading, home visiting, mentoring, and classroom curricula. The children in the Fast Track Intervention were substantially prevented from the development of conduct disorder during the 10-year period and for 2 years thereafter.

A meta-analysis of controlled trials of CBT programs indicates that CBT can result in significant reductions in conduct-disordered symptoms in children and adolescents. CBT treatment interventions that are proven to be efficacious include the following.

Kazdin’s Problem-Solving Skills Training (PSST) in which a 12-week sequential program helps children develop problem-solving solutions when faced with conflictual situations. Assignments called “supersolvers” provide vignette situations in which children can practice these techniques. A companion program, Parent Management Training (PMT) can be added to the intervention, but PSST can be effective even without the parent component. Another CBT-based intervention, the Incredible Years (IY), targeting young children from 3 to 8 years, is administered over 22 weeks and delivers sessions to the child and has a parent training component and a teacher training. Another CBT-based intervention is the Anger Coping Program, an 18-session intervention for school-aged children in the grades 4 to 6 focused on a child’s increased development of emotion recognition and regulation, and managing anger. Anger coping strategies include distraction, self-talk, perspective taking, goal setting, and problem solving.

Overall, treatment programs have been more successful in decreasing overt symptoms of conduct, such as aggression, than the covert symptoms, such as lying or stealing. Treatment strategies for young children that focus on increasing social behavior and social competence are believed to reduce aggressive behavior. A study of 548 third graders administered a school-based intervention instead of a regular health curriculum in several public schools in North Carolina, called Making Choices: Social Problem Solving Skills for Children (MC) program along with supplemental teacher and parent components. Compared with third graders receiving the routine health curriculum, children exposed to the MC program were rated lower on the posttest social and overt aggression, and higher on social competence. In addition, they scored higher on an information-processing skills posttest. These findings support the notion that school-based prevention programs have the potential to strengthen social and
emotional skills and diminish aggressive behavior among normal populations of school-age children. School settings can also use behavioral techniques to promote socially acceptable behavior toward peers and to discourage covert antisocial incidents.

Psychopharmacologic Interventions

Efficacy of psychopharmacologic interventions includes several placebo-controlled studies of risperidone for aggression in youth associated with disruptive behavior disorders, and/or mental retardation. In addition, risperidone has been found to be superior to placebo in reducing aggressive behavior in a large 6-month placebo-substitution study. One randomized double-blind placebo-controlled trial with quetiapine also showed efficacy for aggressive behavior. Early studies of antipsychotics, most notably haloperidol (Haldol), reported decreased aggressive and assaultive behaviors in children with a variety of psychiatric disorders. Atypical antipsychotics risperidone (Risperdal), olanzapine (Zyprexa), quetiapine (Seroquel), ziprasidone (Geodon), and aripiprazole (Abilify) have generally replaced the older antipsychotics in clinical practice due to their comparable efficacy and improved side effect profiles. Side effects of second-generation antipsychotics include sedation, increased prolactin levels, (with risperidone use) and extrapyramidal symptoms, including akathisia. In general, however, the atypical antipsychotics appear to be well tolerated. A study of divalproex in youth with conduct disorder showed that those who responded most robustly exhibited aggression characterized by agitation, dysphoria, and distress. Although early trials suggested that carbamazepine (Tegretol) was useful to control aggression, a double-blind, placebo-controlled study did not show superiority of carbamazepine over placebo in decreasing aggression. A pilot study found that clonidine (Catapres) may decrease aggression. The SSRIs, including fluoxetine (Prozac), sertraline (Zoloft), paroxetine (Paxil), and citalopram (Celexa), are used clinically to target symptoms of impulsivity, irritability, and mood lability, which frequently accompany conduct disorder. Conduct disorder often coexists with ADHD, learning disorders, and, over time, mood disorders and substance-related disorders; thus, the treatment of concurrent disorders must also be addressed.

31.13 Anxiety Disorders of Infancy, Childhood, and Adolescence

Anxiety disorders are among the most common disorders in youth, affecting 10 to 20 percent of children and adolescents. Although observable anxiety behaviors mark normative development in infants, anxiety disorders in childhood predict a wide range of psychological difficulties in adolescence including additional anxiety disorders, panic attacks, and depressive disorders. Fear is an expected response to real or perceived threat; however, anxiety is the anticipation of future danger. Anxiety disorders are characterized by recurrent emotional and physiological arousal in response to excessive perceptions of perceived threat or danger. Anxiety disorders commonly found in youth include separation anxiety disorder, generalized anxiety disorder, social anxiety disorder, and selective mutism. Anxiety is classified into disorders based on how it is experienced, the situations that trigger it, and the course that it tends to follow.

31.13a Separation Anxiety Disorder, Generalized Anxiety Disorder, and Social Anxiety Disorder (Social Phobia)

Separation anxiety disorder, generalized anxiety disorder, and social anxiety disorder in children are often considered together in the evaluation process and differential diagnosis, and in developing treatment strategies, because they are highly comorbid and have overlapping symptoms. A child with separation
Disorders, Fifth Edition

Children with generalized anxiety disorder tend to feel inappropriate and excessive anxiety emerges related to separation from their primary caregiver. Normative separation anxiety peaks between 9 months and 18 months and diminishes by about 2½ years of age, enabling young children to develop a sense of comfort away from their parents in preschool. Separation anxiety or stranger anxiety most likely evolved as a human response that has survival value. The expression of transient separation anxiety is also normal in young children entering school for the first time. Approximately 15 percent of young children display intense and persistent fear, shyness, and social withdrawal when faced with unfamiliar settings and people. Young children with this pattern of significant behavioral inhibition are at higher risk for the development of separation anxiety disorder, generalized anxiety disorder, and social phobia. Behaviorally inhibited children, as a group, exhibit characteristic physiological traits, including higher than average resting heart rates, higher morning cortisol levels than average, and low heart rate variability. Separation anxiety disorder is diagnosed when developmentally inappropriate and excessive anxiety emerges related to separation from the major attachment figure. According to the American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5), separation anxiety disorder is characterized by a level of fear or anxiety regarding separation from their parents or primary caregiver, which is beyond developmental expectations. Furthermore, there may be a pervasive worry that harm will come to a parent upon separation, which leads to extreme distress, and sometimes nightmares. The DSM-5 requires the presence of at least three symptoms related to excessive worry about separation from a major attachment figure for a period of at least 4 weeks. The worries often take the form of refusal to go to school, fears and distress on separation, repeated complaints of physical symptoms such as headaches and stomachaches when separation is anticipated, and nightmares related to separation issues.

SEPARATION ANXIETY DISORDER

Separation anxiety is a universal human developmental phenomenon emerging in infants younger than 1 year of age and marking a child’s awareness of a separation from his or her mother or primary caregiver. Normative separation anxiety peaks between 9 months and 18 months and diminishes by about 2½ years of age, enabling young children to develop a sense of comfort away from their parents in preschool. Separation anxiety or stranger anxiety most likely evolved as a human response that has survival value. The expression of transient separation anxiety is also normal in young children entering school for the first time. Approximately 15 percent of young children display intense and persistent fear, shyness, and social withdrawal when faced with unfamiliar settings and people. Young children with this pattern of significant behavioral inhibition are at higher risk for the development of separation anxiety disorder, generalized anxiety disorder, and social phobia. Behaviorally inhibited children, as a group, exhibit characteristic physiological traits, including higher than average resting heart rates, higher morning cortisol levels than average, and low heart rate variability. Separation anxiety disorder is diagnosed when developmentally inappropriate and excessive anxiety emerges related to separation from the major attachment figure. According to the American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5), separation anxiety disorder is characterized by a level of fear or anxiety regarding separation from their parents or primary caregiver, which is beyond developmental expectations. Furthermore, there may be a pervasive worry that harm will come to a parent upon separation, which leads to extreme distress, and sometimes nightmares. The DSM-5 requires the presence of at least three symptoms related to excessive worry about separation from a major attachment figure for a period of at least 4 weeks. The worries often take the form of refusal to go to school, fears and distress on separation, repeated complaints of physical symptoms such as headaches and stomachaches when separation is anticipated, and nightmares related to separation issues.

GENERALIZED ANXIETY DISORDER

Children with generalized anxiety disorder have significant distress in activities of daily life often focused on the child’s fears of incompetence in many areas, including school performance and in social settings. In addition, children with generalized anxiety disorder, according to DSM-5, experience at least one of the following symptoms: restlessness, being easily fatigued, “mind going blank,” irritability, muscle tension, or sleep disturbance. Children with generalized anxiety disorder tend to feel fearful in multiple settings and expect more negative outcomes when faced with academic or social challenges, compared with peers. Children and adolescents with generalized anxiety disorder may experience symptoms of autonomic hyperarousal such as tachycardia, shortness of breath, or dizziness, and are more likely than nonanxious youth to experience sweating, nausea, or diarrhea when they become anxious. Children and adolescents with generalized anxiety disorder tend to be overly concerned about potential natural disasters such as earthquakes or floods, and these worries can interfere with their daily activities. Finally, children and adolescents with generalized anxiety disorder are continuously worried about the quality of their performance in academics, sports, and other activities, and often seek excessive reassurance about their performance.

SOCIAL ANXIETY DISORDER (SCHOL PHOBIA)

Children who experience intense discomfort and distress in social situations and are impaired by their fear of scrutiny or humiliation are given the diagnosis of social anxiety disorder. Their distress may be expressed in the form of crying, tantrums, avoidance, freezing, or even becoming “mute” in these situations. According to DSM-5, this disorder is characterized by consistent anxiety and distress in almost all social situations. Any situation in which the child feels exposed to possible scrutiny by others can provoke fear or anxiety, and the child will often try to avoid these feared social situations. Children must experience the anxiety in the presence of peers, not only with adults, in order to receive the diagnosis. A child or adolescent with social anxiety disorder may exhibit the performance only type, which targets a specific type of performing, such as fear of public speaking. The performance only type typically manifests in school or academic settings in which public presentations must be performed, such as in front of classmates in school.

Social anxiety disorder has significant implications for future accomplishments, since it is associated with lower levels of satisfaction in leisure activities, increased rates of school dropout, less productivity in the workplace as adults, and increased rates of remaining single. Despite the significant impairment caused by social anxiety disorder, up to half of individuals with the disorder do not receive treatment.

EPIDEMIOLOGY

The prevalence of anxiety disorders has varied with the age group of the children surveyed and the diagnostic instruments used. Lifetime prevalence of any anxiety disorder in children and adolescents ranges from 10 percent to 27 percent. Anxiety disorders are common in preschoolers as well, and follow a similar epidemiologic profile as in older children. An epidemiologic survey using the Preschool Age Psychiatric Assessment (PAPA) found that 9.5 percent of preschoolers met criteria for any anxiety disorder, with 6.5 percent exhibiting generalized anxiety disorder, 2.4 percent meeting criteria for separation anxiety disorder, and 2.2 percent meeting criteria for social phobia. Separation anxiety disorder is estimated to be about 4 percent in children and young adolescents. Separation anxiety disorder is more common in young children than in adolescents and has been reported to occur equally in boys and girls. The onset may
occur during preschool years, but is most common in children 7 to 8 years of age. The rate of generalized anxiety disorder in school-age children is estimated to be approximately 3 percent, the rate of social phobia is 1 percent, and the rate of simple phobias is 2.4 percent. In adolescents, lifetime prevalence for panic disorder was found to be 0.6 percent; the prevalence for generalized anxiety disorder was 3.7 percent.

**ETIOLOGY**

**Biopsychosocial Factors**

Evidence for the influences of parental psychopathology and parenting styles on the emergence of anxiety disorders in childhood has been found in multiple investigations. Longitudinal studies have found that parental overprotection has been associated with an increased risk of the development of anxiety disorders in children, and insecure parent–child attachment is associated with higher than expected rates of anxiety disorders in childhood. It is also well known that maternal depression and anxiety have led to an increased risk for anxiety and depression in children. Psychosocial factors in conjunction with a child’s temperament influence the degree of separation anxiety evoked in situations of brief separation and exposure to unfamiliar environments. The temperamental trait of shyness and withdrawal in unfamiliar situations has been shown to be associated with a higher risk of developing separation anxiety disorder, generalized anxiety disorder, social anxiety disorder, or all three during childhood and adolescence.

External life stresses often coincide with development of the disorder. The death of a relative, a child’s illness, a change in a child’s environment, or a move to a new neighborhood or school is frequently noted in the histories of children with separation anxiety disorder. In a vulnerable child, these changes probably intensify anxiety.

Neurophysiological correlations are found with behavioral inhibition (extreme shyness); children with this constellation are shown to have a higher resting heart rate and an acceleration of heart rate with tasks requiring cognitive concentration. Additional physiological correlates of behavioral inhibition include elevated salivary cortisol levels, elevated urinary catecholamine levels, and greater pupillary dilation during cognitive tasks.

Neuroimaging studies of adolescents with anxiety show an increased activation of the amygdala compared to non-anxious adolescents when presented with anxiety-provoking stimuli. Furthermore, anxious adolescents maintain the hyperactivation of the amygdala over time, rather than showing an attenuation of the effect as in nonanxious adolescents. Structural studies of the amygdala in adolescents with anxiety have led to conflicting results, some studies finding increased amygdala volumes, whereas other studies finding decreased amygdala volumes.

**Social Learning Factors**

Fear, in response to a variety of unfamiliar or unexpected situations, may be unwittingly communicated from parents to children by direct modeling. If a parent is fearful, the child will probably have a phobic adaptation to new situations, especially to a school environment. There are much data to suggest that overprotective parenting promotes increased interpersonal sensitivity in healthy children, and increases the risk of social anxiety disorder in children with behavioral inhibition or other anxiety disorders such as separation anxiety disorder. Some parents appear to teach their children to be anxious by overprotecting them from expected dangers or by exaggerating the dangers. For example, a parent who cringes in a room during a lightning storm teaches a child to do the same. A parent who is afraid of mice or insects conveys the affect of fright to a child. Conversely, a parent who becomes angry with a child when the child expresses fear of a given situation, for example, when exposed to animals, may promote a phobic concern in the child by exposing the child to the intensity of the anger expressed by the parent. Social learning factors in the development of anxiety reactions are magnified when parents have anxiety disorders themselves. These factors may be pertinent in the development of separation anxiety disorder as well as in generalized anxiety disorder and social phobia. A recent study found no association between psychosocial hardships, such as ongoing family conflict, and behavioral inhibition among young children. It appears that temperamental predisposition to anxiety disorders emerges as a highly heritable constellation of traits, and is not created by psychosocial stressor.

**Genetic Factors**

Genetic studies suggest that genes account for at least one third of the variance in the development of anxiety disorders. Heritability for anxiety disorders in children and adolescents ranges from 36 percent to 65 percent, with the highest estimates found in younger children with anxiety disorders. Two heritable characteristics—behavioral inhibition (the tendency toward fear and withdrawal in new situations) and physiological hyperarousal—have both been found to impart significant risk factors for future development of an anxiety disorder. However, although the temperamental constellation of behavioral inhibition, excessive shyness, the tendency to withdraw from unfamiliar situations, and the eventual emergence of anxiety disorders have a genetic contribution, one third to two thirds of young children with behavioral inhibition do not appear to go on to develop anxiety disorders.

Family studies have shown that the offspring of adults with anxiety disorders are at an increased risk of having an anxiety disorder themselves. Separation anxiety disorder and depression in children overlap, and the presence of an anxiety disorder increases the risk of a future episode of a depressive disorder. Current consensus on the genetics of anxiety disorders suggests that what is inherited is a general predisposition toward anxiety, causing heightened levels of arousal, emotional reactivity, and increased negative affect, all of which increase the risk of developing separation anxiety disorder, generalized anxiety disorder, and social phobia.

**DIAGNOSIS AND CLINICAL FEATURES**

Separation anxiety disorder, generalized anxiety disorder, and social phobia are highly related in children and adolescence because, in most children, overlapping symptoms as well as comorbid disorders emerge. Generalized anxiety disorder is the most common anxiety disorder among youth, more common in adolescents than in younger children; in almost one third
of these cases, a child with generalized anxiety disorder also exhibits separation anxiety disorder and social anxiety disorder.

Diagnostic criteria for separation anxiety disorder, according to the DSM-5, include three of the following symptoms for at least 4 weeks: persistent and excessive worry about losing, or possible harm befalling, major attachment figures; persistent and excessive worry that an untoward event can lead to separation from a major attachment figure; persistent reluctance or refusal to go to school or elsewhere because of fear of separation; persistent and excessive fear or reluctance to be alone or without major attachment figures at home or without significant adults in other settings; persistent reluctance or refusal to go to sleep without being near a major attachment figure or to sleep away from home; repeated nightmares involving the theme of separation; repeated complaints of physical symptoms, including headaches and stomachaches, when separation from major attachment figures is anticipated; and recurrent excessive distress when separation from home or major attachment figures is anticipated or involved. The following case history demonstrates separation anxiety disorder along with autonomic arousal symptoms.

Jake was a 9-year-old boy who was referred for outpatient evaluation by his family physician. He refused to sleep in his room alone at night and exhibited violent tantrums each morning in order to avoid going to school. Jake expressed recurrent fears that something bad would happen to his mother. He worried that she would get into a car accident or that there would be a fire at home and his mother would be killed. Developmental history revealed that Jake was anxious and irritable as an infant and toddler. He had trouble adjusting to babysitters in the preschool years. There was a history of panic disorder, with agoraphobia in the mother and major depression in his father. Jake became more concerned and territorial over his mother when his father left the family, and his mother became depressed. Jake always kept track of his mother's whereabouts and insisted that she stay at home.

Nighttime was a particularly difficult time at home. When Jake's mother tried to get Jake to remain in his room, Jake would whine and cry and insist that his mother lie in bed with him until he fell asleep. He also expected his mother to be in the master bedroom across the hall from his room throughout the evening. Jake's mother reported that each evening her son would get up and peek through the crack in the master bedroom door, as frequently as every 10 minutes, to be certain that she was still there. Jake reported frequent nightmares that his mother was killed and that monsters prevented him from rescuing his mother, taking him away from his family forever.

During the daytime, Jake would shadow his mother around the house. Jake would agree to play a game with his sister in the lower level of the house only if his mother was close by. When Jake's mother went upstairs, he would interrupt the game and follow her upstairs. He refused to sleep at a friend's house. Frequently, at home as the evening progressed, Jake described a queasy sensation in his stomach mixed with feelings of sadness.

On school days, Jake usually complained of stomachaches and tried to stay home. Jake appeared distressed and panicky and would become violent when his mother attempted to drop him off at school. Once at school, he seemed calmer and less distressed, but frequently was seen in the nurse's office, complaining of nausea and seeking to be sent home. (Adapted from case material from Gail A. Bernstein, M.D. and Anne E. Layne, Ph.D.)

The essential feature of separation anxiety disorder is extreme anxiety precipitated by separation from parents, home, or other familiar surroundings, whereas in generalized anxiety disorder, fears are extended to negative outcomes for all kinds of events, including academic, peer relationship, and family activities. In generalized anxiety disorder, a child or adolescent experiences at least one recurrent physiological symptom, such as restlessness, poor concentration, irritability, or muscle tension. In social phobia, the child's fears peak during performance situations involving exposure to unfamiliar people or situations. Children and adolescents with social phobia have extreme concerns about being embarrassed, humiliated, or negatively judged. In each of the preceding anxiety disorders, the child's experience can approach terror or panic. The distress is greater than that normally expected for the child's developmental level and cannot be explained by any other disorder. Morbid fears, preoccupations, and ruminations characterize separation anxiety disorder. Children with anxiety disorders overestimate the probability of danger and the likelihood of negative outcome. Children with separation anxiety disorder and generalized anxiety disorder become overly fearful that someone close to them will be hurt or that something terrible will happen to them or their families, especially when they are away from important caring figures. Many children with anxiety disorders are occupied with health and worry that their families or friends will become ill. Fears of getting lost, being kidnapped, and losing the ability to be in contact with their families is predominant among children with separation anxiety disorder.

Adolescents with anxiety disorders may not directly express their worries; however, their behavior patterns often reflect either separation anxiety or other anxiety if they exhibit discomfort about leaving home, engage in solitary activities because of fears about how they will perform in front of peers, or have distress when away from their families. Separation anxiety disorder in children is often manifested at the thought of travel or in the course of travel away from home. Children may refuse to go to camp, a new school, or even a friend's house. Frequently, a continuum exists between mild anticipatory anxiety before separation from an important figure and pervasive anxiety after the separation has occurred. Premontory signs include irritability, difficulty eating, whining, staying in a room alone, clinging to parents, and following a parent everywhere. Often, when a family moves, a child displays separation anxiety by intense clinging to the mother figure. Sometimes, geographical relocation anxiety is expressed in feelings of acute homesickness or psychophysiological symptoms that break out when the child is away from home or is going to a new country. The child yearns to return home and becomes preoccupied with fantasies of how much better the old home was. Integration into the new life situation may become extremely difficult. Children with anxiety disorders may retreat from social or group activities and express feelings of loneliness because of their self-imposed isolation.

Sleep difficulties are frequent in children and adolescents with any anxiety disorder or in severe separation anxiety; a child or adolescent may require having someone remain with him or her until he or she falls asleep. An anxious child may awaken and go to a parent's bed or even sleep at the parents' door in an effort to diminish anxiety. Nightmares and morbid fears may be expressions of anxiety (Fig. 31.13a-1).
Rachel was a 13-year-old girl referred for an evaluation by her pediatrician based on her chronic gastrointestinal complaints without any organic illness. On interview, Rachel appeared withdrawn and meek but responsive to questions. She endorsed a number of worries that included concerns about her health, her parents' safety, her school performance, and her peer relationships. Rachel's greatest worries were related to her health and safety. Rachel's mother reported that Julie had recently been very reluctant to play outside, because she feared she would contract Lyme disease from a tick bite or West Nile virus from a mosquito bite. Rachel was also very distressed by news reports about catastrophic events locally and around the world (e.g., kidnapping, crime, terrorism). Rachel was described by her family and teachers as overly conscientious about her schoolwork and as often being concerned about adult matters (e.g., finances, parents' job security). Symptoms that accompanied Rachel's worries primarily involved stomach pain and problems falling asleep. Rachel tended to be quite perseverative; repetitively verbalizing her worries even after reassurance was given. Rachel admitted that she worried for hours each day and could not “turn off” her worried thoughts.

Rachel was the product of a normal pregnancy and delivery. Her medical history was unremarkable, with the exception of frequent gastrointestinal pain since kindergarten. Julie was described as irritable and difficult to soothe as an infant. Developmental milestones were met within normal limits. She was described as very obedient and had no history of externalizing behavior problems. She was very concerned about her academic performance from an early age and earned A's with an occasional B. Rachel was somewhat shy in social situations but well-liked by her peers. Family history included depression in her maternal grandmother and a maternal history of generalized anxiety disorder, social anxiety, and separation anxiety disorder as a child. Rachel had two younger siblings who were high achievers and without notable problems. (Adapted from case material from Gail A. Bernstein, M.D., and Ann E. Layne, Ph.D.)

This surrealistic photograph symbolically represents the anxiety in a childhood nightmare. (Courtesy of Arthur Tress for Magnum Photos, Inc.)

The next case history demonstrates an adolescent with multiple anxiety and depressive disorders.

Kate is a 15-year-old 10th grader who lives with her biological parents and two sisters, age 9 and 14 years. Kate is a very articulate teen who has always been a good student, although she never volunteers answers in school unless she is called on by her teachers. She gets along well with her sisters when at home, but even since she entered high school in the 9th grade year, she declines invitations to go to friends' homes, has turned down opportunities to go to parties, and has even stopped going on outings with her sisters to the neighborhood mall and the movies. Kate reports that she gets too nervous, and blushes when she is with friends outside of the classroom at school because she can't think of anything to say to them. She reports that she is embarrassed to go shopping or to the movies with her sisters because they often run into neighborhood peers along the way, stop to chat, and this makes her feel "stupid," because even though she is the oldest, she does not say anything, and believes that her sisters' friends will laugh at her shyness. Recently, one of her former best friends confronted her about why she had stopped "hanging out" with her friends. Kate had stopped eating lunch with her friends in school because she felt humiliated when they would talk about their weekend plans and even when they invited her to join, she would just look the other way and ignore the conversation. Kate had become isolated, even

Associated features of most anxiety disorders include fear of the dark and imaginary worries. Children may have the feeling that eyes are staring at them and monsters are reaching out for them in their bedrooms. Children with separation anxiety disorder, generalized anxiety disorder, and social anxiety disorder often complain of somatic symptoms and may be more sensitive to changes in their bodies compared to youth without anxiety disorders. Children with separation anxiety disorder, generalized anxiety disorder, or social anxiety disorder are often more emotionally sensitive than peers and more easily brought to tears. Frequent somatic complaints accompanying anxiety disorders include gastrointestinal symptoms, nausea, vomiting, and stomachaches; unexplained pain in various parts of the body; sore throats; and flu-like symptoms. Older children and adolescents typically complain of somatic experiences classically reported by adults with anxiety, such as cardiovascular and respiratory symptoms—palpitations, dizziness, faintness, and feelings of strangulation. Physiological signs of anxiety are a part of the diagnostic criteria for generalized anxiety disorder, but they are more often also experienced by children with separation anxiety and social phobia than the general population. The following case history demonstrates a young adolescent with generalized anxiety disorder.
in school, and admitted to her sister that she was lonely. Kate was brought for an evaluation after her younger sister commented to her mother that Kate spent all of her time alone whenever her sisters saw their friends, and that she looked sad and stressed out whenever she was around peers. Kate was down, always in poor spirits and had stopped interacting with her sisters even at home, and her sisters were often out with their own friends. On rare occasions Kate's younger sister had invited Kate to parties or to friend's homes, but Kate had declined and burst into tears.

Kate was evaluated by a child psychiatrist who made the diagnoses of social anxiety disorder, generalized anxiety disorder, and major depression and recommended a combination of treatment options, including cognitive-behavioral therapy (CBT) and a trial of a selective serotonin reuptake inhibitor (SSRI), fluoxetine. Kate and her family decided to try the medication first. Kate was started on 10 mg of fluoxetine and over the next month was titrated to a dose of 20 mg. By the third week of the medication trial, Kate was noticeably less resistant to going out with her sisters to places where they were likely to encounter peers. Her sisters noticed that she did not seem as stressed and started to occasionally sit with peers at lunch in the school cafeteria. She stated that she did not feel as self-conscious as she used to in class and was willing to go to a friend's house. She still declined to go to a birthday party of a peer that she didn't know very well. Kate continued on the same medication and within 2 months, she was significantly less anxious in social situations. She complained occasionally of a stomachache, but tolerated the medication well. Her family was impressed when she requested they plan a birthday party for her 16th birthday and decided to invite 10 friends.

**Differential Diagnosis**

The presence of separation anxiety is a developmentally expected feature in a young child and often does not represent an impairing condition, thus clinical judgment must be used in distinguishing normal anxiety from separation anxiety disorder in this age group. In older school-age children, a child experiencing more than normal distress is apparent when school is refused on a regular basis. For children who resist school, it is important to distinguish whether fear of separation, general worry about performance, or more specific fears of humiliation in front of peers or the teacher are driving the resistance. In many cases in which anxiety is the primary symptom, all three of the above-feared scenarios come into play. In generalized anxiety disorder, anxiety is not primarily focused on separation.

When depressive disorders occur in children, possible comorbidities such as separation anxiety disorder should be evaluated as well. A comorbid diagnosis of separation anxiety disorder and depressive disorder should be made when the criteria for both disorders are met; the two diagnoses often coexist. Panic disorder with agoraphobia is uncommon before 18 years of age; the fear is of being incapacitated by a panic attack rather than of separation from parental figures. School refusal is a frequent symptom in separation anxiety disorder, but is not pathognomonic of it. Children with other diagnoses, such as specific phobias, or social anxiety disorder, or fear of failure in school because of learning disorder, may also lead to school refusal. When school refusal occurs in an adolescent, the severity of the dysfunction is generally greater than when it emerges in a young child. Similar and distinguishing characteristics of childhood separation anxiety disorder, generalized anxiety disorder, and social anxiety disorder are presented in Table 31.13a-1.

**Pathology and Laboratory Examination**

No specific laboratory measures help in the diagnosis of separation anxiety disorder, generalized anxiety disorder, or social anxiety disorder.

GAD, generalized anxiety disorder; Soc AD, social anxiety disorder; PTSD, posttraumatic stress disorder.
COURSE AND PROGNOSIS

The course and the prognosis of separation anxiety disorder, generalized anxiety disorder, and social anxiety disorder are varied and are related to the age of onset, the duration of the symptoms, and the development of comorbid anxiety and depressive disorders. Young children who can maintain attendance in school, after-school activities, and peer relationships generally have a better prognosis than children or adolescents who refuse to attend school and withdraw from social activities.

The large multisite randomized clinical trial Child/Adolescent Anxiety Multimodal Study (CAMS) provided acute treatment for children and adolescents with one or more anxiety disorders with sertraline medication alone, cognitive-behavior therapy (CBT) alone, or both together, and found that predictors of future remission included younger age of initiation of treatment, lower severity of anxiety, absence of a comorbid depressive or anxiety disorder, and the absence of social anxiety disorder as the primary anxiety disorder being treated. A follow-up study of children and adolescents with mixed anxiety disorders over a 3-year period reported that up to 82 percent no longer met criteria for the anxiety disorder at follow-up. Of the group followed, 96 percent of those with separation anxiety disorder were remitted at follow-up. Most children who recovered did so within the first year. Early age of onset and later age at diagnosis were factors in this study that predicted slower recovery. Close to one third of the group studied, however, had developed another psychiatric disorder within the follow-up period, and 50 percent of these children developed another anxiety disorder. Studies have shown a significant overlap between separation anxiety disorder and depressive disorders. In cases with multiple comorbidities, the prognosis is more guarded. Longitudinal data indicate that some children with severe school refusal continue to resist attending school into adolescence and remain impaired for many years.

TREATMENT

The treatment of child and adolescent separation anxiety disorder, generalized anxiety disorder, and social anxiety disorder are often considered together, given the frequent comorbidity and overlapping symptomatology of these disorders. A multimodal comprehensive treatment approach usually includes psychotherapy, most often CBT, family education, family psychosocial intervention, and pharmacological interventions, such as SSRIs. The best evidence-based treatments for childhood anxiety disorders include CBT and SSRIs. The comparative efficacy of CBT, SSRI medication, and their combination (CBT + SSRI) in the treatment of childhood anxiety disorders was investigated in the National Institute of Mental Health (NIMH)-funded Child/Adolescent Anxiety Multimodal Study (CAMS). This double-blind, placebo-controlled, multi-site study included 488 children and adolescents with separation anxiety disorder, generalized anxiety disorder, or social anxiety disorder, who were randomly assigned to be treated with either CBT alone, SSRI medication (sertraline) alone, both CBT and sertraline, or placebo. After an acute treatment phase of 12 weeks, those in the combined CBT + sertraline group had an 80.7 percent response rate of much or very much improved on the clinical global improvement (CGI) rating. Response rates for the CBT-only and sertraline-only groups were 59.7 percent and 54.9 percent, respectively. Placebo response was 23.7 percent. Over time, during open follow-up, the combination of CBT plus sertraline continued to provide the most efficacy. All three treatments—CBT, sertraline, and their combination—were superior to placebo, and thus effective treatments in childhood anxiety, but combined treatment was most likely to help children and adolescents with anxiety disorders. A trial of CBT may be applied first, if available, when a child is able to function sufficiently to engage in daily activities while obtaining this treatment. For a child with severe impairment, however, a combination of treatments is recommended. BT is widely accepted as first-line evidence-based treatment for childhood anxiety disorders. A meta-analysis reviewed 16 randomized controlled trials of CBT for childhood anxiety disorders and found CBT to be consistently superior to a wait-list control group or a psychological placebo group. Exposure-based CBT has received the most empiric support among psychotherapeutic interventions for anxiety disorders in youth and has been shown to be superior to wait-list control groups in reducing impairment and symptoms of anxiety.

Several psychosocial interventions have been designed specifically for anxiety disorders in young children. A randomized clinical trial of CBT for 4- to 7-year-old children was administered via a manualized intervention called “Being Brave: A Program for Coping with Anxiety for Young Children and their Parents.” This manual was loosely modeled after the manualized Coping Cat program. The intervention utilized a combination of parent-only sessions and child-and-parent sessions. Response rate, measured as much or very much improved on the Clinical Global Improvement Scale for Anxiety, was 69 percent among completers versus 32 percent of the wait-list controls. The treated children showed significantly better CGI improvement on social anxiety disorder, separation anxiety disorder, and specific phobia, but not on generalized anxiety disorder. This treatment, a developmentally modified parent–child CBT, shows promise in young children.

Coaching Approach behavior and Leading by Modeling (the CALM program) is an intervention aimed at treating anxiety disorders in children younger than 7 years of age, who are too young to effectively engage in traditional CBT. The CALM program draws on previous work with children aged 2 to 7 years through interventions that target a child’s undesired behavior by modifying parents’ behavior, called Parent-Child Interaction Therapy (PCIT). The CALM program is a 12-session manual-based intervention that provides live, individualized coaching via a bug-in-the-ear receiver worn by the parent during sessions. It incorporates exposure tasks and promotes “brave” behavior with parent coaching. A pilot study using the CALM program with nine patients with a mean age of 5.4 years found that all treatment completers (seven patients and families) were rated as global responders, and all but one showed functional improvement. Adapting the PCIT model for anxiety disorders in young children appears to be a promising approach to treating anxiety in early childhood.

A meta-analysis of randomized controlled trials of antidepressant agents for childhood anxiety provides evidence that multiple SSRIs, including fluvoxamine (Luvox), fluoxetine (Prozac), sertraline (Zoloft), and paroxetine (Paxil) are efficacious in the treatment of childhood anxiety. Based on this evidence, SSRIs are the first choice of medication in the treatment of anxiety disorders in children and adolescents.
A large, multisite investigation by the National Institute of Mental Health (Research Units in Pediatric Psychopharmacology [RUPP]) confirmed the safety and efficacy of fluvoxamine in the treatment of childhood separation anxiety disorder, generalized anxiety disorder, and social phobia. This double-blind, placebo controlled study of 128 children and adolescents revealed that 76 percent of children in the group treated with fluvoxamine showed significant improvement compared with 29 percent of those in the placebo group. Response to medication was noticeable after only two weeks of treatment. Fluvoxamine dosages ranged from 50 mg to 250 mg per day in children and up to 300 mg per day in adolescents. Children and adolescents with less comorbid depressive symptoms had the best response. Children and adolescents who responded to this medication were continued on fluvoxamine for a period of 6 months, and almost all of them continued to be responders at the 6-month mark.

Several other randomized clinical trials have also supported the efficacy of SSRIs in the treatment of child and adolescent anxiety disorders. A randomized, controlled trial found fluoxetine, at a dose of 20 mg per day, to be safe and effective for children with these disorders, with minor side effects including gastrointestinal distress, headache, and drowsiness. In addition, a randomized clinical trial for the treatment of generalized anxiety disorder in children lends support for the efficacy of sertraline (Zoloft). Finally, a large industry randomized clinical trial of paroxetine (Paxil) in the treatment of children with social phobia found that paroxetine was associated with response in 78 percent of children treated. Paroxetine was utilized at a dosage range of 10 to 50 mg per day.

The Food and Drug Administration (FDA) has placed a “black box” warning on antidepressants, including all of the SSRI agents, used in the treatment of any childhood disorder, because of concerns about increased suicidality; however, no individual childhood anxiety study has found a statistically significant increase in suicidal thoughts or behaviors.

Tricyclic drugs are not currently recommended due to their potentially serious cardiac adverse effects, β-Adrenergic receptor antagonists, such as propranolol (Inderal), and buspirone (BuSpar) have been used clinically in children with anxiety disorders, but currently no data support their efficacy. Diphenhydramine (Benadryl) may be used in the short term to control sleep disturbances in children with anxiety disorders. Open trials and one double-blind, placebo-controlled study suggested that alprazolam (Xanax), a benzodiazepine, may help to control anxiety symptoms in separation anxiety disorder. Clonazepam (Klonopin) has been studied in open trials and may be useful in controlling symptoms of panic and other anxiety symptoms.

Although SSRIs and CBT alone and in combination have demonstrated efficacy in the treatment of anxiety disorders in youth, approximately 20 to 35 percent of children and adolescents with anxiety disorders do not appear to benefit. Several novel agents have been suggested as potential treatments, some based on their effect on the N-methyl-D-aspartate (NMDA) system. For example, d-cycloserine (DSC), currently FDA approved in the treatment of pediatric tuberculosism, is a partial receptor agonist of the NMDA system and is hypothesized to augment the benefits of exposure treatment for phobias. Some evidence suggests that DCS may increase the speed of exposure interventions; however, long-term gains have not been proven. Riluzole is an antiglutamatergic agent that decreases glutamatergic transmission by inhibiting glutamate release and inactivation of sodium channels in cortical neurons, and blocking γ-aminobutyric acid (GABA) reuptake. Due to its antiglutamatergic effects, Riluzole has been postulated to provide augmentation in the treatment of obsessive-compulsive disorder and generalized anxiety disorder. Another agent, memantine, an NMDA receptor antagonist, with FDA approval in the treatment of Alzheimer’s disease, has been hypothesized to decrease anxiety due to its influence on the glutamatergic system. Published case reports have provided mixed results.

Although most childhood anxiety disorders wax and wane over time, school refusal associated with separation anxiety disorder can be viewed as a psychiatric emergency. A comprehensive treatment plan involves the child, the parents, and the child’s peers and school. Family interventions are critical in the management of separation anxiety disorder, especially in children who refuse to attend school, so that firm encouragement of school attendance is maintained while appropriate support is also provided. When a return to a full school day is overwhelming, a program should be arranged so the child can progressively increase the time spent at school. Graded contact with an object of anxiety is a form of behavior modification that can be applied to any type of separation anxiety. Some severe cases of school refusal require hospitalization. Cognitive-behavioral modalities include exposure to feared separations and cognitive strategies, such as coping self-statements aimed at increasing a sense of autonomy and mastery.

In summary, evidence-based treatments for anxiety disorders have focused SSRIs and CBT. SSRIs have been shown to be both safe and efficacious in the treatment of childhood anxiety disorders; however, in severe disorders, the evidence suggests that optimal treatment is to provide both CBT and SSRI antidepressant agents simultaneously.

31.13b Selective Mutism

Selective mutism, believed to be related to social anxiety disorder, although an independent disorder, is characterized in a child by persistent lack of speaking in one or more specific social situations, most typically, the school setting. A child with selective mutism may remain completely silent or near silent, in some cases only whispering in a school setting. Although selective mutism often begins before age 5 years, it may not be apparent until the child is expected to speak or read aloud in school. Current conceptualization of selective mutism highlights a convergence of underlying social anxiety, along with an increased likelihood of speech and language problems leading to the failure to speak in certain situations. Typically, children with the disorder are silent during stressful situations, whereas some may verbalize almost inaudibly single-syllable words. Despite an increased risk for delayed speech and language acquisition in children with selective mutism, children with this disorder are fully capable of speaking competently when not in a socially anxiety-producing situation. Some children with the disorder will communicate with eye contact or nonverbal gestures but not verbally when at school. Otherwise, children with selective mutism speak fluently at home and in many familiar settings. Selective mutism is believed to be related to social anxiety disorder because of its expression primarily in social situations.

EPIEDEMOLOGY

The prevalence of selective mutism varies with age, with younger children at increased risk for the disorder. According to the DSM-5, the point prevalence of selective mutism using clinic or school samples has been found to range between 0.03 percent and 1 percent, depending on whether a clinic or community sample is studied. A large epidemiologic survey in the United Kingdom reported a prevalence rate of selective mutism to be 0.69 percent in children 4 to 5 years of age, which dropped to 0.8 percent near the end of the same academic year. Another survey in the United Kingdom identified 0.06 percent of 7-year-olds as having selective mutism. Young children are more vulnerable to the disorder than older ones. Selective mutism appears to be more common in girls than in boys. Clinical reports suggest that many young children spontaneously “outgrow” this disorder as they get older; the longitudinal course of the disorder remains to be studied.

ETIOLOGY

Genetic Contribution

Selective mutism may have many of the same etiologic factors leading to the emergence of social anxiety disorder. In contrast to other childhood anxiety disorders, however, children with selective mutism are at greater risk for delayed onset of speech or speech abnormalities that may be contributory. However, in addition to the speech and language factor, one survey found that 90 percent of children with selective mutism met diagnostic criteria for social phobia. These children showed high levels of social anxiety without notable psychopathology in other areas, according to parent and teacher ratings. Thus, selective mutism may not represent a distinct disorder, but may be better conceptualized as a subtype of social phobia. Maternal anxiety, depression, and heightened dependence needs are often noted in families of children with selective mutism, similar to families with children who exhibit other anxiety disorders.

Parental Interactions

Maternal overprotection and anxiety disorders in parents may exacerbate interactions that unwittingly reinforce selective mutism behaviors. Children with selective mutism usually speak freely at home, and only exhibit symptoms when under social pressure either in school or other social situations. Some children seem predisposed to selective mutism after early emotional or physical trauma; thus, some clinicians refer to the phenomenon as traumatic mutism rather than selective mutism.

Speech and Language Factors

Selective mutism is conceptualized as an anxiety-based refusal to speak; however, a higher than expected proportion of children with the disorder have a history of speech delay. An interesting finding suggests that children with selective mutism are at higher risk for a disturbance in auditory processing, which may interfere with efficient processing of incoming sounds. For the most part, however, speech and language problems in children with selective mutism are subtle and cannot account for the diagnosis of selective mutism.

DIAGNOSIS AND CLINICAL FEATURES

The diagnosis of selective mutism is not difficult to make after it is clear that a child has adequate language skills in some environments but not in others. The mutism may have developed gradually or suddenly after a disturbing experience. The age of onset can range from 4 to 8 years. Mute periods are most commonly manifested in school or outside the home; in rare cases, a child is mute at home but not in school. Children who exhibit selective mutism may also have symptoms of separation anxiety disorder, school refusal, and delayed language acquisition. Because social anxiety is almost always present in children with selective mutism, behavioral disturbances, such as temper tantrums and oppositional behaviors, may also occur in the home. Compared to children with other anxiety disorders, except social anxiety disorder, children with selective mutism tend to have less social competence and more social anxiety.

Janine is a 6-year-old Chinese-American first-grade girl who lives with her biological mother, father, and siblings. Janine's parents reported a 2-year history of not speaking at school, beginning in kindergarten, or to any children or adults outside of her family, despite speaking normally at home. At home, she reportedly is animated and quite talkative with her immediate family and a few young cousins as well. Although she speaks to adult relatives outside of her immediate family, her communication is often limited to one-word responses to their questions. By her parents' report, Janine also exhibits extreme social anxiety, to the point of "freezing" in certain situations when attention is focused on her. At the time of her evaluation, Janine had not received prior treatment.

Janine was also given assignments that involved her teacher and classmates. These were implemented in gradual fashion and included waving to the teacher, playing an audiotape of her saying "hello" to the teacher, whispering "hello" to the teacher, speaking "hello" to the teacher in a regular voice, and so on. After approximately 14 sessions, Janine succeeded in speaking a complete sentence in front of the class when called on and spoke to her teacher in front of several other students.

During the last few sessions, Janine's mother took an increasingly active role in assigning and following up on speaking assignments. When Janine entered the 2nd grade it took only a few days for her to speak to her teacher and to most peers in class. After completion of therapy, Janine's mother continued to monitor Janine's speaking behaviors and to promote speaking in new situations by encouraging (and rewarding) Janine's gradual successes with novel people and situations. (Adapted from case material from Lindsey Bergman, Ph.D. and John Piacentini, Ph.D.)

### Pathology and Laboratory Examination

No specific laboratory measures are useful in the diagnosis or treatment of selective mutism.

### Differential Diagnosis

Differential diagnosis of children who are silent in social situations emphasizes ruling out communications disorder, autism spectrum disorder, and social anxiety disorder, which may be diagnosed comorbidly. Once it is confirmed that the child is fully capable of speaking in certain situations, which are comfortable, but not in school and other social situations, an anxiety-related disorder comes to mind. Shy children may exhibit a transient muteness in new, anxiety-provoking situations. These children often have histories of not speaking in the presence of strangers and of clinging to their mothers. Most children who are mute on entering school improve spontaneously and may be described as having transient adaptation shyness. Selective mutism must also be distinguished from mental retardation, pervasive developmental disorders, and expressive language disorder. In these disorders, the symptoms are widespread, and no one situation exists in which the child communicates normally; the child may have an inability, rather than a refusal, to speak. In mutism secondary to conversion disorder, the mutism is pervasive. Children introduced into an environment in which a different language is spoken may be reticent to begin using the new language. Selective mutism should be diagnosed only when children also refuse to converse in their native language and when they have gained communicative competence in the new language but refuse to speak it.

### Course and Prognosis

Children with selective mutism are often excessively shy during preschool years, but the onset of the full disorder is usually not evident until age 5 or 6 years. Many very young children with early symptoms of selective mutism in a transitional period when entering preschool have a spontaneous improvement over a number of months and never fulfill criteria for the disorder. A common pattern for a child with selective mutism is to speak almost exclusively at home with the nuclear family but not elsewhere, especially not at school. Consequently, a child with selective mutism may have academic difficulties, or even failure due to a lack of participation. Children with selective mutism are typically shy, anxious, and at increased risk for a depressive disorder. Many children with early onset selective mutism remit with or without treatment. Recent data suggest that fluoxetine (Prozac) may influence the course of selective mutism, and treatment enhances recovery. Children in whom the disorder persists often have difficulty forming social relationships. Teasing and scapegoating by peers may cause them to refuse to go to school. Some children with any form of severe social anxiety are characterized by rigidity, compulsive traits, negativism, temper tantrums, and oppositional and aggressive behavior at home. Other children with the disorder tolerate the feared situation by communicating with gestures, such as nodding, shaking the head, and saying "Uh-huh" or "No." In one follow-up study, about one half of children with selective mutism
improved within 5 to 10 years. Children who do not improve by age 10 years appear to have a long-term course and a worse prognosis. As many as one third of children with selective mutism, with or without treatment, may develop other psychiatric disorders, particularly other anxiety disorders and depression.

TREATMENT

A multimodal approach using psychoeducation for the family, CBT, and SSRIs as needed is recommended. Preschool children may also benefit from a therapeutic nursery. For school-age children, individual CBT is recommended as a first-line treatment. Family education and cooperation are beneficial. Published data on the successful treatment of children with selective mutism is scant, yet solid evidence indicates that children with social anxiety disorder respond to various SSRIs and, currently, CBT treatments are under investigation in a multi-site, randomized placebo-controlled trial of children with anxiety disorders.

A recent report of 21 children with selective mutism treated in an open trial with fluoxetine suggested that this medication may be effective for childhood selective mutism. Reports have confirmed the efficacy of fluoxetine in the treatment of adult social phobia and in at least one double-blind, placebo-controlled study using fluoxetine with children with autism. A large NIH-funded study of anxiety disorders in children and adolescents called Research Units in Pediatric Psychopharmacology (RUPP), has shown distinct superiority of fluvoxamine over placebo in the treatment of a variety of childhood anxiety disorders. Children with selective mutism may benefit similarly to those with social phobia given the current belief that it is a subgroup of social phobia. SSRI medications that have been shown in randomized, placebo-controlled trials to have benefit in the treatment of children with social phobia include fluoxetine (20 mg to 60 mg per day), fluvoxamine (Luvox; 50 mg to 300 mg per day), sertraline (Zoloft; 25 mg to 200 mg per day), and paroxetine (Paxil; 10 mg to 50 mg per day).

31.14 Obsessive-Compulsive Disorder in Childhood and Adolescence

Childhood obsessive-compulsive disorder (OCD) is characterized by recurrent intrusive thoughts associated with anxiety or fear and/or repetitive purposeful mental or behavioral actions aimed at reducing fears and tensions caused by obsessions. Data suggest that up to 25 percent of cases of OCD have their onset by 14 years of age. The overall clinical presentation of OCD in youth is similar to that in adults; however, compared to adults, children and adolescents with OCD more often do not consider their obsessional thoughts or repetitive behaviors to be unreasonable. In milder cases of OCD, a trial of cognitive-behavioral therapy (CBT) is recommended as an initial intervention. OCD in youth is often treated successfully with selective serotonin reuptake inhibitors (SSRIs) or CBT alone, or in combination. The results of a large-scale, randomized, placebo-controlled study called the Pediatric OCD Treatment Study (POTS), demonstrated that the greatest rates of remission in pediatric OCD are achieved with a combination of both serotonergic agents and CBT treatment.

The American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) removed OCD from its former category of Anxiety Disorders and placed it in a new category called Obsessive-Compulsive and Related Disorders, with related disorders such as trichotillomania (hair pulling disorder), hoarding disorder, body dysmorphic disorder, and excoriation (skin picking) disorder. Nevertheless the relationship between OCD and other anxiety disorders remains significant and supported by research.

EPIDEMIOLOGY

OCD is common among children and adolescents, with a point prevalence of about 0.5 percent and a lifetime prevalence of 2 to 4 percent. The rate of OCD among youth rises exponentially with increasing age, with rates of 0.3 percent in children between the ages of 5 and 7 years, rising to rates between 0.6 percent and 1 percent among teens. According to the DSM-5, the prevalence of OCD in the United States is 1.2 percent, with a slightly higher rate in females. Rates of OCD among adolescents are greater than those for schizophrenia or bipolar disorder. Among young children with OCD there appears to be a slight male predominance, which diminishes with age.

ETIOLOGY

Genetic Factors

Genetic factors have been estimated to contribute significantly to the development of OCD in early onset illness. The rate of OCD among first-degree relatives of children and adolescents who develop OCD is ten times greater than for the general
population. Twin studies have shown that the concordance rates for OCD is higher for monozygotic twins (0.57) than for dizygotic twins (0.22); however, nongenetic factors play a role that may be equal to or greater than genetic contributions in some cases. OCD is a heterogeneous disorder that has been recognized for decades to run in families. In addition, the presence of subclinical symptom constellations in family members appears to breed true. Genetic linkage studies have revealed evidence of susceptibility loci on chromosomes 1q, 3q, 6q, 7p, 9p, 10p, and 15q. The OCD collaborative genetics study found that the Sapap3 gene was associated with grooming disorders and may be a promising candidate gene for OCD. There is evidence that the glutamate receptor–modulating genes may also be associated with and play a role in the emergence of OCD. Family studies have suggested a relationship between OCD and tic disorders such as Tourette’s syndrome. OCD and tic disorders are believed to share susceptibility factors, which may include both genetic and nongenetic factors.

**Neuroimmunology**

Immunological contributions to the emergence of OCD have been hypothesized to be related to an inflammatory process in the basal ganglia associated with an immune response to a systemic infection that may trigger OCD and tics. A prototype of with findings of altered sensitivity to the acute administration of serotonin's role in OCD. In addition, dopamine antagonists administered along with SSRIs may augment effectiveness of SSRIs in the treatment of OCD. Evidence suggests that multiple neurotransmitter systems may play a role in OCD.

**Neuroimaging**

Both computed tomography (CT) and MRI of untreated children and adults with OCD have revealed smaller volumes of basal ganglia segments compared to normal controls. A meta-analysis of voxel-based morphometry (VBM) to assess gray matter density compared 343 OCD patients with 318 healthy controls, and found that gray matter density in OCD patients was smaller in pariotofrontal cortical regions (including the supramarginal gyrus, the dorsolateral prefrontal cortex, and the orbitofrontal cortex), but larger in the basal ganglia (the putamen) and anterior prefrontal cortex compared to healthy controls. Increased gray matter volume in the basal ganglia of patients with OCD has been reported in other studies as well. These structural abnormalities in the prefrontal–basal ganglia are likely to be integrally involved in the pathophysiology of OCD. It is not clear whether the increases in gray matter in individuals with OCD occur before or after the symptoms emerge. In children, evidence suggests that thalamic volume is increased. Adult studies have provided evidence of hypermetabolism of frontal cortical-striatal-thalamocortical networks in untreated individuals with OCD. Of interest, imaging studies of before and after treatment have revealed that both medication and behavioral interventions lead to a reduction of orbit frontal and caudate metabolic rates in children and adults with OCD.

**DIAGNOSIS AND CLINICAL FEATURES**

Children and adolescents with obsessions or compulsions are often referred for treatment due to the excessive time that they devote to their intrusive thoughts and repetitive rituals. For some children, their compulsive rituals are perceived as reasonable responses to their extreme fears and anxieties. Nevertheless, they are aware of their discomfort and inability to carry out usual daily activities in a timely manner due to the compulsions, such as getting ready to leave their homes to go to school each morning.

The most commonly reported obsessions in children and adolescents include extreme fears of contamination—exposure to dirt, germs, or disease—followed by worries related to harm befalling themselves, family members, or fear of harming others due to losing control over aggressive impulses. Also commonly reported are obsessional needs for symmetry or exactness, hoarding, and excessive religious or moral concerns. Typical compulsive rituals among children and adolescents involve cleaning, checking, counting, repeating behaviors, or arranging items. Associated features in children and adolescents with OCD include avoidance, indecision, doubt, and a slowness to complete tasks. In most cases of OCD among youth, obsessions and compulsions are present. According to the DSM-5, diagnosis of OCD is identical to that of adults, with the note that young children may not be able to articulate the aims of their compulsions in diminishing their anxiety. The DSM-5 has also added the following specifiers: with good, fair, poor, or absent insight; that is, the greater the belief in the OCD obsessions and compulsions, the poorer the insight. An additional specifier indicates whether the individual has a current or past history
of a tic disorder. Table 10.1-1 designates the DSM-5 diagnostic criteria for OCD.

Many children and adolescents who develop OCD have an insidious onset and may hide their symptoms as long as possible so that their rituals will not be challenged or disrupted. A minority of children, particularly males with early onset may have a rapid unfolding of multiple symptoms within a few months. OCD is commonly found to be comorbid with anxiety disorders, attention-deficit/hyperactivity disorder (ADHD), and tic disorders, especially Tourette's syndrome. Children with comorbid OCD and tic disorders are more likely to exhibit counting, arranging, or ordering compulsions and less likely to manifest excessive washing and cleaning compulsions. The high comorbidity of OCD, Tourette's syndrome, and ADHD has led investigators to postulate a common genetic vulnerability to all three of these disorders. It is important to search for comorbidity in children and adolescents with OCD so that optimal treatments can be administered.

Jason, a 12-year-old boy in the sixth grade, was brought for evaluation by his parents, who expressed concerns over his repeated questions and anxiety regarding developing acquired immunodeficiency syndrome (AIDS). Jason was a high-functioning and well-adjusted boy who abruptly began to exhibit extremely disruptive behaviors related to his fears of AIDS approximately 2 to 3 months before the evaluation. Jason's new behaviors included relentless concerns about contracting illness, washing rituals, repeated expressions of uncertainty over his own behavior, seeking reassurance, repeating rituals, and avoidance.

Specifically, Jason repeatedly expressed his fear and belief that he was exposed to human immunodeficiency virus (HIV) through exposure to multiple strangers who were infected. For example, while riding in the car, if Jason saw a stranger from the window who appeared to him to be poor or ill, he experienced a surge of extreme anxiety and obsessively agonized about whether the stranger could have AIDS and had exposed him to it. Despite his parents' reassurances about his safety and lack of exposure to illness, Jason insisted on vigorously washing himself for approximately one hour each time he reached home after being out. Jason continually expressed doubts about his own behavior. He often asked his parents, "Did I use the s____ word? Did I use the f____ word?" Reassurance was only slightly calming. Jason, previously an excellent student, began to lose the ability to focus on schoolwork. While reading passages from assigned materials, Jason frequently experienced severe anxiety, wondering if he had missed a word or misunderstood the sentence, and proceeded to reread the material. Completing a page of written material began to take Jason 30 to 60 minutes. Over several weeks, he was less and less able to complete assignments, following which, he became very distressed over his deteriorating grades.

During Jason's evaluation, his family history suggested that Jason's older sister had experienced a period in which she too had similar but milder anxieties, with less interference in functioning, and she had never received any treatment for those symptoms.

At the intake interview, Jason presented as a preoccupied and sad boy who was cooperative with questioning. He did not volunteer much information, and he allowed his parents to recount the extent of his symptoms. Jason believed that his relentless concerns were well founded, and that he required repeated reassurance from his parents in order to continue his daily activities. Jason met full diagnostic criteria for OCD. Symptoms of depression were present but not sufficient for major depressive disorder.

CBT was initiated; however, Jason was so fearful of deviating from his rituals that he was unable to participate fully in his treatment, and he became despondent about his future. Jason refused to go to school due to his increasing distress associated with reading and his shame regarding his diminishing academic performance. Given his limited progress during the first 2 months of CBT, fluoxetine (Prozac) was added and increased up to 40 mg per day. Over a 3-week period some improvement was noted, and Jason was more amenable to cooperating with his CBT treatment.

CBT and SSRI treatment was continued over the next 3 months on a regular basis. Over time, Jason finally began to show some flexibility with his rituals, and he was able to decrease the amount of time he spent with rituals. Once he had found some relief from his symptoms, Jason was able to focus more on his schoolwork and his family life. Follow-up over the next year was positive; Jason had maintained his gains from treatment, with only minimal interference from residual OCD symptoms. Jason's academic achievement improved, he was able to engage in activities with friends, and he spent almost no time preoccupied with obsessional thoughts of illness and cleansing rituals. (Adapted from a case courtesy of James T. McCracken, M.D.)

Pathology and Laboratory Examination

No specific laboratory measures are useful in the diagnosis of obsessive-compulsive disorder.

Even when the onset of obsessions or compulsions appears to be associated with a recent infection with GABHS, antigens and antibodies to the bacteria do not indicate a causal relationship between GABHS and OCD.

Differential Diagnosis

Developmentally appropriate rituals in the play and behavior of young children should not be confused with OCD in that age group. Preschoolers often engage in ritualistic play and request a predictable routine such as bathing, reading stories, or selecting the same stuffed animal at bedtime, to promote a sense of security and comfort. These routines allay developmentally normal fears and lead to reasonable completion of daily activities. On the other hand, obsessions or compulsions are driven by extreme fears, and they significantly interfere with daily function because of the excessive time that they consume and the extreme distress that ensues when they are interrupted. The rituals of preschoolers generally become less rigid by the time they enter grade school, and school-age children do not typically experience a surge of anxiety when they encounter small changes in their routine.

Children and adolescents with generalized anxiety disorder, separation anxiety disorder, and social phobia experience intense worries that are often expressed repeatedly; however, these are mundane compared to obsessions, which are often so extreme that they appear bizarre. A child with generalized anxiety disorder typically worries repeatedly about performance on academic examinations, whereas a child with OCD may experience repeated intrusive thoughts that he may harm someone he loves. The compulsions of OCD are not present in other anxiety disorders; however, children with autism spectrum
disorders often display repetitive behaviors that may resemble OCD. In contrast with the rituals of OCD, children with autism spectrum disorder are not responding to anxiety, but are more often exhibiting stereotyped behaviors that are self-stimulating or self-comforting.

Children and adolescents with tic disorders such as Tourette's syndrome may display complex repetitive compulsive behaviors similar to the compulsions seen in OCD. Children and adolescents with tic disorders, in fact, are at higher risk for the development of concurrent OCD.

Severe OCD symptoms may be difficult to distinguish from delusional symptoms, especially when the obsessions and compulsions are bizarre in nature. In most adults, and often in youth with OCD, despite an inability to control their obsessions or resist completing compulsions, insight into their lack of reasonableness is preserved. That is, an individual's conviction in their beliefs often does not reach delusional intensity. When insight is present, and underlying anxiety can be described, even in the face of significant dysfunction due to bizarre obsessions and compulsion, the diagnosis of OCD is suspect.

COURSE AND PROGNOSIS

OCD with an onset in childhood and adolescence is most often a chronic, waxing and waning disorder with variability in severity and outcome. Follow-up studies suggest that up to 40 to 50 percent of children and adolescents recover from OCD with minimal residual symptoms. A study of childhood OCD treatment with sertraline resulted in close to 50 percent of participants experiencing complete remission, and partial remission in another 25 percent with a follow-up time of one year. Predictors of the best outcome were in those children and adolescents without comorbid disorders, including tic disorders and ADHD. A study of 142 children and adolescents with OCD followed over a period of 9 years at the Maudsley Hospital in England found 41 percent to have a persistence of OCD, with 40 percent exhibiting an additional psychiatric diagnosis at follow-up. The main predictor for persistent OCD was duration of illness at the time of initial assessment. Approximately half of the follow-up group was still receiving treatment, and half believed that they needed continued treatment.

Neuropsychological functioning may also play a role in outcome and prognosis. A study of 63 youth with OCD who completed the Rey-Osterrieth Complex Figure (ROCF) along with specific subtests of the Wechsler Intelligence Scale for Children, Third Edition (WISC-III), found that 5-minute recall accuracy from the ROCF was positively correlated with response to treatment, particularly CBT. These findings imply that poorer performance on the ROCF and poor response to CBT may be in part due to executive functioning difficulties and that treatment may need to be modified to account for these obstacles.

Overall, the prognosis is hopeful for most children and adolescents with mild to moderate OCD. In about 10 percent of cases, OCD may represent a prodrome of a psychotic disorder in children and adolescents. In youth with subthreshold OCD symptoms, there is a high risk of developing the full OCD disorder within a period of 2 years. Childhood OCD has been shown to be responsive to available treatments, resulting in improvement, if not complete remission, in the majority of cases.

TREATMENT

CBT and SSRIs have both been shown to be efficacious treatments for OCD in youth. CBT geared toward children of varying ages is based on the principle of developmentally appropriate exposure to the feared stimuli coupled with response prevention, leading to diminishing anxiety over time on exposure to feared situations. CBT manuals have been developed to ensure that developmentally appropriate interventions are made and that comprehensive education is provided to the child and parents.

Treatment guidelines for children and adolescents with mild to moderate OCD recommend a trial of CBT prior to initiating medication. However, the Pediatric OCD Treatment Study (POTS), a multi-site National Institute of Health (NIH)-funded investigation of sertraline and CBT each alone, and in combination, for the treatment of childhood-onset OCD, revealed that the combination was superior to either treatment alone. Each treatment alone also provided encouraging levels of response. Mean daily dose of sertraline was 133 mg/day in the group administered the combination treatment, and 170 mg/day for the sertraline alone group. Improvement with pharmacologic intervention of childhood OCD usually occurs within 8 to 12 weeks of treatment. Most children and adolescents who experienced a remission with acute treatment using SSRIs were still responsive over a period of a year. Among youth with OCD who obtain partial response to a therapeutic trial of SSR1 treatment, augmentation with a short-term OCD-specific CBT leads to a significantly greater response. Evidence shows that higher treatment expectations by patients and families are linked to better treatment response, greater compliance with home-based CBT assignments, less drop out of treatment, and reduced impairment.

In addition to individual CBT, both family and group CBT interventions have been shown to be efficacious in the treatment of childhood OCD. Family CBT (FCBT) intervention in the treatment of OCD in youth has been shown to increase response rates. A controlled comparison of family CBT and psychoeducation and relaxation (PRT) in 71 families of children with OCD showed that clinical remission rates in the FCBT group were significantly higher than those in the PRT group. The FCBT treatment reduced parent involvement and accommodation in their affected child's symptoms, which led to decreased symptomatology.

A randomized controlled study investigating web-camera delivered FCBT (W-FCBT) compared to a waitlist condition assigned 31 families to one of the above conditions. Assessments were conducted immediately before and after treatment and at 3-month follow-up for the W-FCBT group. The W-FCBT group was superior to the waitlist control group on all primary outcome measures, with large effect sizes. Eighty-one percent of the W-FCBT group responded compared to 13% of the waitlist group. The gains were maintained at the 3-month follow-up assessment. The authors conclude that W-FCBT may be efficacious in the treatment of OCD in youth and may be a promising tool for future dissemination.

Exposure and response prevention (ERP), a common strategy within CBT already shown to be effective on an individual basis for OCD, was studied in a group format in youth with OCD in a community-based program. Group-based ERP was
found to be effective in reducing OCD symptom severity and depressive symptoms, but not anxiety symptoms, in a naturalistic treatment setting for children with OCD and comorbid anxiety and/or depressive features.

Robust evidence of SSR1 efficacy for OCD in youth has been shown through multiple randomized clinical trials. A meta-analysis of 13 studies of SSRIs, including sertraline, fluvoxamine, fluoxetine, and paroxetine have provided evidence of efficacy of SSRIs with a moderate effect size. A randomized controlled clinical trial of citalopram versus fluoxetine in youth with OCD found that citalopram was as safe and effective as fluoxetine for the treatment of OCD in children and adolescents. There have been no apparent differences in the rate of response for the individual SSRIs.

Currently, three SSRIs: sertraline (at least 6 years), fluoxetine (at least 7 years), and fluvoxamine (at least 8 years), as well as another as clomipramine (at least 10 years), have received Food and Drug Administration (FDA) approval for the treatment of OCD in youth. The black box warning for antidepressants used in children for any disorder, including OCD is applicable, so that close monitoring for suicidal ideation or behavior is mandated when these agents are used in the treatment of childhood OCD.

Typical side effects that emerge with the use of SSRIs include insomnia, nausea, agitation, tremor, and fatigue. Dosage ranges for the various SSRIs found to have efficacy in randomized clinical trials are the following: fluoxetine (20 mg to 60 mg), sertraline (50 mg to 200 mg), fluvoxamine (up to 200 mg), and paroxetine (up to 50 mg).

Clomipramine was the first antidepressant studied in the treatment of OCD in childhood and the only tricyclic antidepressant that has FDA approval for the treatment of anxiety disorders in childhood. Clomipramine was found to be efficacious in doses up to 200 mg, or 3 mg/kg, whichever is less, and may be chosen for children or adolescents who cannot tolerate other SSRIs due to insomnia, significant appetite suppression, or activation. Nevertheless, clomipramine is not recommended as a first-line treatment due to its greater potential risks compared to other SSRIs, including cardiovascular risk of hypotension and arrhythmia, and seizure risk.

Pediatric patients with OCD who respond only partially to medications tend to have at least moderate to severe OCD symptoms, high ratings of global impairment and significant comorbidity even after their partial response to an adequate trial of medication. Augmentation strategies with medications to enhance serotonergic effects, such as with atypical antipsychotics (e.g., risperidone) have demonstrated increased response when partial response has been achieved with SSRIs. Aripiprazole augmentation in 39 adolescents with OCD who did not respond to two trials of monotherapy with SSRIs led to 59 percent of patients being rated as improved or very much improved. Patients who responded to aripiprazole were less impaired at baseline in functional impairment but not in clinical severity of their OCD. Aripiprazole final mean dose was 12.2 mg per day. This agent may be effective for pediatric OCD and warrants further controlled trials.

Given the lack of data on discontinuation, recommendations for maintaining medication such as stabilization, education about relapse risk, and tapering medication during the summer are likely in order to minimize academic compromise in case of relapse. For children and adolescents with more severe or multiple episodes of significant exacerbation of symptoms, treatment for more than a year is recommended. Overall, efficacy of treatment for children and adolescents with OCD is high with choices of SSRIs and CBT.

REFERENCES

Early-onset schizophrenia comprises childhood-onset and adolescent-onset schizophrenia. Childhood-onset schizophrenia is a very rare and virulent form of schizophrenia now recognized as a progressive neurodevelopmental disorder. Childhood onset is characterized by a more chronic course, with severe social and cognitive consequences and increased negative symptoms compared to adult-onset schizophrenia. Childhood-onset schizophrenia is defined by an onset of psychotic symptoms before the age of 13 years, believed to represent a subgroup of patients with schizophrenia with an increased heritable etiology, and evidence of widespread abnormalities in the development of brain structures including the cerebral cortex, white matter, hippocampus and cerebellum. Children diagnosed with childhood-onset schizophrenia have higher than normal rates of premorbid developmental abnormalities that appear to be nonspecific markers of abnormal brain development. Early-onset schizophrenia is defined as an onset of disease before the age of 18 years, including childhood-onset as well as adolescent-onset schizophrenia. Early-onset schizophrenia is associated with severe clinical course, poor psychosocial functioning, and increased severity of brain abnormality. Despite the more severe course, current evidence supports the efficacy of both psychosocial and pharmacological interventions in the management of childhood-onset and, particularly, adolescent-onset schizophrenia.

Children with childhood-onset schizophrenia have been shown to have more significant deficits in measures of intelligence quotient (IQ), memory, and tests of perceptuomotor skills compared with adolescent-onset schizophrenia. Increased impairment in childhood-onset schizophrenia of cognitive measures such as IQ, working memory, and perceptuomotor skills such deficits may be premorbid markers of illness, rather than sequelae, of the disorder. Although cognitive impairments are greater in younger patients with schizophrenia, clinical presentation of schizophrenia remains remarkably similar across the ages, and the diagnosis of childhood-onset schizophrenia is continuous with that in adolescents and adults, with one exception: in childhood-onset schizophrenia a failure to achieve expected social and academic functioning may replace a deterioration in functioning. According to the American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5), the diagnosis of schizophrenia includes an “active phase” of the illness, consisting of at least one of the following three symptoms: delusions, hallucinations, or disorganized speech, and at least one additional symptom present most of the time for a month. The additional symptom may be another one of the preceding three, or one of the following two symptoms: grossly disorganized or catatonic behavior, or negative symptoms (i.e., diminished emotional expression or avolition). In the active phase, symptoms are present for a significant amount of time during a single month and cause impairment. To meet full criteria for schizophrenia, continuous signs of disturbance must persist for at least 6 months. Social, academic, or occupational impairment must be present. In contrast to previous diagnostic criteria, the subtypes of schizophrenia (paranoid, disorganized, catatonic, undifferentiated, and residual) have been eliminated due to their lack of diagnostic validity and reliability. Instead, an eight-symptom “Clinician-Rated Dimensions of Psychosis Symptom Severity” scale for determining severity of psychosis across many psychotic illnesses is included in Section III of the DSM-5. Symptom domains rated in this scale include the following: hallucinations, delusions, disorganized speech, abnormal psychomotor behavior, negative symptoms (restricted emotional expression or avolition), impaired cognition, depression, and mania.

HISTORICAL PERSPECTIVE

Before the 1960s, the term childhood psychosis was applied to a heterogeneous group of children, many of whom exhibited autism spectrum disorder symptoms without hallucinations and delusions. In the late 1960s and 1970s, reports of children with evidence of a profound psychotic disturbance very early in life included observations of intellectual disabilities, social deficits, and severe communication and language impairments, and no family history of schizophrenia. Children whose psychoses emerged after the age of 3 years, however, more often exhibited auditory hallucinations, delusions, inappropriate affect, thought disorder, normal intellectual function, and a positive family history of schizophrenia.

In the 1980s, schizophrenia with childhood onset was formally separated from what was then termed autistic disorder, and currently termed autism spectrum disorder. The distinction of childhood schizophrenia from autism spectrum disorder reflected evidence accrued during the 1960s and 1970s showing a divergent clinical picture, family history, age of onset, and course between the two disorders. However, even after the separation of the disorders, controversy and confusion remained as to the distinctiveness in the long-term courses of these disorders. First, research documented a small group of children with autism spectrum disorder who developed schizophrenia in later childhood or adolescence. Second, many children with childhood-onset schizophrenia exhibit neurodevelopmental abnormalities, some of which are also evident in children with autism spectrum disorder. Children with autism spectrum disorder and those with childhood-onset schizophrenia are typically impaired in multiple areas of adaptive functioning from relatively early in life. However, in autism spectrum disorder, the onset is almost always before 3 years of age, whereas the onset of childhood-onset schizophrenia occurs before the age of 13 years, but most often is not recognizable in children until after the age of 3 years. Childhood-onset schizophrenia is significantly less frequent than adolescent-onset or onset in young adulthood, and few reports document cases of schizophrenia onset before 5 years of age. According to the DSM-5, schizophrenia can be diagnosed in the presence of autism spectrum disorder, provided that the diagnosis of schizophrenia is specifically differentiated from autism spectrum disorder.

EPIDEMIOLOGY

The frequency of childhood-onset schizophrenia is reported to be less than one case in about 40,000 children, whereas among adolescents between the ages of 13 and 18 years, the frequency
of schizophrenia is increased by a factor of at least 50. Schizophrenia with childhood onset resembles the more severe, chronic, and treatment-refractory adult-onset schizophrenic subgroups, in that the same core phenomenological features are present; however, in childhood-onset schizophrenia, extremely high rates of comorbidities are present, including attention-deficit/hyperactivity disorder (ADHD), depressive disorders, anxiety disorders, speech and language disorders, and motor disturbances. In adolescents, the prevalence of schizophrenia is estimated to be 50 times that in younger children, with probable rates of 1 to 2 per 1,000. Boys seem to have a slight preponderance among children diagnosed with schizophrenia, with an estimated ratio of about 1.67 boys to 1 girl. Boys often become identified at a younger age than girls do. Schizophrenia rarely is diagnosed in children younger than 5 years of age. The prevalence of schizophrenia among the parents of children with schizophrenia is about 8 percent, which is about twice the prevalence in the parents of patients with adult-onset schizophrenia.

**ETIOLOGY**

Childhood-onset schizophrenia is a neurodevelopmental disorder in which complex interactions between genes and the environment are presumed to result in abnormal early brain development. The consequences of the aberrant brain development in schizophrenia may not be fully evident until adolescence or early adulthood; however, data support the hypothesis that white matter abnormalities and disturbances in myelination in childhood, lead to abnormal connectivity between brain regions. The aberrant connectivity in various regions of the brain is believed to be an important contributing factor in the psychotic symptoms and cognitive deficits in childhood-onset schizophrenia.

**Genetic Factors**

Estimates of heritability for childhood-onset schizophrenia have been as high as 80 percent. The precise mechanisms of transmission of schizophrenia are still not well understood. Schizophrenia is known to be up to eight times more prevalent among first-degree relatives of those with schizophrenia than in the general population. Adoption studies of patients with adult-onset schizophrenia have shown that schizophrenia occurs in the biological relatives, not the adoptive relatives. Additional genetic evidence is supported by higher concordance rates for schizophrenia in monozygotic twins than in dizygotic twins. Higher rates of schizophrenia have been established among relatives of those with childhood-onset schizophrenia than in the relatives of those with adult-onset schizophrenia.

**Endophenotype Markers for Childhood-Onset Schizophrenia.** Currently, no reliable method can identify persons at the highest risk for schizophrenia in a given family. Neurodevelopmental abnormalities and higher-than-expected rates of neurological soft signs and impairments in sustaining attention and in strategies for information processing appear among children at high risk. Increased rates of disturbed communication styles are found in family members of individuals with schizophrenia. Reports have documented higher than expected neuropsychological deficits in attention, working memory, and premorbid IQ among children who later develop schizophrenia and its spectrum disorders.

**Magnetic Resonance Imaging (MRI) Studies**

A National Institute of Mental Health (NIMH) prospective study of more than 100 patients with childhood-onset schizophrenia and their typically developing siblings has demonstrated progressive loss of gray matter, delayed and disrupted white matter growth, and a decline in cerebellar volume in those with childhood-onset schizophrenia. Although siblings of children with childhood-onset schizophrenia also showed some of these brain disruptions, the gray matter abnormalities were normalized over time in the siblings, indicating a protective mechanism in siblings that was not present in those children with childhood-onset schizophrenia. Furthermore, the hippocampal volume loss across the age span appears to be static among children with childhood-onset schizophrenia. An MRI NIMH study of more than 100 children with childhood-onset schizophrenia and their typically developing siblings, studied for about two decades, documented that in childhood-onset schizophrenia, progressive brain gray matter loss occurs continuously over time. This gray matter shrinkage occurs with ventricular increases, with a pattern of loss originating in the parietal region and proceeding frontally to dorsolateral prefrontal and temporal cortices, including superior temporal gyri. Studies of childhood-onset schizophrenia at the NIMH provided evidence that early loss of parietal gray matter followed by frontal and parietal gray matter loss is more pronounced in childhood-onset schizophrenia than in schizophrenia with later onset. Other research utilized diffusion tensor images from children with childhood-onset schizophrenia versus controls and found increased diffusivities in the posterior corona radiata in children with childhood-onset schizophrenia, which implicated abnormal connectivity with the parietal lobes. These results contrasted with findings among subjects with later onset of schizophrenia in whom there were more abnormalities in the frontal lobes.

**DIAGNOSIS AND CLINICAL FEATURES**

All of the symptoms included in adult-onset schizophrenia may be manifest in children and adolescents with the disorder. However, youth with schizophrenia are more likely to have a premorbid history of social rejection, poor peer relationships, clinging withdrawn behavior, and academic trouble than those with adult-onset schizophrenia. Some children with schizophrenia evaluated in middle childhood have early histories of delayed motor milestones and language acquisition similar to some symptoms of autism spectrum disorder. The onset of schizophrenia in childhood is frequently insidious, starting with inappropriate affect or unusual behavior; it may take months or years for a child to meet all of the diagnostic criteria for schizophrenia.

Auditory hallucinations commonly occur in children with schizophrenia. The voices may reflect an ongoing critical commentary, or command hallucinations may instruct children to harm or kill themselves or others. Hallucinatory voices may sound human or animal, or “bizarre,” for example, identified as
“a computer in my head,” martians, or the voice of someone familiar, such as a relative. The childhood-onset schizophrenia project at the NIMH found high rates across all hallucination modalities. However, there were unexpectedly high rates of tactile, olfactory, and visual hallucinations among this study group of patients with childhood-onset schizophrenia. Visual hallucinations were associated with lower IQ and earlier age at onset of disease. Visual hallucinations are often frightening; affected children may “see” images of the devil, skeletons, scary faces, or space creatures. Transient phobic visual hallucinations occur in severely anxious or traumatized children who do not develop major psychotic disorders. Visual, tactile, and olfactory hallucinations may be a marker of more severe psychosis.

Delusions occur in up to half of children and adolescents with schizophrenia, in various forms, including persecutory, grandiose, and religious. Delusions increase in frequency with increased age. Blunted or inappropriate affect appears almost universally in children with schizophrenia. Children with schizophrenia may giggle inappropriately or cry without being able to explain why. Formal thought disorders, including loosening of associations and thought blocking, are common features among youth with schizophrenia. Illogical thinking and poverty of thought are also often present. Unlike adults with schizophrenia, children with schizophrenia do not have poverty of speech content, but they speak less than other children of the same intelligence and are ambiguous in the way they refer to persons, objects, and events. The communication deficits observable in children with schizophrenia include unpredictably changing the topic of conversation without introducing the new topic to the listener (loose associations). Children with schizophrenia also exhibit illogical thinking and speaking and tend to underuse self-initiated repair strategies to aid in their communication. When an utterance is unclear or vague, normal children attempt to clarify their communication with repetitions, revision, and more detail. Children with schizophrenia, on the other hand, fail to aid communication with revision, fillers, or starting over. These deficits may be conceptualized as negative symptoms in childhood schizophrenia.

Although core phenomena for schizophrenia seem to be universal across the age span, a child’s developmental level significantly influences the presentation of the symptoms. Delusions of young children are less complex, therefore, than those of older children, for example, age-appropriate content, such as animal imagery and monsters, is likely to be a source of delusional fear in young children. According to the DSM-5, a child with schizophrenia may experience deterioration of function, along with the emergence of psychotic symptoms, or the child may never achieve the expected level of functioning.

A 12-year-old 6th grade boy named Ian, with a longstanding history of social isolation, academic problems, and temper outbursts began to develop concerns that his parents might be poisoning his food. Over the next year, his symptoms progressed with increased suspiciousness and fearfulness, preoccupation with food, and beliefs that Satan was trying to communicate with him. Ian also appeared to be responding to auditory hallucinations that he believed were coming from the radio and television, which he found frightening and commanded him to harm his parents. Ian had also been informing his mother that their food had a strange smell and that’s why he thought it was poisoned, and at night, he would see frightening figures in his room. During this time, his parents also observed bizarre behaviors, including talking and yelling to himself, perseverating about devils and demons, and finally, assaulting family members because he thought they were evil. On one occasion, Ian was found to be scratching himself with a kitchen knife in an effort to “please God.” No predominant mood symptoms emerged, and there was no history of substance abuse found.

Developmentally, Ian was the product of a full-term pregnancy complicated by a difficult labor and forces delivery. His early motor and speech milestones were each delayed by about 6 months; however, his pediatrician reassured his parents that this was within the limits of normal development. As a younger child, Ian tended to be quiet and socially awkward. His intellectual function was tested and was found to be in the average range; however, academic achievement testing was consistently below grade level. Ian remained lonely and isolated, and he had great difficulty making friends.

Ian has had no medical problems and his immunizations were up to date. Ian’s family psychiatric history was significant for depression in a maternal aunt and a completed suicide in a maternal great-grandparent.

Ian was sent by ambulance to the hospital for the first time from school when he tried to jump off a balcony on the second story of his school in response to auditory hallucinations commanding him to kill himself. During his hospitalization his parents reluctantly consented to a trial of risperidone for him, and he was titrated up to 3 mg per day. His auditory hallucinations were moderately improved after 2 weeks of treatment; however, he continued to be suspicious and mistrustful of his physicians and family. Ian’s family was very confused as to what had caused Ian’s serious symptoms, and the hospital treatment team met with his parents multiple times during his hospitalization to reassure them that they had not caused his illness and that; their continued support might improve his chances of improvement. After discharge from the hospital, 30 days later, Ian was placed in a special education program, in a nonpublic school, and he was assigned a psychotherapist who met regularly with him individually and with his family. At the time of discharge from the hospital, Ian’s symptoms had moderately improved, although he still had auditory hallucinations intermittently. Over the next 5 years subsequent to the onset of his illness, Ian had many exacerbations of his psychosis and he was hospitalized nine times, including placement in a long-term residential program. Ian had received trials of olanzapine, quetiapine, and aripiprazole, each of which seemed to lead to improvement for a period of time, after which he was no longer responsive to the medications. Ian continued to receive individual cognitive behavioral therapy and family therapy, and his family was very supportive. Even with these interventions, Ian’s mental status continued to display tangential and disorganized thinking, paranoid delusions, loose associations, perseverative speech patterns, and a flat, at times inappropriate, affect. He had periods of time in which he resorted to pacing and muttering to himself, with no social interaction with others unless initiated by adults. Finally, Ian achieved significant improvement after being placed on clozapine (Clozaril) therapy, although he remained mildly symptomatic. (Adapted from a case by Jon M. McClellan, M.D.)

**PATHOLOGY AND LABORATORY EXAMINATIONS**

No specific laboratory tests are diagnostically specific for childhood-onset schizophrenia. Electroencephalography (EEG)
studies have not been helpful in distinguishing children with schizophrenia from other children. Although data exist to suggest that hypoprolinemia is associated with the risk of schizoaffective disorder due to an alteration on chromosome 22q11, no association of hyperprolinemia with childhood-onset schizophrenia has been identified.

DIFFERENTIAL DIAGNOSIS

One of the significant challenges in making a diagnosis of childhood-onset schizophrenia is that very young children who report hallucinations, apparent thought disorders, language delays, and poor ability to differentiate reality from fantasy may be manifesting phenomena better accounted for by other disorders such as posttraumatic stress disorder, or sometimes developmental immaturity, none of which evolve into a major psychotic illness.

Nevertheless, the differential diagnosis of childhood-onset schizophrenia includes autism spectrum disorder, bipolar disorders, depressive psychotic disorders, multicompartmental syndromes, drug-induced psychosis, and psychosis caused by organic disease states. Children with childhood-onset schizophrenia have been shown to have frequent comorbidities, including ADHD, oppositional defiant disorder, and major depression. Children with schizotypal personality disorder have some traits in common with children who meet diagnostic criteria for schizophrenia. Blunted affect, social isolation, eccentric thoughts, ideas of reference, and bizarre behavior can be seen in both disorders; however, in schizophrenia, overt psychotic symptoms, such as hallucinations, delusions, and incoherence, must be present at some point. Hallucinations alone, however, are not evidence of schizophrenia; patients must show either a deterioration of function or an inability to meet an expected developmental level to warrant the diagnosis of schizophrenia. Auditory and visual hallucinations can appear as self-limited events in nonpsychotic young children who are experiencing extreme stress or anxiety related to unstable home lives, abuse, or neglect or in children experiencing a major loss.

Psychotic phenomena are common among children with major depressive disorder, in which both hallucinations and, less commonly, delusions may occur. The congruence of mood with psychotic features is most pronounced in depressed children, although children with schizophrenia may also seem sad. The hallucinations and delusions of schizophrenia are more likely to have a bizarre quality than those of children with depressive disorders. In children and adolescents with bipolar I disorder, it often is difficult to distinguish a first episode of mania with psychotic features from schizophrenia if the child has no history of previous depressions. Grandiose delusions and hallucinations are typical of manic episodes, but clinicians often must follow the natural history of the disorder to confirm the presence of a mood disorder. Autism spectrum disorders share some features with schizophrenia, most notably, difficulty with social relationships, an early history of delayed language acquisition, and ongoing communication deficits. However, hallucinations, delusions, and formal thought disorder are core features of schizophrenia and are not expected features of autism spectrum disorder. Autism spectrum disorder is usually diagnosed by 3 years of age, whereas schizophrenia with childhood onset can rarely be diagnosed before 5 years of age.

Among adolescents, alcohol and other substance abuse sometimes can result in a deterioration of function, psychotic symptoms, and paranoid delusions. Amphetamines, lysergic acid diethylamide (LSD), and phencyclidine (PCP) may lead to a psychotic state. A sudden, flagrant onset of paranoid psychosis may suggest substance-induced psychotic disorder. Medical conditions that can induce psychotic features include thyroid disease, systemic lupus erythematosus, and temporal lobe disease.

COURSE AND PROGNOSIS

Important predictors of the course and outcome of childhood and early-onset schizophrenia include the child’s premorbid level of functioning, the age of onset, IQ, response to psycho-social and pharmacological interventions, degree of remission after the first psychotic episode, and degree of family support. Early age at onset, and children with comorbid developmental delays, learning disorders, lower IQ, and premorbid behavioral disorders, such as ADHD and conduct disorder, are less treatment responsive and likely to have the most guarded prognoses. Predictors of a poorer course of childhood-onset schizophrenia include family history of schizophrenia, young age and insidious onset, developmental delays and lower level of premorbid function, and chronic or length of first psychotic episode. Psychosocial and family stressors are known to influence the relapse rate in adults with schizophrenia, and high expression of negative emotion (EE) likely affects children with childhood-onset schizophrenia as well.

An important factor in outcome is the accuracy and stability of the diagnosis of schizophrenia. One study reported that one third of children who received an initial diagnosis of schizophrenia were later diagnosed with bipolar disorder in adolescence. Children and adolescents with bipolar I disorder may have a better long-term prognosis than those with schizophrenia. The NIMH-funded Treatment of Early-Onset Schizophrenia reported outcome of neurocognitive functioning in 8- to 19-year-old youth with schizophrenia or schizoaffective disorders, who participated in a randomized double-blind clinical trial comparing molindone, olanzapine, and risperidone. The three medication groups yielded no group differences in neurocognitive functioning over a year; however, when data from the three groups were combined, a significant modest improvement was observed in several domains of neurocognitive functioning. The authors concluded that antipsychotic intervention in youth with early-onset schizophrenia spectrum disorders led to modest improvement in neurocognitive function.

TREATMENT

The treatment of childhood-onset schizophrenia requires a multimodal approach, including psychoeducation for families, pharmacological interventions, psychotherapeutic interventions, social skills interventions, and appropriate educational placement. A recent randomized controlled trial investigated the effectiveness of several psychosocial interventions on youth in an early prodromal stage, characterized by changes in cognitive and social behavior. The interventions, termed
integrated psychological interventions, specifically included cognitive-behavioral therapy, group skills training, cognitive remediation therapy, multifamily psychoeducation, and supportive counseling on the prevention of psychosis. Of interest, the integrated psychological intervention was shown to be more effective than standard treatments in delaying the onset of psychosis over a 2-year follow-up period. These results sparked interest in the potential utility of psychosocial interventions to mediate psychosis, and to alter relapse rate and severity of illness over time. Children with childhood-onset schizophrenia may have less robust responses to antipsychotic medications than adolescents and adults. Family education and ongoing therapeutic family interventions are critical to maintain the maximum level of support for the patient. Monitoring the most appropriate educational setting for a child with childhood-onset schizophrenia is essential, especially in view of the frequent social skill deficits, attention deficits, and academic difficulties that often accompany childhood-onset schizophrenia.

Pharmacotherapy

Second-generation antipsychotics, serotonin-dopamine antagonists, are current mainstay pharmacological treatments for children and adolescents with schizophrenia, having largely replaced the conventional antipsychotics, that is, dopamine receptor antagonists, due to their more favorable side-effect profiles. Current data include six randomized clinical trials in youth investigating the efficacy of second-generation antipsychotics for early-onset schizophrenia, with limited support for one agent over the others. Although clozapine, a serotonin receptor antagonist with some dopamine (D₂) antagonism, which is hypothesized to be more effective in reducing positive and negative symptoms, has been shown to be highly effective in adults with treatment-refractory schizophrenia, it remains a choice of last resort in youth, based on its serious side effects. To date, however, evidence from multisite randomized clinical trials supports some efficacy of risperidone, olanzapine, aripiprazole, and clozapine in the treatment of childhood- and adolescent-onset schizophrenia. Two randomized clinical trials using risperidone in adolescents with schizophrenia found risperidone at doses up to 3 mg per day to be superior to placebo. A multisite randomized 6-week controlled trial of olanzapine in adolescents with schizophrenia found that it was more efficacious than placebo. A randomized controlled trial of aripiprazole at two fixed doses found that it was superior to placebo in the treatment of positive symptoms of adolescent schizophrenia; however, more than 40 percent of subjects in the active medication group did not achieve remission. Finally, clozapine has been demonstrated to be more effective than haloperidol in improving both positive and negative symptoms in treatment-resistant schizophrenia in youth. More recently, a study compared clozapine to high doses of olanzapine and found that response rates were about twice as great for clozapine as olanzapine (66% vs. 33%) when response was defined by a 30% or greater reduction in symptoms on the Brief Psychiatric Rating Scale and improvement on the Clinical Global Impression Scale. The Treatment of Early Onset Schizophrenia Spectrum Disorders Study compared the efficacy of risperidone and olanzapine with those of molindone, a mid-potency conventional antipsychotic. In this study, lacking a placebo group, each of these agents provided a similar therapeutic effect; however, fewer than half of the patients responded optimally. Despite the limited randomized controlled studies of second-generation antipsychotics for the treatment of schizophrenia in youth, the Food and Drug Administration (FDA) is progressively approving the use of these agents for pediatric schizophrenia and bipolar illness. In 2007, the FDA approved the use of risperidone and aripiprazole for the treatment of schizophrenia in 13- to 17-year-olds. The use of olanzapine and quetiapine were approved by the FDA in 2009 in the treatment of schizophrenia in 13 to 17 year olds.

A double-blind, randomized 8-week controlled trial compared the efficacy and safety of olanzapine to clozapine in childhood-onset schizophrenia. Children with childhood-onset schizophrenia who were resistant to at least two previous treatments with antipsychotics were randomized to treatment for 8 weeks with either olanzapine or clozapine followed by a 2-year open-label follow-up. Using the Clinical Global Impression of Severity of Symptoms Scale and Schedule for the Assessment of Negative/Positive Symptoms, clozapine was found to be associated with a significant reduction in all outcome measures, whereas olanzapine showed improvement on some measures but not on all. The only statistically significant measure in which clozapine was superior to olanzapine was in alleviating negative symptoms, compared with baseline. Clozapine was associated with more adverse events, such as lipid abnormalities and a seizure in one patient.

Several studies have provided evidence that risperidone, a benzisoxazole derivative, is as effective as the older high-potency conventional antipsychotics, such as haloperidol (Haldol), and causes less frequent severe side effects, in the treatment of schizophrenia in older adolescents and adults. Published case reports and limited larger controlled studies have supported the efficacy of risperidone in the treatment of psychosis in children and adolescents. Risperidone has been reported to cause weight gain and dystonic reactions and other extrapyramidal adverse effects in children and adolescents. Olanzapine is generally well tolerated with respect to extrapyramidal adverse effects compared with conventional antipsychotics and risperidone, but it is associated with moderate sedation and significant weight gain.

Psychosocial Interventions

Psychosocial interventions aimed at family education and patient and family support are recognized as critical components of the treatment plan for childhood-onset schizophrenia. Although there are not yet randomized controlled trials of psychosocial interventions in children and adolescents with schizophrenia, family therapy, psychoeducation, and social skills training have been shown to lead to improved clinical symptoms in young adults with a first episode of schizophrenia, and reviews of the adult literature support the benefit of cognitive behavioral therapy, and cognitive remediation as adjunctive treatments to pharmacologic agents in adults. Psychotherapists who work with children with schizophrenia must take into account a child’s developmental level in order to support the child’s reality testing and be sensitive to the child’s sense of self. Long-term supportive family interventions and cognitive
behavioral and remediation interventions combined with pharmacotherapies are likely to be the most effective approach to early-onset schizophrenia.

31.16 Adolescent Substance Abuse

Substance use is a public health concern among American youth. The most common substances used by adolescents in the United States are tobacco, alcohol, and marijuana. Adolescent substance use and abuse, however, includes a wider range of substances, including cocaine, heroin, inhalants, phencyclidine (PCP), lysergic acid diethylamide (LSD), dextromethorphan, anabolic steroids and various club drugs, 3,4-methylenedioxymethamphetamine (MDMA or Ecstasy), flunitrazepam (Rohypnol), gamma-hydroxybutyrate (GHB), and ketamine (Ketalar). It is estimated that approximately 20 percent of 8th graders in the United States have tried illicit drugs and about 30 percent of 10th through 12th graders have used an illicit substance. Alcohol remains the most common substance used and abused by adolescents. Binge drinking occurs in about 6 percent of adolescents, and teens with alcohol use disorders are at greater risk of problems with other substances as well.

The American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5), in contrast to the previous Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR), does not separate the diagnoses of substance abuse from substance dependence. Instead, the DSM-5 provides criteria for substance use disorder, accompanied by criteria for intoxication, withdrawal, and substance-induced disorders. The previous DSM-IV-TR criterion of recurrent substance-related legal problems has been deleted in the DSM-5, and a new criterion, craving, or a strong desire or urge to use a substance, has been added. In the DSM-5, a threshold of two or more criteria must be present. Cannabis withdrawal and caffeine withdrawal are no longer disorders in the DSM-5. The combined substance use criteria including both abuse and withdrawal phenomena may strengthen the validity of the disorder in adolescents, and the elimination of the criterion for “legal problems” is also an appropriate change for adolescents, since this is less common for younger adolescents and for adolescent females who use substances. Two recent commentaries raise concerns regarding the application of DSM-5 criteria to adolescents with respect to the symptom of tolerance, particularly to alcohol, that may occur across the board, and may be developmentally normal for adolescents who use alcohol but for whom there is no clinical impairment, and for withdrawal symptoms, which may have clinical significance but is only moderately associated with level of severity of substance use.

Many risk and protective factors influence the age of onset and severity of substance use among adolescents. Psychosocial risk factors mediating the development of substance use disorders include parent modeling of substance use, family conflict, lack of parental supervision, peer relationships, and individual...
stressful life events. Protective factors that mitigate substance use among adolescents include variables such as a stable family life, strong parent–child bond, consistent parental supervision, investment in academic achievement, and a peer group that models prosocial family and school behaviors. Interventions that diminish risk factors are likely to mitigate substance use.

Approximately one of five adolescents has used marijuana or hashish. Approximately one third of adolescents have used cigarettes by age 17 years. Studies of alcohol use among adolescents in the United States have shown that by 13 years of age, one third of boys and almost one fourth of girls have tried alcohol. By 18 years of age, 92 percent of males and 73 percent of females reported trying alcohol, and 4 percent reported using alcohol daily. Of high school seniors, 41 percent reported using marijuana; 2 percent reported using the drug daily.

Drinking among adolescents follows adult demographic drinking patterns: The highest proportion of alcohol use occurs among adolescents in the northeast; whites are more likely to drink than are other groups; among whites, Roman Catholics are the least likely nondrinkers. The four most common causes of death in persons between the ages of 10 and 24 years are motor vehicle accidents (37 percent), homicide (14 percent), suicide (12 percent), and other injuries or accidents (12 percent). Of adolescents treated in pediatric trauma centers, more than one third are treated for alcohol or drug use.

Studies considering alcohol and illicit drug use by adolescents as psychiatric disorders have demonstrated a greater prevalence of substance use, particularly alcoholism, among biological children of alcoholics than among adopted youth. This finding is supported by family studies of genetic contributions, by adoption studies, and by observing children of substance users reared outside the biological home.

Numerous risk factors influence the emergence of adolescent substance abuse. These include parental belief in the harmlessness of substances, lack of anger control in families of substance abusers, lack of closeness and involvement of parents with children's activities, maternal passivity, academic difficulties, comorbid psychiatric disorders such as conduct disorder and depression, parental and peer substance use, impulsivity, and early onset of cigarette smoking. The greater the number of risk factors, the more likely it is that an adolescent will be a substance user.

**Epidemiology**

**Alcohol**

The Centers for Disease Control and Prevention Youth Risk Behavior Survey found that 72.5 percent of high school students had tried at least one alcoholic drink, and 24.2 percent reported an episode of heavy drinking in the month preceding the survey. Findings from the Monitoring the Future Survey suggest that about 39 percent of adolescents have used alcohol before the 8th grade. Another survey found that drinking was a significant problem for 10 to 20 percent of adolescents. Drinking was reported by 70 percent of 8th grade students: 54 percent reported drinking within the past year, 27 percent reported having gotten drunk at least once, and 13 percent reported binge drinking in the 2 weeks before the survey. By the 12th grade, 88 percent of high school students reported drinking, and 77 percent drank within the past year; 5 percent of 8th grade students, 1.3 percent of 10th grade students, and 3.6 percent of 12th grade students reported daily alcohol use. In the age range of 13 to 17 years, in the United States, reports indicate there are 3 million problem drinkers and 300,000 adolescents with alcohol dependence. The gap between male and female alcohol consumers is narrowing.

**Marijuana**

For the last two decades, marijuana has been one of the most widely used drugs by young people in developed countries, and recently it has become highly used globally. The United Nations Office on Drugs and Crime estimated that marijuana was used by 3.9 percent of people worldwide between ages 15 years and 64 years. Marijuana is the most commonly used illicit drug among high school students in the United States. It is estimated that about 10 percent of those who try marijuana become daily users, and 20 to 30 percent become weekly users. Marijuana has been termed a “gateway drug,” because the strongest predictor of future cocaine use is frequent marijuana use during adolescence. Of 8th grade, 10th grade, and 12th grade students, 10, 23, and 36 percent, respectively, report using marijuana, a slight decrease from the year preceding the survey. Of 8th grade, 10th grade, and 12th grade students, 0.2, 0.8, and 2 percent, respectively, report daily marijuana use. Prevalence rates for marijuana are highest among Native American males and females; these rates are nearly as high in white males and females and Mexican American males. The lowest annual rates are reported by Latin American females, African American females, and Asian American males and females.

**Cocaine**

The annual cocaine use reported by high school seniors decreased more than 30 percent between 1990 and 2000. Currently, about 0.5 percent of 8th grade students, 1 percent of 10th grade students, and 2 percent of 12th grade students are estimated to have used cocaine. The prevalence rates for crack cocaine use, however, is increasing and is most common among those between the ages of 18 and 25.

**Crystal Methamphetamine**

Crystal methamphetamine, or “ice,” was at a relative low level of use in adolescence about one decade ago of 0.5 percent, and has steadily increased to a recent rate of 1.5 percent among 12th graders.

**Opioids**

A survey of 7,374 high school seniors found that 12.9 percent reported nonmedical use of opioids. Of users, more than 37 percent reported intranasal administration of prescription opioids.

**Lysergic Acid Diethylamide (LSD)**

Lysergic acid diethylamide is reportedly used by 2.7 percent of 8th grade students, 5.6 percent of 10th grade students, and
8.8 percent of 12th grade students. Of 12th grade students, 0.1 percent report daily use. The current LSD rates are lower than rates of LSD use during the past two decades.

3,4-Methylenedioxymethamphetamine (MDMA)

The popularity of MDMA has increased over the last decade, and current rates of use in the United States are in the range of about 5 percent for 10th graders and 8 percent of 12th graders, despite that the perceived harmfulness of this drug has increased over the last decade to almost 50 percent among 12th graders. Accidental adolescent deaths have been associated with the use of MDMA.

Gamma-Hydroxybutyrate (GHB)

Gamma-hydroxybutyrate, a club drug, has been found in surveys to have an annual prevalence rate of 1.1 percent for 8th graders, 1.0 percent rate for 10th graders, and a 1.6 percent rate of use for 12th graders.

Ketamine (Ketalar)

Ketamine, another club drug, was found recently to have a rate of 1.3 percent annual prevalence for 8th graders, 2.1 percent for 10th graders, and 2.5 percent rate for 12th graders.

Flunitrazepam (Rohypnol)

Flunitrazepam (Rohypnol), a third club drug, has been found to have an annual prevalence rate of about 1 percent for all high school grades combined.

Anabolic Steroids

Despite reported knowledge of the risks of anabolic steroids among high school students, surveys over the last 5 years found rates of anabolic steroid use to be 1.6 percent among 8th graders and 2.1 percent among 10th graders. Up to 45 percent of 10th and 12th graders reported knowledge of the risks of anabolic steroids; however, over the last decade it appears that high school seniors reported less disapproval of their use.

Inhalants

The use of inhalants in the form of glue, aerosols, and gasoline is relatively more common among younger than older adolescents. Among 8th grade, 10th grade, and 12th grade students, 17.6, 15.7, and 17.6 percent, respectively, report using inhalants; 0.2 percent of 8th grade students, 0.1 percent of 10th grade students, and 0.2 percent of 12th grade students report daily use of inhalants.

Multiple Substance Use

Among adolescents enrolled in substance abuse treatment programs, 96 percent are polydrug users; 97 percent of adolescents who abuse drugs also use alcohol.

ETIOLOGY

Genetic Factors

The concordance for alcoholism is reportedly higher among monozygotic than dizygotic twins. Considerably fewer studies have been conducted of families of drug abusers. One twin study of drug users showed that the drug abuse concordance for male monozygotic twins was twice that for dizygotic twins. Studies of children of alcoholics reared away from their biological homes have shown that these children have about a 25 percent chance of becoming alcoholics.

Psychosocial Factors

Among adolescents, substance use, particularly marijuana use, is strongly influenced by peers, and especially for those adolescents who report using marijuana for relaxation, the drug is used to escape from stress, and as a social activity. There are data to suggest, however, that marijuana use is also associated with both social anxiety disorder and depressive symptoms. Among young adolescents who start using alcohol, tobacco, and marijuana at an early age, data suggest that they often come from families with low parental supervision. The risk of early initiation of substances is greatest for children below 11 years of age. Increased parental supervision during middle childhood years may diminish drug and alcohol sampling and ultimately diminish the risk of using marijuana, cocaine, or inhalants in the future.

Comorbidity

Rates of alcohol and marijuana use are reportedly higher in relatives of youth with depression and anxiety disorders. On the other hand, mood disorders are common among those with alcoholism. Evidence indicates another strong link between early antisocial behavior, conduct disorder, and substance abuse. Substance abuse can be viewed as one form of behavioral deviance that, unsurprisingly, is associated with other forms of social and behavioral deviance. Early intervention with children who show early signs of social deviance and antisocial behavior may conceivably impede the processes that contribute to later substance abuse.

Comorbidity, the occurrence of more than one substance use disorder or the combination of a substance use disorder and another psychiatric disorder, is common. It is important to know about all comorbid disorders, which may show differential responses to treatment. Surveys of adolescents with alcoholism show rates of 50 percent or higher for additional psychiatric disorders, especially mood disorders. A recent survey of adolescents who used alcohol found that more than 80 percent met criteria for another disorder. The disorders most frequently present were depressive disorders, disruptive behavior disorders, and drug use disorders. These rates of comorbidity are even higher than those for adults. The diagnosis of alcohol abuse or dependence was likely to follow, rather than precede, other disorders; that a large proportion of adolescents with alcoholism have a previous childhood disorder may have both etiological and treatment implications. In this survey, the onset of alcohol disorders did not systematically
precede drug abuse or dependence. In 50 percent of cases, alcohol use followed drug use. Alcohol use may be a gateway to drug use, but is not in most cases. The presence of other psychiatric disorders was associated with an earlier onset of alcohol disorder, but it did not seem to indicate a more protracted course of alcoholism.

**DIAGNOSIS AND CLINICAL FEATURES**

According to the DSM-5, substance-related disorders include the following three categories: substance use, substance intoxication, and substance withdrawal disorder. Whereas in DSM-IV-TR, substance abuse and dependence were two separate categories, in DSM-5, they are combined in one diagnosis called substance use disorder.

*Substance use* refers to a maladaptive pattern of substance use leading to clinically significant impairment or distress, manifest by one or more of the following symptoms within a 12-month period: recurrent substance use in situations that causes physical danger to the user, recurrent substance use in the face of obvious impairment in school or work situations, recurrent substance use despite resulting legal problems, or recurrent substance use despite social or interpersonal problems.

*Substance intoxication* refers to the development of a reversible, substance-specific syndrome caused by use of a substance. Clinically significant maladaptive behavioral or psychological changes must be present.

*Substance withdrawal* refers to a substance-specific syndrome caused by the cessation of, or reduction in, prolonged substance use. The substance-specific syndrome causes clinically significant distress or impairs social or occupational functioning.

Two new disorders in DSM-5 include Cannabis withdrawal disorder and caffeine withdrawal disorder.

The diagnosis of alcohol or drug use in adolescents is made through careful interview, observations, laboratory findings, and history provided by reliable sources. Many nonspecific signs may point to alcohol or drug use, and clinicians must be careful to corroborate hunches before jumping to conclusions. Substance use can be viewed on a continuum with experimentation (the mildest use), regular use without obvious impairment, abuse, and finally, dependence. Changes in academic performance, nonspecific physical ailments, and changes in relationships with family members, changes in peer group, unexplained phone calls, or changes in personal hygiene may indicate substance use in an adolescent. Many of these indicators, however, also can be consistent with the onset of depression, adjustment to school, or the prodrome of a psychotic illness. It is important, therefore, to keep the channels of communication with an adolescent open when substance use is suspected.

**Nicotine**

Nicotine is one of the most addictive substances known; it involves cholinergic receptors, and enhancing acetylcholine, serotonin, and β-endorphin release. Young teens who smoke cigarettes are also exposed to other drugs more frequently than nonsmoking peers.

**Alcohol**

Alcohol use in adolescents rarely results in the sequelae observed in adults with chronic use of alcohol, such as withdrawal seizures, Korsakoff’s syndrome, Wernicke’s aphasia, or cirrhosis of the liver. One report, however, has stated that adolescent exposure to alcohol may result in diminished hippocampal brain volume. Because the hippocampus is involved with attention, it is conceivable that adolescent alcohol use could result in compromised cognitive function, especially with respect to attention.

**Marijuana**

The short-term effects of the active ingredient in marijuana, tetrahydrocannabinol (THC), include impairment in memory and learning, distorted perception, diminished problem-solving ability, loss of coordination, increased heart rate, anxiety, and panic attacks. Abrupt cessation of heavy marijuana use by adolescents has been reported to result in a withdrawal syndrome characterized by insomnia, irritability, restlessness, drug craving, depressed mood, and nervousness followed by anxiety, tremors, nausea, muscle twitches, increased sweating, myalgia, and general malaise. Typically, the withdrawal syndrome begins 24 hours after the last use, peaks at 2 to 4 days, and diminishes after 2 weeks. Marijuana use has been associated with increased risk of psychiatric disorders. Poor cognitive functioning has been associated with chronic marijuana use, although it is not clear whether marijuana impairs cognitive function. Deficits in verbal learning, memory, and attention have been reported in chronic marijuana users, and both acute and chronic marijuana use is associated with changes in cerebral blood flow to certain brain regions, which can be detected by positron emission tomography. Functional imaging studies suggest that there is less activity in brain regions involved with attention and memory in chronic marijuana users. A 15-year follow-up of 50,465 Swedish males in the military reported that participants who had used marijuana by 18 years of age were 2.4 times more likely to develop schizophrenia. Risks associated with chronic marijuana use include higher rates of motor vehicle accidents, impaired respiratory function, increased risk of cardiovascular disease, and potential increased risk for psychotic symptoms and disorders.

**Cocaine**

Cocaine can be sniffed or snorted, injected, or smoked. Crack is the term given to cocaine after it has been changed to a free base for smoking. Cocaine’s effects include constriction of peripheral blood vessels, dilated pupils, hyperthermia, increased heart rate, and hypertension. High doses or prolonged use of cocaine can induce paranoid thinking. There is immediate risk of death secondary to cardiac arrest or from seizures followed by respiratory arrest. In contrast to stimulants used to treat attention-deficit/hyperactivity disorder (ADHD), such as methylphenidate, cocaine quickly crosses the blood–brain barrier and moves off the dopamine transporter within 20 minutes; methylphenidate remains bound to dopamine for long periods.

**Heroin**

Heroin, a derivative of morphine, is produced from a poppy plant. Heroin usually appears as a white or brown powder that
can be snorted, but more commonly, it is used intravenously. Withdrawal symptoms include restlessness, muscle and bone pain, insomnia, diarrhea and vomiting, cold flashes with goose bumps, and kicking movements. Withdrawal occurs within a few hours after use; symptoms peak between 48 and 72 hours later and remit within about a week.

**Club Drugs**

Adolescents who frequent nightclubs, raves, bars, or music clubs also frequently use MDMA, GHB, Rohypnol, and ketamine. GHB, Rohypnol (a benzodiazepine), and ketamine (an anesthetic) are primarily depressants and can be added to drinks without detection because they are often colorless, tasteless, and odorless. The Drug-Induced Rape Prevention and Punishment Act was passed after these drugs were found to be associated with date rape. MDMA is a derivative of methamphetamine, a synthetic with both stimulant and hallucinogenic properties. MDMA can inhibit serotonin and dopamine reuptake. MDMA can result in dry mouth, increased heart rate, fatigue, muscle spasm, and hyperthermia.

**Lysergic Acid Diethylamide**

LSD is odorless, colorless, and has a slightly bitter taste. Higher doses of LSD can produce visual hallucinations and delusions and, in some cases, panic. The sensations experienced after ingestion of LSD usually diminish after 12 hours. Flashbacks can occur up to 1 year after use. LSD can produce tolerance; that is, after multiple uses, more is needed to provide the same degree of intoxication.

Substance use is related to a variety of high-risk behaviors, including early sexual experimentation, risky driving, destruction of property, stealing, “heavy metal” or alternative music, and, occasionally, preoccupation with cults or Satanism. Although none of these behaviors necessarily predicts substance use, at the extreme, these behaviors reflect alienation from the mainstream of developmentally expected social behavior. Adolescents with inadequate social skills may use a substance as a modality to join a peer group. In some cases, adolescents begin their substance use at home with their parents, who also use substances to enhance their social interactions. Although no evidence indicates what determines a typical adolescent user of alcohol or drugs, many substance users seem to have underlying social skills deficits, academic difficulties, and less than optimal peer relationships.

**TREATMENT**

Interventions for substance use disorders in adolescents first require effective screening and identification of those teens in need of treatment. Once a substance use disorder has been identified in a teen, a variety of treatment options can be sought. In accordance with the goals of the U.S. Substance Abuse Mental Health Services Administration (SAMHSA), a school-based alcohol and drug Screening, Brief Intervention, and Referral to Treatment (SBIRT) has been initiated in a study with 629 adolescents ages 14 to 17 years in 13 participating high schools in New Mexico. Initially, school-based health centers provided substance use screenings for all students who were seen in the clinic for any reason. Once identified, substance using adolescents were offered either brief intervention by clinic staff (85.1 percent of those identified), whereas 14.9 percent received brief treatment or referral to treatment. The brief intervention was based on motivational interviewing, with the goal of helping the student to gain motivation for behavioral change, and being referred for more intensive treatment if needed. Students who received the intervention, regardless of the severity of their substance use, reported decreases in self-reported drinking to intoxication at the 6-month follow-up. Furthermore, students who reported drug use, self-reported decreased use at follow-up. Alcohol use was reported by 42 percent of the student participants, and alcohol intoxication was reported by 37 percent. Eighty-five percent of study participants who reported drug use, reported only marijuana use in the month prior to entering the study. The frequency of alcohol and marijuana as the most predominant substances in this age group is consistent with epidemiological data. Overall, this school-based intervention had the advantage of being easily accessible to adolescents and provided a graded option for treatment according to the severity of the substance use. This study suggests that school-based programs for identifying and providing brief interventions for high school students is viable and merits further study.

Treatment of substance use disorders in adolescents is designed to directly prevent the substance use behaviors and to provide education for the patient and family and to address cognitive, emotional, and psychiatric factors that influence the substance use in a variety of settings such as a residential milieu, group, and individual psychosocial session.

One validated instrument used as a guide for clinicians in the treatment of adolescent substance use designates levels of care appropriate for the symptoms. This instrument called the *Child and Adolescent Levels of Care Utilization Services* (CALO-CUS) outlines six levels of care:

- **Level 0**: Basic services (prevention)
- **Level 1**: Recovery maintenance (relapse prevention)
- **Level 2**: Outpatient (once per week visits)
- **Level 3**: Intensive outpatient (2 or more visits per week)
- **Level 4**: Intensive integrated services (day treatment, partial hospitalization, wraparound services)
- **Level 5**: Nonsecure, 24-hour medically monitored service (group home, residential treatment facility)
- **Level 6**: Secure 24-hour medical management (inpatient psychiatric or highly programmed residential facility)

Treatment settings that serve adolescents with alcohol or drug use disorders include inpatient units, residential treatment facilities, halfway houses, group homes, partial hospital programs, and outpatient settings. Basic components of adolescent alcohol or drug use treatment include individual psychotherapy, drug-specific counseling, self-help groups (Alcoholics Anonymous [AA], Narcotics Anonymous [NA], Alateen, Al-Anon), substance abuse education and relapse prevention programs, and random urine drug testing. Family therapy and psychopharmacological intervention may be added.

Before deciding on the most appropriate treatment setting for a particular adolescent, a screening process must take place in which structured and unstructured interviews help to determine the types of substances being used and their quantities and frequencies. Determining coexisting psychiatric disorders is
also critical. Rating scales are typically used to document pre-treatment and posttreatment severity of abuse. The Teen Addiction Severity Index (T-ASI), the Adolescent Drug and Alcohol Diagnostic Assessment (ADAD), and the Adolescent Problem Severity Index (APS) are several severity-oriented rating scales. The T-ASI is broken down into dimensions that include a family function, school or employment status, psychiatric status, peer social relationships, and legal status.

After most of the information about substance use and the patient's overall psychiatric status has been obtained, a treatment strategy must be chosen and an appropriate setting must be determined. Two very different approaches to the treatment of substance abuse are embodied in the Minnesota model and the multidisciplinary professional model. The Minnesota model is based on the premise of AA; it is an intensive 12-step program with a counselor who functions as the primary therapist. The program uses self-help participation and group processes. Inherent in this treatment strategy is the need for adolescents to admit that substance use is problematic and that help is necessary. Furthermore, they must be willing to work toward altering their lifestyle to eradicate substance use. The multidisciplinary professional model consists of a team of mental health professionals that usually is led by a physician. Following a case-management model, each member of the team has specific areas of treatment for which he or she is responsible. Interventions may include cognitive-behavioral therapy, family therapy, and pharmacological intervention. This approach usually is suited for adolescents with comorbid psychiatric diagnoses.

Cognitive-behavioral approaches to psychotherapy for adolescents with substance use generally require that adolescents be motivated to participate in treatment and refrain from further substance use. The therapy focuses on relapse prevention and maintaining abstinence.

Psychopharmacological interventions for adolescent alcohol and drug users are still in their early stages. The presence of mood disorders clearly indicates the need for antidepressants, and generally, the selective serotonin reuptake inhibitors are the first line of treatment. Occasionally, an intervention is made to substitute the illicit drug with another drug that is more amenable to the treatment situation; for example, using methadone instead of heroin. Adolescents are required to have documented attempts at detoxification and consent from an adult before they can enter such a treatment program.

Peter, a 16-year-old 11th grader, was admitted to substance abuse treatment for the second time, following a relapse and threats of suicide. He was initially admitted to an adolescent psychiatric inpatient unit following a serious suicide attempt. Peter reported a longstanding history of ADHD, but he had been a good student and had not had any difficulties until middle school. Peter reported an onset of substance use at age 13 years, rapid progression in substance involvement since age 14 years, and then current use of marijuana on a daily basis, drinking alcohol up to five times each week, and experimentation with a variety of substances, such as LSD and Ecstasy. After being discharged from the psychiatric hospital, Peter attended teen group sessions focusing on his substance use problems. Family sessions led to the realization that Peter's mother had been depressed for some time, and she entered into her own treatment. Peter was improv-
Attenuated Psychosis Syndrome (APS) is a new diagnostic category included in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) as a condition for further study. It is a syndrome characterized by subthreshold psychotic symptoms, less severe than those found in psychotic disorders, but which are often present in prodromal psychotic states.

Debate and controversy among clinicians and researchers have surrounded the inclusion of APS in the DSM-5. There are those who believe that the identification and treatment of a prodromal syndrome of a psychotic disorder would either delay or diminish the severity of the future psychotic illness. And, there are others who believe that identification of a prodromal syndrome, which may rarely if ever progress to a full psychotic illness, would lead to unnecessary exposure to antipsychotic agents with unpredictable and possibly harmful effects. There is agreement, however, that patients with subthreshold prodromal psychotic symptoms are often impaired and are in need of psychological and psychiatric intervention.

A recent meta-analysis reported that the rate of onset of psychotic disorders in those patients with prodromal psychotic symptoms was 18 percent at 6 months, 22 percent at 1 year, 29 percent at 2 years, and 36 percent at 3 years. In a follow up study it was found that of those with prodromal symptoms who went on to develop a threshold psychotic illness, 73 percent met criteria for schizophrenia.

In children and adolescents psychotic symptoms are not necessarily a hallmark of a threshold psychotic disorder compared to adults. For example, in 50 percent of children with major depressive episodes, psychotic symptoms were present. In addition, epidemiological studies have found that globally, auditory hallucinations occur in 9 percent to 21 percent of children and in 8.4 percent of adolescents. Thus, in youth, the association between subthreshold psychotic symptoms and the emergence of full psychotic illness may not be a reliable predictor. Nevertheless, identification and follow up of youth with APS may provide an increased understanding of the longitudinal significance of these symptoms.

**ETIOLOGY**

**Genetic Factors**

Family studies have demonstrated that genetic factors influence vulnerability for schizophrenia spectrum disorders and other psychotic disorders. To the extent that APS and schizophrenia are related, genetic contributions are likely to be significant. Adoption and twin studies have confirmed that monozygotic twins have about a 50 percent concordance rate for schizophrenia compared to dizygotic twins who have a concordance rate of about 10 percent. In addition, adopted children of parents with schizophrenia do not have higher rates of schizophrenia; but biological children of schizophrenic parents do. However, genetic factors do not account fully for the emergence of schizophrenia spectrum disorders, since there is only a 50 percent concordance of exhibiting these disorders among monozygotic twins. Environmental factors also play an important role.

**Environmental Factors**

Early environmental factors that increase the risk of developing schizophrenia include fetal malnutrition, hypoxia at birth, and possibly prenatal infections. Other environmental factors include trauma, stress, social adversity and isolation. Finally, gene–environment interactions may influence an individual's sensitivity to adverse environmental events.

**DIAGNOSIS**

Attenuated psychosis syndrome, according to DSM-5, is based on the presence of at least one of the following: delusions, hallucinations, or disorganized speech, which causes functional impairment. Although the symptoms may not have progressed to full psychotic severity, they must have been present at least once per week for one month, and must have emerged or worsened in the past year. The symptoms must cause impairment and warrant clinical attention.

Attenuated delusions are described as either suspiciousness, persecutory, or grandiose, resulting in a lack of trust in others, and a sense of danger. Attenuated delusions, in contrast to delusions of threshold illness, may lead to loosely organized beliefs about hostile intentions of others, or danger; however, the delusions are not as fixed as they become in full blown psychotic illness. Attenuated hallucinations include altered sensory perceptions such as perception of murmurs, rumblings, or shadows that are disturbing; but they can be challenged, and skepticism about their reality is likely to be present. Disorganized communication or speech may be displayed as vague, or confused explanations, or circumstantial or tangential communication. When severe, but still in the attenuated range, thought blocking or loose associations may emerge; however, in contrast to psychotic illness, redirection is possible, and a logical conversation is typically achieved. Although impairment is present in APS, the individual retains an awareness and insight into the mental changes that are occurring.

**TREATMENT**

A recent review of the literature on treatment trials with patients at ultra-high-risk for psychosis found that early intervention with both psychological interventions and pharmacological agents can reduce symptoms and either delay or prevent the onset of a full psychotic illness. Other studies, however, found mixed results for early psychological or pharmacological interventions to prevent the onset of psychotic illness. One study found that most patients who became frankly psychotic did so within a few months after joining the study,
making it difficult to determine if these patients were already exhibiting early signs of onset of schizophrenia when identified as prodromal.

A variety of treatment approaches have been used including treatment with risperidone, olanzapine, omega-3 polyunsaturated fatty acid (w-3 PUFA), cognitive-behavioral therapy (CBT), cognitive therapy (CT), and one using an integrated psychological intervention (IPI) including cognitive approaches, psychoeducation, and social skills intervention. A review of treatment effectiveness in APS found that receiving treatment was associated with lower risk of psychotic illness at 1 year, 2 years, and 3 years. Given the limited data, however, it is not clear which interventions are most efficacious. Therefore, until additional treatment trials provide efficacy data, the safest choices for treatment of APS includes psychological interventions rather than the use of antipsychotic agents. In summary, APS identifies a group of patients with psychotic-like phenomena that warrant interventions in order to improve their distress and functional levels. Further study is needed, however, to determine the relationship between APS and the development of schizophrenia and other psychotic illnesses.

31.17b Academic Problem

Academic underachievement or failure is a major public health concern in youth, affecting between 10 percent and 20 percent of youth, with long-ranging associations with high-risk behaviors and poorer adjustment in early adulthood. The DSM-5 includes the category Academic or Educational Problem in the section “other conditions that may be a focus of clinical attention,” since school failure requires clinical intervention and influences a child’s level of overall functioning.

An investigation of the effects of students’ perception of support from parents, teachers, and peers showed a correlation with adolescent academic achievement. That is, adolescents’ perception of support from their teachers and parents was directly related to their academic achievement, whereas perceived peer support was indirectly related to actual academic achievement, which contributed to an adolescent’s overall perception of support, which was correlated to achievement.

Academic difficulties and externalizing behavior problems have been found to coexist at higher rates than would be expected by chance. This association has been found in both clinical and epidemiological samples. A longitudinal study of academic underachievement and behavior problems in school-aged children from 1st grade to 6th grade found that the combination of academic and behavior problems in the 1st grade predicted continued academic difficulties and behavioral problems 5 years later. This combination was more frequently seen in boys than in girls, beginning with the 1st grade. This is also true for children with reading difficulties, attentional problems, and behavioral problems.

Behavioral choices and life events can exacerbate academic problems in the absence of learning disorder and can interfere with lessening academic failures. For example, once a student perceives that he or she is falling behind academically, a greater temptation is to replace academic pursuits with other activities, such as drug use. A recent study assessed the level of, and deterioration in, academic achievement in relation to initiation of marijuana use among young teens. In a sample of rural teens, 36 percent of boys and 23 percent of girls initiated use of marijuana by the end of the 9th grade and that deteriorating academic performance was a significant predictor of initiating marijuana use. The hypothesis remaining to be tested is whether timely intervention to improve academic standing would lower the risk of beginning drug use.

The DSM-5 Academic and Educational problem category is used when a child or adolescent is having significant academic difficulties that are not caused by a specific learning disorder or communication disorder or directly related to a psychiatric disorder. Nevertheless, intervention is necessary because the child’s achievement in school is significantly impaired, and this
has an impact on the well-being of the child and may negatively influence concurrent psychiatric disorders.

**ETIOLOGY**

Many risk factors may play a role in academic underachievement or failure, including genetic factors, and developmental factors such as premature birth, as well as environmental factors such as level of maternal education. Very preterm children exhibit difficulties in working memory, which is a crucial ability and skill in learning new information and developing academic skills.

Children and adolescents troubled by social isolation, identity issues, or extreme shyness may withdraw from full participation in academic activities. Academic problems may be the result of a confluence of multiple contributing factors and may occur in adolescents who were previously high academic achievers. School is the main social and educational venue for children and adolescents. Success and acceptance in the school setting depend on children's physical, cognitive, social, and emotional adjustment. Children and adolescents' competency in general coping with developmental tasks are reflected in their academic and social success in school.

Anxiety can play a major role in interfering with children's academic performance. Anxiety can hamper their ability to perform well on tests, to speak in public, and to ask questions when they do not understand something. Depressed youth also may withdraw from academic pursuits; they require specific interventions to improve their academic performance and to treat their depression. Youth consumed by family problems, such as financial troubles, marital discord in their parents, and mental illness in family members, may be distracted and unable to attend to academic tasks.

Cultural and economic background can play a role in how well accepted a child feels in school and can affect the child's academic achievement. Familial socioeconomic level, parental education, race, religion, and family functioning can influence a child's sense of fitting in and can affect preparation to meet school demands.

Schools, teachers, and clinicians can share insights about how to foster productive and cooperative environments for all students in a classroom. Teachers' expectations about their students' performance influence these performances. Teachers serve as agents whose varying expectations can shape the differential development of students' skills and abilities. Such conditioning early in school, especially when negative, can disturb academic performance. A teacher's affective response to a child, therefore, can prompt the appearance of an academic problem. Most important is a teacher's humane approach to students at all levels of education, including medical school.

**DIAGNOSIS**

The DSM-5 contains the following statement about academic or educational problem:

This category can be used when an academic or educational problem is the focus of clinical attention or has an impact on the individual's diagnosis, treatment, or prognosis. Problems to be considered include illiteracy or low-level literacy; lack of access to schooling owing to unavailability or unattainability; problems with academic performance (e.g., failing school examinations, receiving failing marks, or grades) or underachievement (below what would be expected given the individual's intellectual capacity); discord with teachers, school staff, or other students; and any other problems related to education and/or literacy.

A 15-year-old 10th grade boy, Greg, with a history of prematurity and ADHD, was called to a meeting with his parents and school counselor due to his 12-week report card reflecting failure in two classes, and Cs and Ds in the rest. Until the end of the 9th grade, Greg was a B and C student, and he had been stabilized for many years on his treatment for ADHD. In the 10th grade, however, since the beginning of the semester, Greg had not been able to keep up. His counselor had also noticed insidiously increasing isolative behavior for the past 2 months; previous evaluation of ADHD had included a full intellectual evaluation, which showed his full-scale intelligence quotient (IQ) to be 100 and revealed no specific areas of academic weakness. Discussion with his parents and school counselor revealed that Greg had become upset when his parents had announced that they would be separating. Greg had not been doing his homework, and felt that school was no longer relevant for his social life or future. After getting behind in his classes in the first 6 weeks of the semester, Greg stopped trying, feeling overwhelmed and demoralized. It was decided that Greg would give accommodations from his teachers so that he could pass his classes without having to hand in every assignment that had long passed. Greg would receive daily tutoring, and was referred for a psychiatric evaluation to determine the severity of his mood disorder.

**TREATMENT**

The initial step in determining a useful intervention for an academic problem is an evaluation of educational problems and psychosocial issues. Identifying and addressing family-, school-, and peer-related stressors are critical. An individualized evaluation may be indicated so that specific educational accommodations can be applied.

In children with poor working memory, that is, a poor ability to store and retrieve information, learning and academic achievement is often impeded. Children with attention-deficit/hyperactivity disorder, as well as children born prematurely, often exhibit difficulties in working memory. In an effort to improve working memory in very preterm children, a computerized working memory training program (Cogmed) is being evaluated, consisting of 25 sessions of 35 minutes each, to be administered at home. Participants will undergo a baseline cognitive assessment, and then be randomized to either an adaptive or placebo version of Cogmed.

Psychosocial intervention may be applied successfully for scholastic difficulties related to poor motivation, poor self-concept, and underachievement. In some cases, on the other hand, excessive hours spent in extracurricular activities, such as mandatory practices for multiple high school sports can result in compromised academic achievement. Early efforts to resolve academic problems are critical: Sustained problems in learning and school performance frequently are compounded and precipitate severe difficulties. Feelings of anger, frustration, shame, loss of self-respect, and helplessness—emotions that most often
accompany school failures—damage self-esteem emotionally and cognitively, disabling future performance and clouding expectations for success. Generally, children with academic problems require either school-based intervention or individual attention.

Tutoring on an individual and frequent basis is an effective technique for increasing academic production and is typically included in a comprehensive educational program. Tutoring has proved of value in preparing for standardized multiple choice exams repetitively and using relaxation skills are techniques of great value in diminishing interference of test anxiety.

31.17c Identity Problem

The normative developmental process for an adolescent was conceptualized by the developmentalist Erik Erikson as an adolescent “crisis of identity.” The transition between a childhood identity and the process of accepting a more mature sense of self is the resolution of the “crisis.” Consolidation of identity encompasses cognitive, psychodynamic, psychosexual, neurobiological, and cultural development. As identity is confirmed in adolescence, a sense of self-sameness and continuity over time unfolds. The notion of an identity crisis in adolescence gained widespread attention by clinicians and the popular media during the late 1960s and early 1970s, when many adolescents displayed rejection of mainstream cultural values and ideas and demonstrated alternative lifestyles. The concept of identity disorder as a psychiatric diagnosis was embraced in the 1980s when the DMS-III was devised, as a disorder usually first evident in childhood. It was meant to include adolescents who presented with “severe subjective distress regarding uncertainty about a variety of issues relating to identity” to the point where they became impaired.

Identity problem is not currently conceptualized as a psychiatric disorder, rather it refers to uncertainty about issues, such as goals, career choice, friendships, sexual behavior, moral values, and group loyalties. An identity problem can cause severe distress for a young person and can lead a person to seek psychotherapy or guidance; however, it is not included in the DSM-5. It sometimes occurs in the context of such mental disorders as mood disorders, psychotic disorders, and borderline personality disorder. A study examining Intolerance of Uncertainty (IU), that is, the tendency to react negatively to uncertain situations, in 191 adolescents found that IU is correlated with adolescent social anxiety, worry, and to a lesser extent, depression.

EPIDEMIOLOGY

No reliable information is available regarding overall prevalence; however, factors increasing risk for identity problems include psychiatric disorders, psychosocial difficulties, and the pressures of assimilation as an ethnic minority into mainstream society.

ETIOLOGY

The causes of identity problems often are multifactorial and include the pressures of a dysfunctional families, the influences of coexisting mental disorders, and the degree to which adolescents feel integrated into their school and family environments. In general, adolescents with social skills deficits, major depressive disorder, psychotic disorders, and other mental disorders report feeling alienated from their peer group and family members, and experience some turmoil. Children who have had difficulty mastering expected developmental tasks all along are likely to have difficulty with the pressure to establish a well-defined identity during adolescence. Erikson used the term identity versus role diffusion to describe the developmental and psychosocial tasks challenging adolescents to incorporate past experiences and present goals into a coherent sense of self.

CLINICAL FEATURES

The essential features of identity problem seem to revolve around the question, “Who am I?” Conflicts are experienced as irreconcilable aspects of the self that the adolescent cannot integrate into a coherent identity. As Erikson described identity problem, youth manifests severe doubting and an inability to make decisions, a sense of isolation, inner emptiness, a growing inability to relate to others, disturbed sexual functioning, a distorted time perspective, a sense of urgency, and the assumption of a negative identity. The associated features frequently include marked discrepancy between the adolescent’s self-perception and the views that others have of the adolescent; moderate anxiety and depression that are usually related to inner preoccupation, rather than external realities; and self-doubt and uncertainty about the future, with either difficulty making choices or impulsive experiments in an attempt to establish an independent identity. Adolescents with identity problem may join “outcast” cult-like groups. A study examining relationships of social context and identity of high-risk Hispanic adolescents
found that school problems and identity confusion among these adolescents were related to behavioral problems and risk-taking behaviors including alcohol use, illicit drug use, and sexual risk-taking behaviors.

DIFFERENTIAL DIAGNOSIS

Identity problems must be differentiated from sequelae of a mental disorder (e.g., borderline personality disorder, schizophrenia, depression, or a mood disorder). At times, what initially seems to be an identity problem may be the prodromal manifestations of one of these disorders. Intense, but normal, conflicts associated with maturing, such as adolescent turmoil and midlife crisis, may be confusing, but they usually are not associated with marked deterioration in school, in vocational or social functioning, or with severe subjective distress. Considerable evidence indicates that adolescent turmoil often is not a phase that is outgrown but an indication of true psychopathology.

COURSE AND PROGNOSIS

The onset of identity problem most frequently occurs in late adolescence, as teenagers separate from the nuclear family and attempt to establish an independent identity and value system. The onset usually is characterized by a gradual increase in anxiety, depression, and regressive phenomena (e.g., loss of interest in friends, school, and activities), irritability, sleep difficulties, and changes in eating habits. The course usually is relatively brief, as developmental lags respond to support, acceptance, and the provision of a psychosocial moratorium.

Extensive prolongation of adolescence with continued identity problem can lead to the chronic state of role diffusion, which may indicate a disturbance of early developmental stages and the presence of borderline personality disorder, a mood disorder, or schizophrenia. An identity problem usually resolves by the mid-20s. If it persists, the person with the identity problem may have difficulty with career commitments and lasting attachments.

Jenna, an 8-year-old girl, was adopted in Taiwan at 10 months of age by a white midwestern couple. As she grew, her vulnerability to separations became increasingly more pronounced. Jenna developed school refusal, and would exhibit outbursts of rage and misbehavior when she was forced to go to school. She pleaded with her mother to care for the many aches and pains that plagued her.

By the time she reached adolescence, Jenna had an entrenched habit of cutting and self-mutilating. She responded to frustration, separations, or perceived threats of abandonment by cutting herself or burning herself with cigarette lighters. Eventually, she was able to verbalize the multiple functions that self-injury served for her. She noted that she was able to stay home from school, be in the company of her mother, and avoid the stresses of peer interactions. Jenna and her mother began a course of psychotherapy in which Jenna learned that she would still need to attend school, regardless of her cutting behavior, and her mother learned to provide incentives for Jenna to diminish her maladaptive behaviors.

Over time, Jenna became more flexible and realized that she was harming herself, and not others around her. Jenna was able to return to school, and with the help of her therapist, she was able to discontinue her self-injurious behaviors and focus on succeeding in school and with her peers. (Adapted from Efrain Bleiberg, M.D.)

TREATMENT

Considerable consensus exists among clinicians that adolescents experiencing identity problems may respond to brief psychosocial intervention. Individual psychotherapy directed toward encouraging growth and development usually is considered the therapy of choice. Adolescents with identity problems often feel developmentally unprepared to deal with the increasing demands for social, emotional, and sexual independence. Issues of separation and individuation from their families can be challenging and overwhelming. Enlisting the concepts outlined by Erikson with regard to adolescent development, psychotherapy may include discussion of adolescent exploration (active search among alternatives for activities and friendships that fit) and commitment (demonstrated investment) in activities that promote independence and autonomy. Treatment is aimed at helping these adolescents develop a sense of competence and mastery about necessary social and vocational choices. A therapist's empathic acknowledgment of an adolescent's struggle can be helpful in the process.

31.18 Psychiatric Treatment of Children and Adolescents

31.18a Individual Psychotherapy

Individual psychotherapy with children and adolescents generally begins by establishing rapport through developmentally appropriate psychoeducation regarding the target symptoms and disorders to be addressed. As a rule, the younger the child, the more extensively family members participate in the treatment. Even among adolescents, family members are often
directly involved in some components of the treatment in order to achieve the maximum benefit. In recent years, randomized clinical trials have provided a body of literature to support the efficacy of cognitive-behavioral psychotherapy for a wide range of childhood psychiatric disorders including obsessive-compulsive disorder (OCD), anxiety disorders, and depressive disorders. Additional therapeutic approaches including supportive, psychodynamic, and more recently, mindfulness-based stress reduction (MBSR), mindful meditation, and yoga are sometimes incorporated into psychosocial treatments, creating an “eclectic” mixture. The initial goal of any psychotherapeutic strategy is to establish a working relationship with the child or adolescent. In general, successful individual psychotherapeutic interventions with youth also necessitate establishing a therapeutic rapport with parents. To establish a therapeutic relationship with a child of any age requires a knowledge of normal development as well as an understanding of the context in which the symptoms emerged. Individual psychotherapy with children focuses on improving adaptive skills as well as diminishing specific symptomatology. Most children do not seek psychiatric treatment; typically, they are brought to a psychotherapist due to symptoms noted by a family member, schoolteacher, or, pediatrician. Children often believe that they are being taken for treatment because of their misbehavior or as a punishment for wrongdoing.

Children and adolescents are the most accurate informants of their own thoughts, feelings, moods, and perceptual experiences; however, external behavior problems are often more accurately identified by parents or teachers. Psychotherapists for children frequently function as their advocates in interactions with schools, after-school programs, and community organizations. Individual psychotherapy with a child often takes place in conjunction with family therapy, group therapy, educational remediation, and psychopharmacological interventions.

PSYCHOTHERAPEUTIC TECHNIQUES AND UNDERLYING THEORIES

Cognitive-Behavioral Therapy

Cognitive-behavioral therapy (CBT) is an amalgam of behavioral therapy and cognitive psychology. It emphasizes how children may use thinking processes and cognitive modalities to reframe, restructure, and solve problems. A child's distortions are addressed by generating alternative ways of dealing with problematic situations. Cognitive-behavioral strategies have been shown in multiple studies to be effective in the treatment of child and adolescent mood disorders, OCD, and anxiety disorders. A recent study compared a family-focused CBT, the “Building Confidence Program,” with traditional child-focused CBT, with minimal family involvement for children with anxiety disorders. Both interventions included coping skills training and in vivo exposure, but the family CBT intervention also included parent communication training. Compared with the child-focused CBT, family CBT was associated with greater improvement on independent evaluators' ratings and parent reports of child anxiety, but not on children's self-reports of improvement. Family-focused CBT has also been used in the treatment of pediatric bipolar disorder with promising results.

One of the limiting factors in providing CBT to children with OCD, anxiety disorders, and depressive disorders is the lack of sufficient numbers of trained child and adolescent cognitive-behavioral therapists. A recent study addressed the feasibility of combining a CBT via clinic-plus-Internet treatment. Children who received the clinic-plus-Internet treatment showed significantly greater reductions in anxiety from pretreatment to posttreatment, and maintained gains for a period of 12 months compared with children who received no active treatment, but were on a wait-list. The Internet treatment was acceptable to families and dropout rate was minimal.

Psychoanalysis and Psychoanalytic Therapy

Child Psychoanalysis. Child psychoanalysis, an intensive, uncommon form of psychoanalytic psychotherapy, involves three to four sessions a week and places an emphasis on unconscious resistance and defenses. In this approach, therapists anticipate unconscious resistance and allow transference manifestations to mature to a full transference neurosis, through which neurotic conflicts are ultimately resolved. Interpretations of dynamically relevant conflicts are emphasized in psychoanalytic descriptions, and elements that are predominant in other types of psychotherapies are included. In all psychotherapy, children should derive support from a consistently understanding and accepting relationship with their therapists. Remedial educational guidance is provided when necessary.

In classic psychoanalytic theory, exploratory psychotherapy is applicable to patients of all ages and involves reversing the evolution of psychopathological processes. A principal difference noted with advancing age is a sharpening distinction between psychogenetic and psychodynamic factors. The younger the child, the more the genetic and dynamic forces are intertwined. The development of pathological processes generally is believed to begin with experiences that have proved to be particularly significant to children and to have affected them adversely. Although in one sense the experiences were real, in another sense, they may have been misinterpreted or imagined. In any event, to children, these were traumatic experiences that caused unconscious complexes. Being inaccessible to conscious awareness, the unconscious elements readily escape rational adaptive maneuvers and are subject to pathological misuse of adaptive and defensive mechanisms. The result is the development of conflicts leading to distressing symptoms, character attitudes, or patterns of behavior that constitute the emotional disturbance.

Psychoanalytic Psychotherapy. Psychoanalytic psychotherapy, a modified form of psychoanalysis, is expressive and exploratory and endeavors to reverse the evolution of emotional disturbance through reenacting and desensitizing traumatic events. This is achieved by having children freely express thoughts and feelings in an interview-play situation. Ultimately, therapists help patients understand feelings that they may have avoided, as well as fears and wishes that have been self-defeating.

Behavioral Therapy

All behavior, whether adaptive or maladaptive, is a consequence of the same basic principles of behavior acquisition and
maintenance. Behavior is either learned or unlearned. What renders behavior abnormal or disturbed is its social significance. Although theories and their derivative therapeutic intervention techniques have become increasingly complex over the years, all learning can be subsumed in two global basic mechanisms. One is classic respondent conditioning, akin to Ivan Pavlov's famous experiments, and the second is operant instrumental learning, which is associated with B. F. Skinner; the latter is also basic to both Edward Thorndike's law of effect, which is about the influence of reinforcing consequences of behavior, and to Sigmund Freud's pain-pleasure principle. Behavior therapy assigns the highest priority to the immediate precipitants of behavior and deemphasizes remote underlying causal determinants that are important in the psychoanalytic tradition.

Respondent conditioning theory asserts that only two types of abnormal behavior exist: behavioral deficits that result from a failure to learn, and deviant maladaptive behavior that is a consequence of learning inappropriate things. Such concepts have always been an implicit part of the rationale underlying all child psychotherapy. Intervention strategies derive much of their success, particularly with children, from rewarding previously unnoticed good behavior, thereby highlighting it, and making it occur more frequently than in the past.

Family Therapy

Family therapies have been influenced by conceptual contributions from systems theory, communications theory, object relations theory, social role theory, ethology, and ecology. The core premise entails the idea of a family as a self-regulating, open system that possesses its own unique history and structure. This structure is constantly evolving as a consequence of dynamic interaction between the family's mutually interdependent systems and persons who share a complementarity of needs. From this conceptual foundation, a wealth of ideas has emerged under rubrics such as family development, life cycle, homeostasis, functions, identity, values, goals, congruence, symmetry, myths, and rules; roles, such as spokesperson, symptoms-bearer, scapegoat, affect barometer, pet, persecutor, victim, arbitrator, distractor, saboteur, rescuer, breadwinner, disciplinarian, and nurturer; structure, such as boundaries, splits, pairings, alliances, coalitions, enmeshed, and disengaged; and double bind, scapegoating, and mystification. Increasingly, appreciation of the family system sometimes explains why a minute therapeutic input at a critical junction may result in far-reaching changes.

Tim was a 3-year-old child, developing normally and quite verbal, until he started preschool, at which time he suddenly refused to speak at all outside his home. Tim had begun preschool shortly after his parents had separated and his father had left the home. Prior to his parents' separation, Tim was highly verbal and developmentally ahead of many children his age in language skill. Although he was observed constantly in preschool, he was never "caught" speaking to peers. He was described as a compliant child who didn't smile as easily as the other children, who played with others and followed requests without problem but would not speak. During his psychiatric evaluation, it was revealed that Tim enjoyed eating Froot Loops in a favorite cup as a treat. Treatment was designed to provide incentive for speaking through the delivery of a reinforcement of high value, the Froot Loops. Hence, Froot Loops became available only in the preschool and the therapist's office and, temporarily, were not available in his home. The therapist enacted a process of graduated shaping of communication behaviors—first nonverbal and then vocal noises—and trained the preschool teacher to do the same. Froot Loop boxes were kept in full view of Tim at all times during the initial phase of treatment and, when he was "caught" gazing at the box, the therapist or teacher would prompt Tim for acknowledgment that he wanted the treat. Pointing, looking, and nodding in their direction resulted in receiving four Froot Loops. Next, Tim was asked to make a sound or ask for the Froot Loop to receive the reward. This step was accomplished as he granted and eventually said, "Loop." Finally, prompts to ask for the Froot Loops in a sentence were enacted, and Tim complied with this demand. This phase of treatment took 2 days at the preschool and 2 hours of therapy to accomplish. Eventually, the boxes of Froot Loops were removed from the environments, but the teacher kept the cereal with her to deliver four Loops whenever Tim made sounds or spoke in school. This shaping procedure took an additional 3 days to result in Tim speaking to the teacher and peers, albeit in short sentences. The treat was faded—that is, delivered on a variable ratio schedule.

Justin was a 14-year-old boy from a middle-class family enrolled in the 9th grade at a public school. He was brought in by his parents for treatment of a long-standing history of shyness and anxiety in social situations, which was more evident now that most of his peers were getting together after school and he was spending his weekends alone. Evaluation revealed social anxiety disorder as the primary disorder. Justin was initially resistant to treatment despite his wish to feel more comfortable with other people and in social situations with peers. After much discussion and some pressure from his parents, Justin began to attend a cognitive-behavioral group treatment for adolescents with social anxiety. Justin became mildly agitated each time he was scheduled for a session; however, once he arrived, he was able to participate. He began, a 16-session course of treatment combining education, cognitive restructuring, behavioral exposure, relapse prevention, and four sessions of parent involvement. As treatment progressed, Justin increased his visibility at school, and even attended a school football game with a few peers. Justin told his therapist that he wanted to go to the next school dance but was afraid that he would be embarrassed and would have to go home before the dance was over. The therapists designed several exposures whereby the various things that could happen at a dance were presented to Justin, including being offered alcohol or drugs, having a good time dancing, being left alone or ignored by his friends, or being turned down if he asked a girl to dance with him. As it turned out, Justin's few school acquaintances ignored him and left him at the dance. Justin, prepared for this less-than-desired outcome in his group experience, asked two girls to dance, and forced himself to interact with other peers. To his surprise, despite his shyness, one girl agreed to dance with him. He considered the evening a success. Justin subsequently went to another social event with a new group of peers who seemed more accepting of him. In Justin's case, the importance of practicing responses to potential rejections in the safety of his treatment group was crucial to his success at the dance, and it increased his motivation to continue treatment. Through his treatment, Justin became more and more appropriately prepared, through behavioral exposure and practice, to handle what might previously have been awkward and discouraging situations. (Adapted from a case contributed by Anne Marie Albano, Ph.D.)
Supportive Psychotherapy

Supportive psychotherapy is particularly helpful in enabling a well-adjusted youngster to cope with emotional turmoil engendered by a crisis. It also is used to treat disturbances related to traumatic experiences, losses, mild mood disorders, and mild forms of anxiety.

Jenna was a 13-year-old teen with a family history of anxiety and depression. Her parents brought her to treatment because of recurrent obsessions involving contamination and germs, with corresponding compulsions during which she had convinced her parents to check her food, while she washed her hands repeatedly until they became raw and bleeding. Evaluation revealed a fear that, unless her parents checked her food for bugs or germs, the meal was likely contaminated. Jenna's parents, attempting to ease her fear, would physically pull apart her food and examine it to her satisfaction, often spending upward of 1 hour before each meal. However, this process caused much distress and discord between Jenna and her family. Jenna's hand washing had generalized to almost every daily activity—after opening a door, reading a book, using a pencil, or touching any object that she deemed dirty. Jenna's evaluation led to a recommendation of behavioral therapy utilizing exposure and response prevention. This consisted of formulating a hierarchy of her obsessions and compulsions, from the least upsetting (checking food prepared by her mother) to the most upsetting (touching something that was wet or slimy and then touching her mouth). Systematically, the therapist engaged Jenna first in a series of imaginal exposures to a scene (e.g., you take a bite of hamburger and something tastes gritty to you and you realize that your mom did not check the burger) until her anxiety dropped to an acceptable level. The drop in anxiety typically took approximately 25 minutes. Next, the scene was enacted in vivo, whereby foods were introduced with "contaminants" in them (e.g., putting pieces of uncooked rice into the burger to mimic "grit"), and Jenna ate the food without having her parents check. As treatment progressed, Jenna learned that her chronic fear of becoming sick was not likely to occur. Similarly, washing rituals were addressed by having her touch items with various substances coating them and then touching her face and mouth. Jenna's treatment entailed a 14-session program during which her parents were taught to assist her with these exposures in the home. Her parents were also instructed to refrain from engaging in her rituals. Relapse prevention plans were added to expand her range of food choices and situational contexts (cafeterias, food stands, restaurants) for exposure. By the end of treatment, Jenna was eating without the need for checking and with minimal anxiety. Moreover, she was engaging in a wide range of activities without the need to wash after touching each object. (Adapted from a case contributed by Anne Marie Albano, Ph.D.)

A 6-year-old boy was brought for treatment because of long-standing severe aggression and destruction of property. In addition to an evaluation for medication, the child was seen in twice-weekly psychoanalytically oriented psychotherapy. The beginning sessions were marked by the repeated need to set limits and contain the boy's aggressive behaviors. Two months into treatment, he began to pump himself up, roar, and announce that he was "the Incredible Hulk." He would then proceed to stomp around the play therapy room, attempting to destroy the toys. The therapist then suggested, "You know you can't really be the Hulk. You can pretend that you are the Hulk, and then maybe we can play this together." After a number of similar exchanges, the child gradually allowed the therapist to join in the game with him. Over the next 6 months, the boy was able to modulate his behavior in that he was able to "play the part" of the Hulk, but without destroying property, and limiting himself to actions that were less aggressive. He was able to understand that he could pretend to be the Hulk without literally trying to be the Hulk. (Adapted from a case contributed by David L. Kaye, M.D.)

Combined Psychodynamic and Behavioral Therapy

Probably the most vivid examples of the integration of psychodynamic and behavioral approaches are demonstrated in the milieu of child and adolescent inpatient, residential, and partial hospital or intensive outpatient treatment programs. Behavioral change is initiated in these settings, and its repercussions are explored concurrently in individual psychotherapeutic sessions, so that the action in one arena and the information stemming from it augment and illuminate what transpires in the other arena.

Alternative and Complementary Psychosocial interventions: Mindfulness-Based Stress Reduction (MBSR), Mindfulness Meditation, and Yoga

Mindfulness-Based Stress Reduction (MBSR), a psychoeducational training program leading to applying the practice of mindfulness into everyday life was studied in adolescent psychiatric outpatients. Mindfulness practices focus on paying sustained attention to moment-to-moment stimuli without engaging in cognitive judgments or self-criticism, and promoting an attitude of acceptance. In adults, this practice has been shown to facilitate improved coping and decrease symptoms of anxiety, stress, and in some cases, self-harming behaviors. The current study was a trial of approximately 100 adolescents aged 14 to 18, with heterogeneous diagnoses, who were randomized to a waitlist control group receiving treatment as usual (TAU), which consisted of individual or group therapy, or to manualized sessions of MBSR for 2 hours per week for 8 weeks. The MBSR group was led by trained instructors who facilitated the use of mindfulness practices by the participants during formal sessions and encouraged practice at home as well. The participants were tested diagnostically at the end of the 8-week study period and again at 3 months following the end of the study. The results found that
both the MBSR and the TAU groups reported significantly reduced anxiety, depressive, and somatization symptoms, and improved self-esteem; but only the MBSR group reported significant declines in perceived stress, obsessive symptoms, and interpersonal problems. Furthermore, although more than 45 percent of the MBSR group showed changes in diagnoses at the end of the study (such as no longer meeting criteria for a mood disorder) none of the TAU group was found to have remitted from a diagnosis.

Mindfulness meditation practices have been applied in various forms to a multitude of psychiatric conditions including mood disorders, chronic pain syndromes, anxiety disorder, and ADHD. Mindfulness, according to Kabat-Zinn, is characterized by paying complete attention to the present moment without judgment, with an ability to be aware of inner and outer experiences in the present. There are many forms of meditation which incorporate mindfulness, and both MBSR, and Mindfulness-Based Cognitive Therapy (MBCT) developed by Teasdale, can be considered forms of mindfulness meditation. There is evidence based on neuroimaging studies that mindfulness meditation can induce specific brain states. One study indicated that Vipassana meditation is associated with activation of the rostral anterior cingulate cortex as well as the dorsal medial prefrontal cortex. There is evidence to suggest that mindfulness meditations can improve attention, and that these changes may lead to clinically important improvements.

Yoga originated in ancient India, and while there are many varieties, key components include physical postures, controlled breathing, deep relaxation, and meditation. Randomized controlled trials using yoga have provided evidence of its benefit as an adjunctive intervention in mild depression, sleep disturbance, and attention problems. Clinical trials comparing yoga to cooperative game playing or physical exercises in children with ADHD found moderate improvements in ADHD symptoms when yoga was added as an adjunct to medication. There is some evidence suggesting that yoga may be beneficial as an adjunctive intervention for mild depression, even in the absence of medication and potentially for schizophrenia, as an adjunct to medication.

THE ROLE OF PLAY

Observing play and engaging in play with children can be extremely informative in assessing developmental abilities, and in understanding sensitive situations. This is particularly relevant for young children, and for children who have experienced trauma, which is difficult to describe in words.

Although the choices of play material vary among therapists, the following equipment can constitute a well-balanced playroom or play area: multi-generational families of dolls of various races; dolls representing special roles and feelings, such as police officer, doctor, and soldier; dollhouse furnishings with or without a dollhouse; toy animals; puppets; paper, crayons, paint, and blunt-ended scissors; a sponge-like ball; clay or something comparable; tools such as rubberhammers, rubber knives, and guns; building blocks, cars, trucks, and airplanes; and eating utensils. The toys should enable children to communicate through play. Therapists should avoid fragile objects that can break easily, that can result in physical injury to a child, or that can increase a child’s guilt.

Psychotherapy with children and adolescents generally is more directed and active than it is with adults. Children usually cannot synthesize histories of their own lives, but they are excellent reporters of their current internal states. Even with adolescents, a therapist often takes an active role, is somewhat less open-ended than with adults, and offers more direction and advocacy than with adults.

Nurturing and maintaining a therapeutic alliance may require educating children about the process of therapy. Another educational intervention may entail assigning labels to affects that have not been part of a youngster’s experience.

The temptation for therapists to offer themselves as a quasiparent role model for children may stem from helpful educational attitudes toward children. Although this may sometimes be an appropriate therapeutic strategy, therapists should not lose sight of the potential pitfalls of engaging in a highly parental role with their child and adolescent patients.

PARENTS AND FAMILY MEMBERS

Parents and family members are involved in child psychotherapy to varying degrees. For preschool-age children, the entire therapeutic effort may be directed toward the parents, without any direct treatment of the child. At the other extreme, children can be treated in psychotherapy without any parental involvement beyond the payment of fees and transporting the child to the therapy sessions. Most practitioners, however, prefer to maintain an alliance with parents to obtain additional information about the child.

Probably the most frequent parental arrangements are those developed in child guidance clinics—that is, parent guidance focused on the child or the parent–child interaction and therapy for the parents’ own individual needs concurrent with the child’s therapy. Parents may be seen by their child’s therapist or by someone else. Recently, increasing efforts have been made to shift the focus from the child as the primary patient to the child as the family’s emissary to the clinic. In such family therapy, all or selected members of the family are treated simultaneously as a family group. Although the preferences of specific clinics and practitioners for either an individual or a family therapeutic approach may be unavoidable, the final decision regarding which therapeutic strategy or combination to use should be derived from the clinical assessment.

CONFIDENTIALITY

The issue of confidentiality takes on greater meaning as children grow older. Very young children are unlikely to be as concerned about this issue as are adolescents. Confidentiality usually is preserved unless a child is believed to be in danger or to be a danger to someone else. In other situations, a child’s permission usually is sought before a specific issue is raised with parents. Advantages exist to creating an atmosphere in which children can feel that all words and actions are viewed by therapists as simultaneously both serious and tentative. In other words, children’s communications do not bind therapists to a commitment; nevertheless, they are too important to be communicated to a third party without a patient’s permission. Although such an attitude may be implied, sometimes therapists should explicitly discuss confidentiality with children. Most of what children do and say in psychotherapy is common knowledge to the parents.
The therapist should try to enlist parents’ cooperation in respecting the privacy of children’s therapeutic sessions. The respect is not always readily honored, because parents are naturally curious about what transpires, and they may be threatened by a therapist’s apparently privileged position.

 Routinely reporting to a child the essence of communications with third parties about the child underscores the therapist’s reliability and respect for the child’s autonomy. In certain treatments, the report can be combined with soliciting the child’s guesses about these transactions. A therapist also may find it fruitful to invite children, particularly older children, to participate in discussions about them with third parties.

INDICATIONS

Psychotherapy usually is indicated for children with psychiatric symptoms or disorders that interfere with their ability to function at home and in school, and causes significant distress. A developmental perspective always informs psychosocial interventions with a given child, so that it matches that child’s cognitive function and emotional maturity. If a psychotherapy situation is not effective, it is important to determine whether the therapist and patient are poorly matched, whether the type of psychotherapy is inappropriate to the nature of the problems, and whether the child is cognitively inappropriate for the treatment.

31.18b Group Psychotherapy

Therapeutic groups for children and adolescents are varied in terms of problems addressed, age of patients, group structure, and therapeutic approach implemented. Group formats have been used to treat a broad range of clinical symptoms, including anger-management for aggressive children and adolescents, social skills improvement, support groups for survivors of childhood sexual abuse, and other traumatic events such as the September 11th World Trade Center tragedy. In addition, groups have also been settings for the treatment of adolescents with social anxiety and OCD, and youth with depressive disorders. Groups have successfully used cognitive-behavioral techniques to treat childhood anxiety disorders, adolescents with substance abuse, and youth with specific learning disorders. Support groups for youth exposed to loss have provided evidence of efficacy, including data from a study investigating the benefits of a psychotherapy group for adolescent survivors of homicide victims. Group therapies can be utilized with children of all ages using developmentally appropriate formats. The groups can focus on behavioral, educational, and social skills and psychodynamic issues. The mode in which the group functions depends on children’s developmental levels, intelligence, and problems to be addressed. In behaviorally oriented and cognitive-behavioral groups, the group leader is a directive, active participant who facilitates prosocial interactions and desired behaviors. In groups using psychodynamic approaches, the leader may monitor interpersonal interactions less actively than in behavior therapy groups.

Gathering children and adolescents into groups may lead to greater psychological impact than treating them individually. A number of factors, described by Irving Yalom, may contribute to the effectiveness of groups. These factors include the following theoretical components:

**Hope**: Hope may be generated by gathering with others who are experiencing similar difficulties and by observing others actively mastering the problems.

**Universality**: Children and adolescents with psychiatric disorders often feel isolated and alienated from peers. Working together in groups may diffuse the isolation and help children and adolescents view their disorder as only a small part of their overall identity.

**Imparting Information**: Children and adolescents are familiar with a format of gaining new information in a group setting, such as in school. The group therapy format provides an opportunity to reinforce learning when the child or adolescent “helps” or demonstrates what he or she has learned to peers.

**Altruism**: Helping other peers in a group setting by supporting them and identifying with their struggles can improve a child or adolescent’s self-esteem and help them gain a sense of mastery over their own issues.

**Improved Social Skills**: Group therapy is a safe format in which children and adolescents with poor social skills can improve their interpersonal and communication abilities under the supervision of a leader and with peers who also benefit from the practice scenarios.

Groups can be highly effective modalities to provide peer feedback and support to children who are either socially
isolated or unaware of their effects on their peers. Groups with very young children generally are highly structured by the leader and use imagination and play to foster socially acceptable peer relationships and positive behavior. Therapists must be keenly aware of the level of children’s attention span and the need for consistency and limit setting. Leaders of preschool-age groups can model supportive adult behavior in meaningful ways for children who have been deprived or neglected. School-age children’s groups can be single sex or include both boys and girls. School-age children are more sophisticated in verbalizing their feelings than preschoolers, but they also benefit from structured therapeutic games. Children of school age need frequent reminders about rules, and they are quick to point out infractions of the rules to each other. Interpersonal skills can be addressed nicely in group settings with school-age children.

Same-sex groups are often used among adolescents. Physiological changes in early adolescence and the new demands of high school lead to stress that may be ameliorated when groups of same-age peers compare and share. In older adolescence, groups more often include both boys and girls. Even with older adolescents, the leader often uses structure and direct intervention to maximize the therapeutic value of the group. Adolescents who are feeling rejected or alienated may find a special sense of belonging in a therapy group.

Keith was a high-functioning, 14-year-old boy diagnosed with autism spectrum disorder. Keith was an awkward-looking adolescent who seemed younger than his chronological age. His academic level was above average, but his social development was odd. His pedantic speaking style contributed considerably to his social isolation, particularly after starting 7th grade. He was referred to a group of adolescents with social skills problems in order to improve his ability to make friends and have more successful social interactions. Initially, Keith limited his participation to monosyllabic answers to direct questions, and then he would go back to reading a book on the history of Napoleon, his favorite subject and object of fascination. Group members chose to ignore him after a while. Over a period of several weeks, his interest in the book seemed to abate. Keith brought it, but it remained unopened on his lap. He would make an occasional remark, which was often not related to the topic of conversation. The other adolescents in the group seemed to respect his “differentness”; however, it was still difficult to have successful social interactions. Two months later a very shy 13-year-old boy joined the group. After a few sessions Keith developed an unexpected interest in the newer member and sat near him and encouraged him to interact with the group. Soon Keith was not bringing a book any longer and was more involved with group members. In response to the group leader’s guidance and practice exercises in the group, Keith learned to respond to social cues in a more appropriate manner, and although he continued having morbid preoccupations with power and a fascination with Napoleon, he was able to converse with group members about more pertinent social topics. Keith’s increasing social skills and greater interest in people was clinically evident. Social skills practice within the group became a most significant tool to help Keith with his interpersonal interactions in school and with his family. (Adapted from a case contributed by Alberto C. Serrano, M.D.)

**PRESCHOOL-AGE AND EARLY SCHOOL-AGE GROUPS**

Work with a preschool-age group usually is structured by a therapist through the use of a particular technique, such as puppets or artwork. In therapy with puppets, children project their fantasies onto the puppets in the same way as in ordinary play. Here, the group aids the child less by interaction with other members than by action with the puppets.

In play group therapy, the emphasis rests on children’s interactional qualities with each other and with the therapist in the permissive playroom setting. A therapist should be a person who can allow children to produce fantasies verbally and in play but who can also use active restraint when children undergo excessive tension. The toys are the traditional ones used in individual play therapy. The children use the toys to act out aggressive impulses and to relieve their home difficulties with group members and with the therapist. The children selected for group treatment have a common social hunger and need to be like their peers and be accepted by them. Selected children usually include those with phobias, effeminate boys, shy and withdrawn children, and children with disruptive behavior disorders.

Modifications of these criteria have been used in group psychotherapy for autistic children, parent group therapy, and art therapy. A modification of group psychotherapy has been used for toddlers with physical disabilities who show speech and language delays. The experience of twice-weekly group activities involves mothers and children in a mutual teaching–learning setting. This experience has proved effective for mothers who received supportive psychotherapy in the group experience; their formerly hidden fantasies about their children emerged and were dealt with therapeutically.

**SCHOOL-AGE GROUPS**

Activity group psychotherapy is based on the idea that corrective experiences in a therapeutically conditioned environment may increase appropriate social interactions between children and with adults. The format uses interview techniques, verbal explanations of fantasies, group play, work, and other communications. In this type of group psychotherapy, children verbalize in a problem-oriented manner, with the awareness that problems brought them together and that the group aims to change them. They report dreams, fantasies, daydreams, and unpleasant experiences.

Therapists vary in their use of time, co-therapists, food, and materials. Most groups meet after school for at least 1 hour, although other group leaders prefer a 90-minute session. Some therapists serve food during the last 10 minutes; others prefer serving times when the children are together for talking. Food, however, does not become a major feature and is never central to the group’s activities.

**PUBERTAL AND ADOLESCENT GROUPS**

Group therapy methods similar to those used in younger-age groups can be modified to apply to pubertal children, who are often grouped monosexually. Their problems resemble those of late latency-age children, but they (especially the girls) are also beginning to feel the effects and pressures of early adolescence.
Groups offer help during a transitional period; they seem to satisfy the social appetite of preadolescents, who compensate for feelings of inferiority and self-doubt by forming groups. This therapy takes advantage of the influence of the socialization process during these years. Because pubertal children experience difficulties in conceptualizing, pubertal therapy groups tend to use play, drawing, psychodrama, and other nonverbal modes of expression. The therapist's role is active and directive.

Activity group psychotherapy has been the recommended group therapy for pubertal children who do not have significantly disturbed personality patterns. The children, usually of the same sex and in groups of not more than eight, freely engage in activities in a setting especially designed and planned for its physical and environmental characteristics. Samuel Slavson, a pioneer in group psychotherapy, pictured the group as a substitute family in which the passive, neutral therapist becomes the surrogate for parents. The therapist assumes various roles, mostly in a nonverbal manner, as each child interacts with the therapist and other group members. Currently, however, therapists tend to see the group as a form of peer group, with its attendant socializing processes, rather than a reenactment of the family.

Late adolescents, 16 years of age and older, often may be included in groups of adults. Group therapy has been useful in the treatment of substance-related disorders. Combined therapy (the use of group and individual therapy) also has been used successfully with adolescents.

**OTHER GROUP SITUATIONS**

Groups are also helpful in more focused treatments, such as specific social skills training for children with ADHD, cognitive-behavioral group interventions for depressed children and for children with bereavement problems or eating disorders. In these more specialized groups, the issues are more specific, and actual tasks (as in social skills groups) can be practiced within the group. Some residential and day treatment units use group psychotherapy techniques. Group psychotherapy in schools for underachievers and children from low socioeconomic levels has relied on reinforcement and on modeling theory, in addition to traditional techniques, and has been supplemented by parent groups.

In controlled conditions, residential treatment units have been used for specific studies in group psychotherapy, such as behavioral contracting. Behavioral contracting with reward–punishment reinforcement provides positive reinforcements among preadolescent boys with severe concerns in basic trust, low self-esteem, and dependence conflicts. Somewhat akin to informal residential treatment units are social group work homes. For children who undergo many psychological assaults before placement, supportive group psychotherapy offers ventilation and catharsis, but more often it succeeds in letting children become aware of the enjoyment of sharing activities and developing skills.

Public schools—also a structured environment, although not usually considered the best site for group psychotherapy—have been used by several workers. Group psychotherapy as group counseling readily lends itself to school settings. One such group used gender- and problem-homogeneous selection for groups of six to eight students, who met once a week during school hours over 2 to 3 years.

**INDICATIONS**

Many indications exist for the use of group psychotherapy as a treatment modality. Some indications are situational; a therapist may work in a reformatory setting, in which group psychotherapy seems to reach adolescents better than individual treatment does. Another indication is time economics; more patients can be reached in a given time by the use of groups than by individual therapy. Group therapy best helps a child at a given age and developmental stage and with a given type of problem. In young age groups, children's social hunger and their potential need for peer acceptance help determine their suitability for group therapy. Criteria for unsuitability are controversial and have been loosened progressively.

**PARENT GROUPS**

In group psychotherapy, as in most treatment procedures for children, parental difficulties can present obstacles. Sometimes, uncooperative parents refuse to bring a child or to participate in their own therapy. The extreme of this situation reveals itself when severely disturbed parents use a child as their channel of communication to work out their own needs. In such circumstances, a child is in the unfortunate position of receiving positive group experiences that seem to create havoc at home.

Parent groups, therefore, can be a valuable aid to group psychotherapy for their children. A recent study of a cognitive-behavioral group intervention for parents to learn how to utilize therapeutic interventions with their anxiety disordered children suggested that parent groups to teach these skills can be successfully utilized with their children. Parents of children in therapy often have difficulty understanding their children's ailments, discerning the line of demarcation between normal and pathological behavior, relating to the medical establishment, and coping with feelings of guilt. Parent groups assist in these areas and help members formulate guidelines for action.

31.18c Residential, Day, and Hospital Treatment

Inpatient, partial hospital, and residential treatment are designed for the management of acute stabilization, stepdown care, and longer-term management of children and adolescents with psychiatric disorders. Given the limited number of psychiatric inpatient units for children and adolescents, however, intensive outpatient programs and partial hospital treatment programs are often used for children with severe psychiatric disorders. Partial hospital programs are increasingly being offered by managed care companies as alternatives to hospitalization to contain treatment cost. These programs are designed to serve the needs of children and adolescents with severe disorders who require immediate psychosocial and/or pharmacological interventions but who may not meet the acuity criteria of “medical necessity” for hospitalization. Residential treatment centers are appropriate settings for children and adolescents with psychiatric disorders who require a highly structured and supervised setting for several months or longer. Such settings provide a stable, consistent environment with a high level of psychiatric monitoring that is less intensive than in a hospital. Children and adolescents with serious psychiatric disturbances are sometimes admitted to residential facilities due to family situations in which appropriate supervision and parenting are impossible.

Dan was a 16-year-old adolescent boy with a long history of depression and multiple suicide attempts. He was admitted to a local adolescent psychiatric inpatient unit after a life-threatening suicide attempt. At the end of the first week of hospitalization, Dan’s family’s managed care company refused continued coverage, since they determined that he was no longer an acute suicide risk. Dan was remorseful about his recent suicide attempt and was determined not to repeat his self-destructive behavior. However, due to continued serious depressive symptoms and chronic family dysfunction, the inpatient treatment team did not feel that Dan was ready to be discharged to weekly outpatient treatment. Dan was transferred to a partial hospital program affiliated with the inpatient unit. Over the course of Dan’s 8-week treatment, he developed a strong therapeutic alliance with his individual therapist, and the psychoeducation provided to the family resulted in the beginning of meaningful changes. The partial hospital program child psychiatrist met with Dan regularly, managed his medication, and collaborated with his therapist to manage his suicidal ideation. At the end of 8 weeks, Dan’s depressive symptoms were decreased, and he was safely transitioned to outpatient therapy and returned to school successfully. The partial hospital program allowed for a safe transition from full hospitalization with continued consolidation of progress in a highly structured system. (Adapted from case material courtesy of Laurel J. Kiser, Ph.D., M.B.A., Jerry Heston M.D., and David Pruitt, M.D.)

Mark was an 8-year-old boy referred to a rural community mental health center for evaluation and treatment. Mark presented with extreme irritability, labile mood, tantrums, and physical violence toward his peers and adults. Even when he was not having a tantrum, he seemed discontent and irritated and had a short fuse. He had received multiple school suspensions and was at risk for expulsion. His family psychiatric history was positive for schizophrenia in his maternal grandmother. Upon finishing his outpatient psychiatric evaluation, the clinician recommended participation in a newly established partial hospital/day treatment program that used a behavioral management program close to Mark’s elementary school. The clinician also recommended a trial of fluoxetine to determine whether Mark’s irritability would be ameliorated, and individual therapy, social skills group, and family therapy.

During Mark’s 6-month participation in the day program, his behavioral management program extended into the classroom setting as well as in therapeutic activities. His daily goals included increasing compliance, decreasing anger outbursts, and decreasing physical aggression. He was able to improve peer relations while receiving immediate feedback and direct instruction on social skills in a group setting and also in his individual therapy. Each staff member was able to consistently apply behavior management principles in their domain areas. Mark’s parents actively participated in family therapy sessions and parent conferences. Mark seemed to be benefiting from the fluoxetine and was less irritable. Although he still had occasional outbursts, they were milder and shorter. Mark was gradually transitioned to half a day in a regular classroom setting, and he remained the other half day in the day program. After 8 more weeks of this transition, he was able to return to his public school. (Adapted from case material courtesy of Laurel J. Kiser, Ph.D., M.B.A., Jerry Heston, M.D., and David Pruitt, M.D.)

HOSPITALIZATION

Psychiatric hospitalization is necessary when a child or adolescent is contemplating or exhibiting dangerous behaviors directed at him or herself or toward others. The most frequent reasons for psychiatric hospitalization among youth include suicidal thoughts or behavior, and aggressive and assaultive behaviors. Safety, stabilization, and initiation of effective treatment are the main goals of hospitalization. In some cases, psychiatric hospitalization may be a given child’s first experience of a stable, safe environment. Hospitals are often the most appropriate places to initiate a new psychopharmacological agent, especially when side effects are prevalent, in order to provide around-the-clock observations of a child’s behavior. Children who have been maltreated often show remission of certain symptoms by virtue of being removed from a stressful and abusive environment. Given the frequency of uncontrollable aggression as the trigger for many psychiatric admissions among youth, inpatient units must provide safe and effective ways to defuse and stabilize
aggressive and violent acts. Placing a child or adolescent on the verge of a violent act in a contained room away from the rest of the milieu is one method of de-escalating a potentially violent situation. Both restraint and seclusion have been considered therapeutic interventions for youth who cannot control aggressive impulses, but given the rare but reported deaths of patients by asphyxiation during restraint procedures, there have been efforts to reduce this intervention. However, seclusion and restraint cannot be abandoned until another form of intervention is found to be highly effective. In some cases, psychopharmacological interventions, that is, "chemical restraint," has been utilized to defuse acutely dangerous situations on an inpatient unit. Optimally, identifying and recognizing antecedents of aggressive behaviors and intervening before the aggression is enacted is the goal. Inpatient care is a setting for stabilization and the initiation of treatment, with the expectation that when a child or adolescent is discharged to a less restrictive environment, the patient will no longer pose a danger to him or herself or others, and that treatment and support services will be in place for continued care.

Partial Hospital

In most cases, children and adolescents who attend partial hospital, or day treatment programs, have serious mental disorders and might warrant psychiatric hospitalization without the program's support. Family therapy, group and individual psychotherapy, psychopharmacology, behavioral management programs, and special education are integral parts of these programs. Partial hospital programs are excellent alternatives for children and adolescents who require more intensive support, monitoring, and supervision than is available in the community, but who can live successfully at home if they receive the proper level of intervention.

The concept of daily comprehensive therapeutic experiences that do not require removing children from their homes or families is derived partly from experiences with a therapeutic nursery school. The main advantages of partial hospital programs are that children remain with their families and the families can be more involved in day treatment than they are in residential or hospital treatment. Partial hospital also is much less expensive than residential treatment. At the same time, the risks of day treatment include a child's relative social isolation and confinement to a narrow band of social contacts in the program's disturbed peer population.

Indications. The primary indication for a partial hospital plan is the need for a more structured, intensive, and specialized treatment program than can be provided on an outpatient basis. At the same time, the home in which the child is living should be able to provide an environment that is at least not destructive to the child's development. Children who are likely to benefit from day treatment may have a wide range of diagnoses, including autistic disorder, conduct disorder, ADHD, and mental retardation. Exclusion symptoms include behavior that is likely to be destructive to the children themselves or to others under the treatment conditions. Therefore, some children who threaten to run away, set fires, attempt suicide, hurt others, or significantly disrupt the lives of their families while they are at home are not suitable for day treatment.

Programs. Ingredients that lead to a successful partial hospital program include clear administrative leadership, team collaboration, open communication, and an understanding of children's behavior.

A major function of child-care staff in partial hospital programs is to provide positive experiences and a structure that enables the children and their families to internalize controls and to function better than in the past. Because the ages, needs, and range of diagnoses of children who may benefit from some form of day treatment vary, many day treatment programs have been developed. Some programs specialize in the special educational and structured environmental needs of mentally retarded children. Others offer therapeutic efforts designed to treat children with autism and schizophrenia. Still other programs provide the total spectrum of treatment usually found in full residential treatment, of which they may be an extension. Children may move from one part of the program to another and may be in residential treatment or partial hospital according to their needs. A school program is always a major component of partial hospital treatment. Attempts have been made to analyze the treatment outcome of partial hospitalization. Many different dimensions exist to analyze the overall benefits of such programs; assessment of level of improvement in clinical status, academic progress, peer relationships, community interactions (legal difficulties), and family relationships are some pertinent areas to measure. In a follow-up 1 year after discharge from a partial hospital program, comparison of patients at admission and 1-year post-discharge showed statistically significant improvement in clinical symptoms on each subscale of the Child Behavior Checklist, except for sex problems. Improvements were found in mood, somatic complaints, attention problems, thought problems, delinquent behavior, and aggressive behavior. The assessment of long-term effectiveness of day treatment is fraught with difficulties, and may differ when measuring a child's maintenance of gains, a therapist's view of psychological gains, or cost-to-benefit ratios.

The lessons learned from day treatment programs have encouraged mental health disciplines to have services follow children, rather than have separate programs, which result in discontinuity of care. The experiences of partial hospital programs for psychiatric conditions of children and adolescents have also encouraged pediatric hospitals and departments to adopt models that promote continuity of care for children with chronic physical illness.

Residential Treatment

Children in residential treatment often have combinations of severe psychiatric disorders and severely troubled families who cannot adequately care for their children. In some cases, a child or adolescent requires a more structured environment than is possible at home. In other cases, a family is unable to oversee a child's psychiatric treatment due to their own psychiatric illness, substance abuse, or medical debilitation. In cases of child abuse or neglect, a family does not provide a safe and nurturing environment for a child. When families are available and motivated, their participation is strongly encouraged while their children are in residential treatment. The aim is to enable them to reunite with their children and care for them at home in the future.
Staff and Setting

Staffing patterns include various combinations of child-care workers, teachers, social workers, psychiatrists, pediatricians, nurses, and psychologists; therefore, residential treatment can be very expensive. The Joint Commission on the Mental Health of Children made the following structural and setting recommendations:

In addition to space for therapy programs, there should be facilities for a first-rate school and a rich evening activity program, and there should be ample space for play, both indoors and out. Facilities should be small, seldom exceeding 60 patients in capacity with a limit of 100 patients, and they should make provisions for children to live in small groups. The centers should be located near the families they serve and should be readily accessible by public transportation. They should be located for ready access to special medical and educational services and to various community resources, including consultants. The centers should be open institutions whenever possible; locked buildings, wards, or rooms should be required only rarely. In designing residential programs, the guiding principle should be that children should be removed from their normal life settings the least possible distance in space, in time, and in the psychological texture of the experience.

Indications

Most children who are referred for residential treatment have had multiple evaluations by professionals, such as school psychologists, outpatient psychotherapists, juvenile court officials, or state welfare agency staff. Attempts at outpatient treatment and foster home placement usually precede residential treatment. Sometimes, the severity of a child's problems or the inability of a family to provide for the child's needs prohibits sending a child home. Many children sent to residential treatment centers have disruptive behavior problems in addition to other problems, including mood disorders and psychotic disorders. In some cases, serious psychosocial problems, such as physical or sexual abuse, neglect, indigence, or homelessness, necessitate out-of-home placement. The age range of the children varies among institutions, but most children are between 5 and 15 years of age. Boys are referred more frequently than girls.

An initial review of data enables the intake staff to determine whether a particular child is likely to benefit from the treatment program; often, for every child accepted for admission, three are rejected. The next step usually is interviews with the child and the parents by various staff members, such as a therapist, a group-living worker, and a teacher. Psychological testing and neurological examinations are given, when indicated, if they have not already been performed. The child and parents should be prepared for these interviews.

Milieu

Most of a child's time in a residential treatment setting is spent in the milieu. The staff consists of clinicians and care workers who offer a structured environment that forms a therapeutic milieu; the environment places boundaries and limitations on the children. Tasks are defined within the limits of children's abilities; incentives, such as additional privileges, encourage them to progress rather than regress. In milieu therapy, the environment is structured, limits are set, and a therapeutic atmosphere is maintained.

The children often select one or more staff members with whom to form a relationship; through this relationship, they express, consciously and unconsciously, many of their feelings about their parents. The child-care staff should be trained to recognize such transference reactions and to respond to them in a way that differs from the children's expectations, which are based on their previous or even current relationships with their parents. This requires an awareness of countertransference in staff members.

To maintain consistency and balance, the group-living staff members must communicate freely and regularly with each other and with the other professional and administrative staff members of the residential setting, particularly the children's teachers and therapists. Behavior modification principles are typically embedded into the daily program for children in residential settings. A recent study examined the association between use of antipsychotic medication and seclusion/restraint (S/R) frequency in the management of acute aggressive behavior in adolescents in residential facilities. Adolescents who were in the moderate and high groups for having S/R were significantly more likely to have changes in antipsychotic medication and receive higher doses of medication. However, even with high doses, their rates of S/R continued to be frequent. These findings bring into question the efficacy of antipsychotic agents for managing acute aggression in residential settings.

Education

Children in residential treatment frequently have severe learning disorders, disruptive behavior, and ADHD. Usually, the children cannot function in a regular community school and consequently need a special on-grounds school. A major goal of the on-grounds school is to motivate children to learn. The educational process in residential treatment is complex; Table 31.18c-1 shows its components.

Therapy

Most residential facilities use a basic behavior modification program to set guidelines and to give the residents a concrete sense of how to earn privileges. These behavioral programs range in detail and intensity. Some programs operate with level systems that are associated with privileges and responsibilities. Some programs use a token economy system in which residents earn points for appropriate behavior and for meeting specific goals. Most programs include basic tasks of living as well as specific therapeutic goals for the residents.

Psychotherapy offered in these programs generally is supportive and oriented toward reunion with the family when possible. Insight-oriented psychotherapy is included when it can be used by a resident.

Parents

Concomitant work with parents is essential. Children usually have a strong tie to at least one parent, no matter how disturbed the parent may be. Sometimes, a child idealizes the parent, who repeatedly fails the child. Other times, the parent has an ambivalent or unrealistic expectation that the child will return home. In some instances, the parent must be helped to enable the child to

live in another setting when it is in the child's best interest. Most residential treatment centers offer individual or group therapy for parents, couples, or marital therapy, and in some cases, conjoint family therapy.

**DAY TREATMENT**

The concept of daily comprehensive therapeutic experiences that do not require removing children from their homes or families is derived partly from experiences with a therapeutic nursery school. Day hospital programs for children were then developed, and the number of programs continues to grow. The main advantages of day treatment are that children remain with their families and the families can be more involved in day treatment than they are in residential or hospital treatment. Day treatment also is much less expensive than residential treatment. At the same time, the risks of day treatment are a child's social isolation and confinement to a narrow band of social contacts in the program's disturbed peer population.

**Indications**

The primary indication for day treatment is the need for a more structured, intensive, and specialized treatment program than can be provided on an outpatient basis. At the same time, the home in which the child is living should be able to provide an environment that is at least not destructive to the child's development. Children who are likely to benefit from day treatment may have a wide range of diagnoses, including autistic disorder, conduct disorder, ADHD, and mental retardation. Exclusion symptoms include behavior that is likely to be destructive to the children themselves or to others under the treatment conditions. Therefore, some children who threaten to run away, set fires, attempt suicide, hurt others, or significantly disrupt the lives of their families while they are at home may not be suitable for day treatment.

**Programs**

The same ingredients that lead to a successful residential treatment program apply to day treatment. These ingredients include clear administrative leadership, team collaboration, open communication, and an understanding of children's behavior. Indeed, having a single agency offer both residential and day treatment has advantages.

A major function of child-care staff in day treatment for psychiatrically disturbed children is to provide positive experiences and a structure that enables the children and their families to internalize controls and to function better than in the past regarding themselves and the outside world. Again, the methods used are essentially similar to those in full residential treatment programs.

Because the ages, needs, and range of diagnoses of children who may benefit from some form of day treatment vary, many day treatment programs have been developed. Some programs
specialize in special educational and structured environmental needs of mentally retarded children. Others offer special therapeutic efforts required to treat children with autism and schizophrenia. Still other programs provide the total spectrum of treatment usually found in full residential treatment, of which they may be a part. Children may move from one part of the program to another and may be in residential treatment or day treatment according to their needs. The school program always is a major component of day treatment, and psychiatric treatment varies according to a child's needs and diagnosis.

Results
Recently, attempts have been made to analyze the treatment outcome of day treatment and partial hospitalization. Many different dimensions exist to analyzing overall benefits of such programs. Assessment of level of improvement in clinical status, academic progress, peer relationships, community interactions (legal difficulties), and family relationships are some pertinent areas to measure. In a recent follow-up 1 year after discharge from a partial hospital program, comparison of patients at admission and 1-year post-discharge showed statistically significant improvement in clinical symptoms on each subscale of the Child Behavior Checklist, except for sex problems. These improvements were in mood symptoms, somatic complaints, attention problems, thought problems, delinquent behavior, and aggressive behavior. The assessment of long-term effectiveness of day treatment is fraught with difficulties, from the point of view of a child's maintenance of gains, a therapist's view of psychological gains, or cost-to-benefit ratios.

At the same time, the advantage of day treatment has encouraged further development of programs. Moreover, the lessons learned from day treatment programs have moved mental health disciplines toward having services follow children, rather than perpetuating discontinuities of care. The experiences of day treatment for psychiatric conditions of children and adolescents have also encouraged pediatric hospitals and departments to adopt a model that promotes continuity of care for the medical treatment of children with chronic physical illnesses.

References
THERAPEUTIC CONSIDERATIONS

As psychopharmacologic interventions for childhood psychiatric disorders have gained an evidence base, establishing a therapeutic alliance, identifying and monitoring target symptoms, and promoting medication compliance are important components of successful clinical outcomes. Teamwork between the child, parents, and psychiatrist is critical in successful treatment of childhood disorders with psychopharmacologic agents.

An evaluation for psychopharmacotherapy must first include an assessment of a child's psychopathology and physical condition to rule out any predisposition for side effects (Table 31.18d-1). An assessment of the child's caregivers focuses on their ability to provide a safe, consistent environment in which a clinician can conduct a drug trial. The physician must consider the risk-to-benefit ratio and must explain it to the patient, if he or she is old enough, and to the child's caregivers and others (e.g., child welfare workers) who may be involved in the decision to medicate.

The clinician must obtain baseline ratings before medicating. Behavioral rating scales help objectively the child's response to medication. The physician generally starts at a low dose and titrates upward on the basis of the child's response and the appearance of adverse effects. Optimal drug trials cannot be rushed (e.g., by insurance-imposed, inadequately short hospital stays or by infrequent outpatient visits), nor can drug trials be prolonged by the physician's insufficient contact with the patient and the caregivers. The success of drug trials often hinges on the physician's daily accessibility.

CHILDHOOD PHARMACOKINETICS

Compared with adults, children have greater hepatic capacity, more glomerular filtration, and less fatty tissue. Thus, stimulants, antipsychotics, and tricyclic drugs are eliminated more rapidly by children than by adults; lithium (Eskalith) may also be eliminated more rapidly, and children may be less able to store drugs in their fat. Because of children's quick elimination, the half-lives of many medications may be shorter in children than in adults.

Little evidence indicates that clinicians can predict a child's blood level from the dosage or a treatment response from the plasma level. Relatively low serum levels of haloperidol seem to be adequate to treat Tourette's disorder in children. No correlation is seen between the methylphenidate (Ritalin) serum level and a child's response. The data are incomplete and conflicting about major depressive disorder and serum levels of tricyclic drugs. Serum level is related to response for tricyclic drugs in the treatment of enuresis.

With lithium therapy, a ratio of lithium concentration in saliva to that in serum can be established for a child by averaging three to four individual ratios. The average ratio can then be used to convert subsequent saliva levels to serum levels and, thus, avoid some venipuncture in children who are stressed by blood tests. As with serum levels, regular clinical monitoring for adverse effects is necessary. Table 31.18d-2 lists representative agents, their indications, dosages, adverse reactions, and monitoring requirements.

STIMULANT AGENTS, ATOMOXETINE, AND α-AGONIST AGENTS

Stimulant pharmacologic agents remain the primary treatment for ADHD in children, adolescents, and adults. Multiple studies support the efficacy of stimulant medications for ADHD. Current practice is leaning toward more use of once-a-day, long-acting preparations of stimulants such as methylphenidate, amphetamine and amphetamine salts, and dextemethylphenidate (Focalin LA). The most frequently researched and used stimulant is methylphenidate. Dextroamphetamine (Dexedrine) has comparable efficacy and, unlike methylphenidate, is approved by the FDA for children 3 years of age and older; the starting age for methylphenidate is 6 years. The amphetamine, Adderall, combines dextroamphetamine and amphetamine salts. The extended-release preparations, such as Concerta and Adderall XR, have the advantages of coverage of symptoms throughout the school day without the necessity of taking another dose, as well as a more continuous delivery of medication. Stimulants reduce hyperactivity, inattentiveness, and impulsivity in about 75 percent of children with ADHD. The effects are not paradoxical, because normal children respond similarly. The dose-related adverse effects of stimulants are listed in Table 31.18d-3.

The methylphenidate transdermal patch (Daytrana) is approved by the FDA for the treatment of ADHD in children age 6 to 12 years. Daytrana comes in patches that can deliver 15 mg, 20 mg, and 30 mg when worn for 9 hours per day. The medication begins to have its effects on the target symptoms of ADHD approximately 2 hours after the patch is placed, and continues to deliver medication throughout the wear time. Given that its active ingredient is methylphenidate, the side effects are generally the same as those for methylphenidate, except for the potential skin irritation that may emerge from wearing the patch. The patch should not be worn in the presence of a heating pad or electric blanket because heat increases the rate of methylphenidate delivery into the skin. Patients with glaucoma or known hypersensitivity to methylphenidate products should not begin treatment with Daytrana. Daytrana has the advantages of being able to deliver medication until the patch is removed and, for children who are unable to swallow pills, Daytrana offers a unique administration option.

Lisdexamfetamine dimesylate (LDX), sold as Vyvanse, is a pro-drug of dextroamphetamine upon cleavage of the lysine portion of the molecule. LDX was created to be longer lasting than dextroamphetamine and less likely to become a drug of abuse because it requires enzymes to convert it to dextroamphetamine. LDX has been approved by the FDA for the treatment of ADHD in children 6 to 12 years of age as well as in adults with ADHD. In contrast to Adderall, which contains approximately 75 percent dextroamphetamine, LDX comprises the dextro enantiomer only. In trials, LDX has also been shown to be effective and safe in the treatment of adolescents with ADHD. Similar to other stimulant agents, the most common side effects of LDX

were decreased appetite, headache, insomnia, decreased weight, and irritability.

Recent studies support the use of atomoxetine (Strattera), a norepinephrine reuptake inhibitor, as an efficacious nonstimulant treatment for ADHD in children and adolescents. Atomoxetine is well absorbed after ingestion and reaches its maximal plasma concentration after about 1 to 2 hours. Common side effects of atomoxetine include abdominal discomfort, decreased appetite, dizziness, and irritability. Rarely, minor increases in blood pressure and heart rate have been noted. Atomoxetine is metabolized by the cytochrome P450 (CYP) 2D6 hepatic enzyme system, and a fraction of the population (about 7 percent of Caucasians and 2 percent of African Americans) are poor metabolizers, which may increase the plasma half-life by about fivefold. When combined with other medications that inhibit CYP 2D6, such as fluoxetine and paroxetine, diminished metabolism of atomoxetine can occur, and the dose may need to be decreased. Atomoxetine is generally initiated at 0.5 mg/kg.
given once per day and increased to a therapeutic dose ranging between 1.4 mg/kg and 1.8 mg/kg, either in one dose or in two divided doses.

SECOND GENERATION ANTIPSYCHOTICS (SGAS) AND CONVENTIONAL ANTIPSYCHOTIC AGENTS

The SGAs represent a major advance in the pharmacological treatment of schizophrenia in children and adolescents, as well as in adults. The atypical antipsychotic agents have largely replaced traditional antipsychotics because of their more favorable side-effect profiles, greater effectiveness for negative symptomatology, and mood-stabilizing effects. Although the SGAs are generally recommended currently as first-line agents in the treatment of psychotic disorders in children and adolescents, only one controlled NIMH trial has been conducted using an atypical agent in the treatment of schizophrenia for youth. This study examined clozapine and found it to be superior to haloperidol for treating positive and negative symptoms of schizophrenia in 21 youth. The serious drawbacks of clozapine, however, limit it as a first-line agent for this disorder. In the NIMH trial, five participants developed significant neutropenia, and two experienced seizures. Clozapine is generally used only for treatment-resistant schizophrenia.

Open label trials in youth with schizophrenia have suggested efficacy of other atypical antipsychotic agents such as olanzapine, risperidone, and quetiapine. Case reports have suggested that ziprasidone is effective. One of the main side effects of the atypical antipsychotic agents is significant weight gain. A newer atypical agent, aripiprazole awaits clinical trials to confirm its potential to be an efficacious and more weight neutral agent for the treatment of childhood psychoses. Although conventional antipsychotics, such as haloperidol, loxapine (Loxitane), and thioridazine (Mellaril) have been shown to be significantly superior to placebo in the treatment of psychosis in youth, given their side effect profiles they are typically chosen as first-line treatments. Schizophrenia with onset in late adolescence is treated, as is adult-onset schizophrenia.

Aggressive, explosive, and assaultive behaviors associated with disruptive behavior disorders, psychotic disorders, and posttraumatic stress disorders have been treated with antipsychotic agents with varying reports of success. Randomized controlled trials with several atypical antipsychotics, such as risperidone, olanzapine, quetiapine (Seroquel), and aripiprazole (Abilify), have provided evidence of effectiveness for behavioral improvement, with fewer long-term adverse effects than typical antipsychotics.

When conduct disorder is associated with ADHD, a trial of a stimulant is indicated; stimulants are faster acting than atypical antipsychotics or mood-stabilizing agents used in clinical practice to control dangerously aggressive behaviors.

The management of severe aggression, disruptive behavior, and ADHD remains a challenge. Combinations of antipsychotics with mood-stabilizing agents or stimulants are sometimes used in treatment-resistant cases, although few studies attest to the efficacy or safety of drug combinations. Newer “atypical” antipsychotic medications—SDAs—such as risperidone, olanzapine, clozapine (Clozaril), ziprasidone (Geodon), and aripiprazole have enabled a wider range of treatment-resistant patients to benefit from neuroleptic treatment. The SDAs are believed to relieve both the positive and negative symptoms of schizophrenia and to produce less risk of extrapyramidal adverse effects and less potential for the development of tardive dyskinesia. Nevertheless, all antipsychotics pose some risk of extrapyramidal adverse effects and tardive dyskinesia. One challenge in obtaining optimal pharmacological treatment for children is to decrease maladaptive behaviors while promoting productive academic functioning. To this end, clinicians must consider adverse effects of medication that result in cognitive “dulling.” Certain pharmacological agents used in pediatric populations are associated with a specific disorder or with target symptoms that appear in several disorders. For example, haloperidol was shown in past studies to be effective in the treatment of Tourette’s disorder, but it has also been used to control severe aggression. The high-potency antipsychotics haloperidol and pimozide (Orap) still have the greatest body of evidence as effective medications for Tourette’s disorder, although they also have considerable drawbacks. Pimozide prolongs the QT interval and, thus, requires electrocardiography (ECG) monitoring. Clonidine, a presynaptic α-adrenergic blocking agent, is less effective than each of the above-mentioned antipsychotics, but has the advantage of avoiding the risk for tardive dyskinesia; sedation is a frequent side effect of clonidine.

Tic disorders often coexist with ADHD in children and adolescents. Stimulant use is controversial; it can precipitate tics and should be avoided in these patients, although recent studies indicate that the prohibition may not be totally warranted. Clonidine sometimes reduces tics in both ADHD and the comorbid cases.

SELECTIVE SEROTONIN REUPTAKE INHIBITOR (SSRI) ANTIDEPRESSANTS AND OTHER ANTIDEPRESSANTS

SSRI antidepressants have been found in randomized clinical trials to have efficacy in the treatment of childhood anxiety disorders, depressive disorders, and OCD. A substantial evidence base exists for the efficacy of SSRIs in the treatment of separation anxiety, generalized anxiety disorder, and social phobia in children and adolescents. Thus, SSRIs are currently recommended as first-line medications in the treatment of childhood anxiety. Separation anxiety disorder, generalized anxiety disorder, and social phobia are often studied together because they so commonly coexist. A given child with one of the preceding anxiety disorders has a 60 percent chance of having a second one, and in 30 percent of cases, all three are comorbid. Alprazolam (Xanax) may be helpful in separation anxiety disorder, but randomized clinical trials are still needed.

The SSRIs currently are the drugs of choice in the pharmacological treatment of depressive disorders in children and adolescents. Given the FDA placement of the “black-box” warning on all antidepressants used in children and adolescents because of the slightly increased risk of suicidal behaviors, close monitoring of suicidal ideation and behavior is imperative. Although most side effects of SSRIs are tolerable, anecdotal recent reports indicate occasional SSRI-induced apathy
in children and adolescents. Previously, clomipramine proved effective in diminishing obsessions and compulsions in children and adolescents and was generally well tolerated. However, the SSRIs have a more favorable adverse-effect profile and appear to be as effective as clomipramine.

MOOD-STABILIZING AGENTS

Classic mania in children and adolescents is treated as it is treated in adults. Use of lithium in treating adolescent mania has been supported in many open trials. Divalproex is used frequently to treat bipolar disorder in children and adolescents. A recent double-blind, randomized pilot study comparing quetiapine (400 to 600 mg a day) or divalproex (serum level 80 to 120 mg/mL) in a trial lasting approximately 1 month, found that quetiapine is at least as effective as divalproex in treating acute manic symptoms. Reduction of symptoms occurred more quickly with quetiapine compared with divalproex. Lithium has been shown in multiple investigations to reduce aggression in conduct disorder, and propranolol (Inderal) has been chosen as an agent to control aggression in open trials, although no evidence supports its use in children and adolescents. Carbamazepine (Tegretol) has not been shown to be effective in controlling aggression in child and adolescent conduct disorders.

Table 31.18d-4 summarizes the effects of drugs on cognitive tests of learning functions. In children with learning disorders who have attention problems, even in the absence of meeting full criteria for ADHD, methylphenidate facilitates performance on several standard cognitive, psycholinguistic, memory, and vigilance tests, but does not improve children's academic achievement ratings or teacher ratings. Cognitive impairment from psychotropic drugs, especially antipsychotics, may be an even greater problem for persons who are mentally retarded than for those with learning disorders.

BENZODIAZEPINES

Sleep terror disorder and sleepwalking disorder occur in the transition from deep delta-wave sleep (stages 3 and 4) to light sleep. Benzodiazepines may be effective in these disorders. They work by reducing both delta-wave sleep and arousals between sleep stages. The medications should be used temporarily and only in severe cases, because tolerance to the medications develops. Cessation of these medications can lead to severe rebound worsening of the disorders, and reducing delta sleep in children may have deleterious effects; thus, behavioral approaches are preferred for these disorders.

Patients with early-onset panic disorder and panic attacks have benefited from clonazepam (Klonopin) in several open trials.

ADVERSE EFFECTS AND COMPLICATIONS

Antidepressants

Adverse effects related to antidepressants have diminished significantly since SSRI antidepressants have been widely accepted as first-line treatments for depressive disorders in children and adolescents. Tricyclics are rarely recommended because of the significant risks of dangerous adverse effects. The adverse effects of tricyclics for children usually are similar to those for adults and result from the drugs' anticholinergic properties. These effects include dry mouth, constipation, palpitations, tachycardia, loss of accommodation, and sweating. The most serious adverse effects in children are cardiovascular; diastolic hypertension is more common and postural hypotension occurs more rarely than in adults. ECG changes are most likely seen in children receiving high doses. Slowed cardiac conduction (PR interval greater than 0.20 seconds or QRS interval greater

than 0.12) may necessitate lowering the dosage. FDA guidelines limit dosages to a maximum of 5 mg/kg a day. The drugs can be toxic in an overdose, and in small children, ingestion of 200 to 400 mg can be fatal. When the dosage is lowered too rapidly, withdrawal effects occur, mainly gastrointestinal symptoms—cramping, nausea, and vomiting—and sometimes apathy and weakness.

Antipsychotics

The SGAs have generally replaced the conventional antipsychotics as first-line agents in the treatment of all psychotic disorders in children and adolescents. Historically, the best-studied antipsychotics given to pediatric age groups are chlorpromazine (Thorazine) and haloperidol. High-potency and low-potency antipsychotics are thought to differ in their adverse-effect profiles. The phenothiazine derivatives (chlorpromazine and thioridazine) have the most pronounced sedative and atropinic actions, whereas the high-potency antipsychotics are commonly believed to be associated with extrapyramidal reactions, such as parkinsonian symptoms, akathisia, and acute dystonias. The risk of tardive dyskinesia in relation to antipsychotics leads to caution in the use of drugs. Tardive dyskinesia, which is characterized by persistent abnormal involuntary movements of the tongue, face, mouth, or jaw and sometimes the extremities, is a known hazard when giving antipsychotics to patients of all age groups. No known treatment is effective. Because transient choreiform movements of the extremities and trunk are common after abrupt discontinuation of antipsychotics, clinicians must distinguish these symptoms from persistent dyskinesia.

REFERENCES

31.18e Psychiatric Treatment of Adolescents

Adolescence, biologically beginning with puberty, is a period in which social, intellectual, and sexual development take place alongside specific brain processes that enhance teens' abilities for increased abstract reasoning and greater sensitivity to social nuances. However, the developmental brain processes are spread over many years, and maturation is subject to individual variation. Inherent in development is continuing change; however, most adolescents adapt to changes gradually, and their path toward greater autonomy and independence is not characterized by perpetual crises and struggle. Milestones achieved by adolescents during their developmental journey to adulthood are typically reached without overwhelming strife or intervention. However, psychiatric treatment is indicated for an adolescent who develops a disturbance of thought, affect, or behavior that disrupts normal functioning. In adolescents, disruption of functioning influences eating, sleeping, and school function, as well as relationships with family and peers. A variety of serious psychiatric disorders, including schizophrenia, bipolar disorder, eating disorders, and abuse or substance abuse typically have their onset during adolescence. In addition, the risk for completed suicide drastically increases in adolescence. Although some degree of stress is virtually universal in adolescence, most teenagers who do not develop serious mental disorders cope well with environmental demands. Teenagers with preexisting mental disorders often experience exacerbations during adolescence and may become frustrated, alienated, and demoralized. Clinicians and parents seeking a window into an adolescent's viewpoint should be sensitive to their self-perceptions. A range of emotional maturity exists in teens of the same chronological age. Issues characteristic of adolescence are related to new evolving identities, the development of sexual activity, and developing plans to meet future life goals.

DIAGNOSIS

Adolescents can be assessed with a focus on general progress in accomplishing the tasks of individuating and developing a sense
of autonomy. For many adolescents in today’s culture, school performance and peer relationship successes are the primary barometers of healthy functioning. Adolescents with normative intellectual function who are deteriorating academically, or teens who become isolated from peers, are typically experiencing significant psychological disturbance, which merits investigation.

Questions to be asked regarding adolescents’ stage-specific tasks are the following: What degree of separation from their parents have they achieved? What sort of identities are evolving? How do they perceive their past? Do they perceive themselves as responsible for their own development or only the passive recipients of their parents’ influences? How do they perceive themselves with regard to the future, and how do they anticipate their future responsibilities for themselves and others? Can they think about the varying consequences of different ways of living? How do they express their sexual and affectionate interests? These tasks occupy the lives of all adolescents and normally are performed at different times.

Adolescents’ family and peer relationships must be evaluated. Do they perceive and accept both “good and bad” qualities in their parents? Do they feel comfortable with their peers and romantic partners as “separate persons” with needs that may not completely match their own?

Respect and acceptance of an adolescent’s subcultural and ethnic background are essential.

INTERVIEWS

Adolescent patients and their parents should be interviewed separately in a comprehensive psychiatric evaluation. Other family members also may be included, depending on their involvement in the teenager’s life and difficulties. Clinicians often prefer to see the adolescent first, however, in order to develop a rapport with the adolescent and promote being an advocate for the adolescent and avoid the appearance of being the parents’ agent. In psychotherapy with an older adolescent, the therapist and the parents usually have little contact after the initial part of the therapy, because ongoing contact inhibits the adolescent’s desire to open up.

Interview Techniques

Adolescents may feel pressured by their parents to receive psychiatric treatment and may at first be defensive, or appear guarded. Clinicians must establish themselves as trustworthy and helpful adults to promote a therapeutic alliance. They should encourage adolescents to tell their own stories, without interrupting to check discrepancies; such a tactic may make the therapist seem correcting and disbelieving. Clinicians should ask patients for explanations and theories about what happened. Why did these behaviors or feelings occur? When did things change? What caused the identified problems to begin when they did?

Sessions with adolescents generally follow the adult model; the therapist sits across from the patient. In early adolescence, however, board games may help to stimulate conversation in an otherwise quiet, anxious patient.

Language is crucial. Even when a teenager and a clinician come from the same socioeconomic group, their language use is seldom the same. Psychiatrists should use their own language, explain any specialized terms or concepts, and ask for an explanation of unfamiliar in-group jargon or slang. Many adolescents do not talk spontaneously about illicit substances and suicidal tendencies but do respond honestly to a therapist’s questions. A therapist may need to ask specifically about each substance and the amount and frequency of its use. The sexual histories and current sexual activities of adolescents are increasingly important pieces of information for adequate evaluation. The nature of adolescents’ sexual behavior often is a vignette of their whole personality structures and ego development, but a long time may elapse in therapy before adolescents begin to talk about their sexual behavior.

**A 15-year-old adolescent male was referred for a psychiatric evaluation by his high school counselor when he disclosed that he was late to school each day because it took him 3 hours to get ready in the mornings. Even after he finally got to school, he often missed classes and was found in the bathroom. In speaking to his counselor, he further disclosed that he had developed a number of bedtime and morning rituals that took longer and longer to complete because if he did them incorrectly, he had to repeat them. They included checking the locks on the windows and doors, placing objects in the “right” places on his dresser, and repeating a prayer 16 times. He also revealed that when in the bathroom, he had to wash his hands a certain way and dry them “just so,” or he feared something terrible would happen. He had not wanted his parents to know about his difficulties, and he often told them that he had headaches or stomachaches, which made him late. However, he did explain some of his difficulties to his parents during the course of his psychiatric evaluation. His evaluation revealed significant OCD and social phobia. Treatment was initiated, including use of fluoxetine, an SSRI; CBT; and problem-solving family therapy. Over the course of 6 months, his OCD responded well to the combination of medications and CBT, and he was relieved that his family learned ways of helping him both at home and in school. (Adapted from case material courtesy of Eugene V. Beresin, M.D. and Steven C. Schlozman, M.D.)**

**A 14-year-old girl, one of the stars of her high school gymnastic team, began increasing her daily exercise and restricting her diet after her coach indicated that she should lose a few pounds. She became fixated on the size of her thighs and belly, and once she started losing weight, she found that she was not satisfied and wanted to lose a few more pounds. Over the next four months she lost so much weight that her coach and pediatrician no longer allowed her to participate in athletics. Although she was heartbroken about being restricted from gymnastics and planned to eat enough to be able to participate again with her team, she was unable to gain weight, and continued to lose more. She became increasingly terrified of getting fat and secretly exercised any chance she could. She was a perfectionist in academics as well as in gymnastics. She had started her menses 6 months previously, but after she lost a significant amount of weight, her menses stopped. She was seen by a therapist and she and her parents agreed to a meal plan that would result in weight gain, but her family was baffled because she continued to lose more weight. Finally, when it became clear that she was not able to be gain weight under the supervision of her family and her outpatient therapist, she was hospitalized, and the diagnosis of anorexia nervosa, was established. After a 30-day**
hospitalization with a modest weight gain, she was stepped down to a partial hospital program in which she was supervised for all of her meals, and went home at night. She remained in this program for 8 weeks, and was able to gain 1 to 2 pounds per week. As part of this program, her weight was monitored twice weekly, her vital signs were monitored, and she participated in family therapy, individual psychodynamic psychotherapy, and weekly meetings with a nutritionist. In her psychotherapy, over the course of the next year, she was able to understand that her anorexia had served to prevent her from separating from her parents and kept her close to home and isolated from her peers. She learned that she was slower to mature than many of her peers and felt unable to cope with the social pressures of being a high school student. Over time, she was able to maintain her weight and begin to socialize with friends whom she hadn't seen for many months. When she was able to maintain an optimal weight she was thrilled to be able to resume her athletics, and she began to develop closer friendships. (Adapted from case material courtesy of Eugene V. Beresin, M.D., and Steven C. Schlozman, M.D.)

TREATMENT

Psychiatric treatment of an adolescent can occur in numerous venues and modalities. Treatment can take place in individual or group settings, and can include interventions that are pharmacological (when indicated), psychosocial, and from an environmental perspective. The best choices for treatment must take into account the characteristics of the individual adolescent and the family or social milieu. Adolescents’ striving for autonomy may complicate problems of compliance with therapy and may result in the need for stabilization in inpatient settings, whereas this level of care might not be necessary at a different stage of life. The following discussion is less a set of guidelines than a brief summary of what each treatment modality can or should offer.

Individual Psychotherapy

Individual psychosocial modalities with an evidence base for efficacy with adolescents include cognitive-behavioral treatments for diagnoses of anxiety disorders, mood disorders, and OCD. Interpersonal therapy is a technique that has been used to treat mood disorders in adolescents. Few adolescent patients are trusting or open without considerable time and testing of therapists, and it is helpful to anticipate the testing period by letting patients know that it is expected and is natural and healthy. Pointing out the likelihood of therapeutic problems—for instance, impatience and disappointment with the psychiatrist, with the therapy, with the time required, and with the often intangible results—may help keep problems under control. Therapeutic goals should be stated in terms that adolescents understand and value. Although they may not see the point in exercising self-control, enduring dysphoric emotions, or forgoing impulsive gratification, they may value feeling more confident than in the past and gaining more control over their lives and the events that affect them.

Typical adolescent patients need a relationship with a therapist they can perceive as a real person, whom they feel respected by and they can trust. The therapist may seem like another parent in some respects, since adolescents still need appropriate guidance, especially in situations of high-risk behaviors. Thus, a professional who is impersonal and anonymous is a less useful model than one who can accept and respond rationally to an angry challenge or confrontation without fear or false conciliation—one that can impose limits and controls when adolescents cannot, can admit mistakes and ignorance, and can openly express the gamut of human emotions.

Combined Pharmacotherapy and Psychotherapy

Current evidence suggests that for many psychiatric disorders, optimal treatment includes a combination of psychosocial and psychopharmacological interventions. Randomized clinical trials have provided evidence of the superiority of CBT in combination with SSRIs in the treatment of mood disorders, OCD, and anxiety disorders, to name a few.

ADHD is often comorbid with additional disorders, thus, although the Multimodal Treatment Study of Children with ADHD (MTA) found that psychosocial interventions did not add to the efficacy of stimulant treatments for the core symptoms of ADHD, it is important to consider that other concurrent disorders that affect overall functioning often require psychosocial treatments. Advances in drug development have widened the choice of medications to treat mood disorders (e.g., SSRIs) and schizophrenia (e.g., SGAs, including risperidone [Risperdal], olanzapine [Zyprexa], and clozapine [Clozaril]). Although these medications have been used to treat psychiatric disorders in adolescents, more research is required to determine their efficacy and safety profiles for treatment of adolescent psychopathology.

A 17-year-old girl complained of recurrent episodes of rapid heartbeat, sweating, trembling, and a fear that she was "going crazy." Her first episode had occurred in her high school cafeteria during a "college night" event, when multiple college representatives were displaying their college’s information packets. After running out of the cafeteria, she stood outside of her school and the episode gradually dissipated over a period of about 15 minutes. Although she was a little nervous about going back to school the next day, she did not have another episode. She had almost forgotten about the episode, when it happened again, and even more intensely, when she was shopping at the mall and talking about college applications with her friends. After this episode, she became fearful of going out alone to the shopping mall. She was at the beginning of her senior year in high school, considering her options for college and was planning to take her SAT for the last time. Her parents wanted her to maintain the family tradition and pressured her to try for the same college from which her mother graduated. She was not opposed to applying to her mother's alma mater, but was very angry and upset about her parents’ pressure on her to make a commitment to this school as her first choice. She became irritable and tearful, and she was experiencing several panic attacks per week, all of which indicated that she needed to get some help. She was evaluated by a psychiatrist and started on Lexapro (escitalopram) to alleviate the panic disorder symptoms, as well as weekly psychotherapy. The psychotherapy focused on the patient's conflicts with her parents, highlighting her chronic concern that she could not meet parental expectations and fears
Group Psychotherapy

In many ways, group psychotherapy is a natural setting for adolescents. Most teenagers are more comfortable with peers than with adults. A group diminishes the sense of unequal power between the adult therapist and the adolescent patient. Participation varies, depending on an adolescent’s readiness. Not all interpretations and confrontations should come from the parent-figure therapist; group members often are adept at noticing symptomatic behavior in each other, and adolescents may find it easier to hear and consider critical or challenging comments from their peers.

Group psychotherapy usually addresses interpersonal and current life issues. Some adolescents, however, are too fragile for group psychotherapy or have symptoms or social traits that are too likely to elicit peer group ridicule; they need individual therapy to attain sufficient ego strength to struggle with peer relationships. Conversely, other adolescents must resolve interpersonal issues in a group before they can tackle intrapsychic issues in the intensity of one-on-one therapy.

Family Therapy

Family therapy is the primary modality when adolescents’ difficulties mainly reflect a dysfunctional family (e.g., teenagers with school refusal, runaways). The same may be true when developmental issues, such as adolescent sexuality and striving for autonomy, trigger family conflicts or when family pathology is severe, as in cases of incest and child abuse. In these instances, adolescents usually need individual therapy as well, but family therapy is mandatory if an adolescent is to remain in the home or return to it. Serious character pathology, such as that underlying antisocial and borderline personality disorders, often develops from highly pathogenic early parenting. Family therapy is strongly indicated whenever possible for such disorders, but most authorities consider it adjunctive to intensive individual psychotherapy when individual psychopathology has become so internalized that it persists regardless of the current family status.

Inpatient Treatment

Residential treatment schools often are preferable for long-term therapy, but hospitals are more suitable for emergencies, although some adolescent inpatient hospital units also provide educational, recreational, and occupational facilities for long-term patients. Adolescents whose families are too disturbed or incompetent, who are dangerous to themselves or others, who are out of control in ways that preclude further healthy development, or who are seriously disorganized require, at least temporarily, the external controls of a structured environment.

Long-term inpatient therapy is the treatment of choice for severe disorders that are considered wholly or largely psychogenic in origin, such as major ego deficits that are caused by early massive deprivation and that respond poorly or not at all to medication. Severe borderline personality disorder, for example, regardless of the behavioral symptoms, requires a full-time corrective environment in which regression is possible and safe and in which ego development can take place. Psychotic disorders in adolescence often require hospitalization; however, psychotic adolescents often respond to appropriate medication well enough that therapy is feasible in an outpatient setting, except during exacerbations. Adolescent patients with schizophrenia who exhibit a long-term deteriorating course may require hospitalization periodically.

Day Hospitals

In day hospitals, which have become increasingly popular, adolescents spend the day in class, individual and group psychotherapy, and other programs, but they go home in the evenings. Day hospitals are less expensive than full hospitalization and usually are preferred by patients.

CLINICAL PROBLEMS

Atypical Puberty

Pubertal changes that occur 2.5 years earlier or later than the average age are within the normal range. Body image is so important to adolescents, however, that extremes of the norm may be distressing to some, either because markedly early maturation subjects them to social and sexual pressures for which they are unready or because late maturation makes them feel inferior and excludes them from some peer activities. Medical reassurance, even if based on examination and testing to rule out pathophysiology, may not suffice. An adolescent’s distress may show as sexual or delinquent acting out, withdrawal, or problems at school that are sufficiently serious to warrant therapeutic intervention. Therapy also may be prompted by similar disturbances in some adolescents who fail to achieve peer-valued stereotypes of physical development despite normal pubertal physiology.

Substance-Related Disorders

Some experimentation with psychoactive substances is almost ubiquitous among adolescents, especially if this category of behavior includes alcohol use. Most adolescents, however, do not become abusers, particularly of prescription drugs and illegal substances. Any regular substance abuse represents disturbance. Substance abuse sometimes is self-medication against depression or schizophrenic deterioration and sometimes it signals a character disorder in teenagers whose ego deficits render them unequal to the stresses of puberty and the tasks of adolescence. Some substances, including cocaine, have a psychologically reinforcing action that acts independent of preexisting psychopathology. When substance abuse covers an underlying illness or is a maladaptive response to current stresses or disturbed family dynamics, treatment of the underlying cause may diminish the substance use; in most cases of significant abuse,
however, the drug-taking behavior typically requires intervention. Substance abuse treatments typically include a 12-step program with behavioral monitoring to accomplish sobriety as well as the ability to verbalize regarding the motivations for substance use. These philosophies are adapted to inpatient, intensive outpatient, and once-a-week outpatient treatment.

Suicide

Suicide is the third leading cause of death among adolescents. Many hospital admissions of adolescents result from suicidal ideation or behavior. Among adolescents who are not psychotic, the highest suicidal risks occur in those who have a history of parental suicide, who are unable to form stable attachments, who display impulsive behavior, and who abuse alcohol or other substances. Many adolescents who complete suicide have backgrounds that include long-standing family conflict and social problems since early childhood and the escalation of subjective distress under the pressure of a sudden perceived conflict or loss. Early childhood loss of parents also can increase the risk of depression in adolescence. Adolescents who are susceptible to rapid and extreme mood swings and a history of impulsive behavior are at greater risk of responding to despair with impulsive suicide attempts. Abuse of alcohol and other substances are known added risks for suicidal behavior in adolescents with suicidal ideations. The developmentally predictable “omnipotent” attitudes of adolescents may cloud the immediate sense of permanence of death and result in impulsive self-destructive behavior in adolescents.

During a psychiatric evaluation of an adolescent with suicidal thoughts, plans and past attempts must be discussed directly when the concern arises and information is not volunteered. Recurring suicidal thoughts should be taken seriously, and a clinician must evaluate the imminent clinical danger requiring inpatient hospitalization versus an adolescent’s ability to engage in an agreement or contract mandating that the adolescent will seek help before engaging in self-destructive behavior. Adolescents typically are honest in their refusal of such agreements, and, in such cases, hospitalization is indicated. Hospitalization of a suicidal adolescent by a clinician is an act of serious, protective concern.

References

Forensic evaluations of youth span a broad spectrum of situations and settings, including child custody during a parental divorce, trauma and abuse situations, and juvenile offender evaluations pertaining to juvenile and criminal court cases. Child and adolescent psychiatrists are increasingly being sought out by patients and attorneys for evaluations and expert opinions related to child sexual and physical abuse, to criminal behaviors perpetrated by minors, and to evaluate the relations between traumatic life events and the emergence of psychiatric symptoms in children and adolescents. As more youth enter the juvenile justice system, an increasing need exists for forensic psychiatrists with expertise in evaluation and treatment for detainees and committed youths.

The specific tasks and role of a child and adolescent psychiatric forensic evaluator are distinctly different from a child and adolescent psychiatrist doing a clinical evaluation and clinical treatment intervention. In clinical settings, child mental health professionals provide psychotherapy, medication evaluations, and advocacy for youth with psychiatric diagnoses. As a forensic child psychiatric evaluator, however, the main task is to be an expert, to report objective psychiatric findings related to the questions asked. Two essential characteristics of a forensic evaluator, in contrast to a clinician are (1) the relationship between the evaluator and the patient is not therapeutic, rather, it is information seeking, and (2) there are clear limits of confidentiality in this situation, that is, the information disclosed during a forensic evaluation may be brought to court, or to an attorney, or to whomever initiated the evaluation.

Society’s view of children and their rights has evolved dramatically. In 1980, the American Academy of Child and Adolescent Psychiatry (AACAP) published a code of ethics that
was developed to publicly endorse the ethical standards of this discipline. The code is based on the assumption that children are vulnerable and unable to take adequate care of themselves; as they mature, however, their capacity to make judgments of, and choices about, their well-being develops as well. The code has several caveats: From the standpoint of child and adolescent psychiatrists, issues of consent, confidentiality, and professional responsibility must be seen in the context of overlapping and potentially conflicting rights of children, parents, and society.

Confidentiality, or intensive trust, refers to the relationship between two persons with respect to the “entrustment of secrets.” Until the 1970s, little attention was paid to issues of confidentiality pertaining to minors. In 1980, among the items in the AACAP Code of Ethics, six principles were related to confidentiality. Breaches and limits of confidentiality can be obtained in cases of child abuse or maltreatment or for purposes of appropriate education. Although unnecessary, with a child or adolescent, consent for disclosure should be obtained when possible. In 1979, the American Psychiatric Association (APA) stated that a child 12 years of age could give consent for disclosure of confidential information and, with the exception of safety issues, a minor’s consent is required for disclosure of information to others, including the child’s parents. According to the AACAP Code of Ethics, the consent of a minor is not required for disclosure of confidential information. Specific ages for consent are not addressed in the code. Child and adolescent psychiatrists often face the dilemma of weighing the potential benefits and possible harm in sharing information obtained confidentially from a child with the child’s parents. Although the smoothest transition occurs when the child and the physician agree that certain information can be shared, in many situations that border on “dangerousness to the child or others,” the child or adolescent does not agree to share the information with a parent or another responsible adult. Among adolescents, these secrets that are sometimes shared with a psychiatrist may involve drug or alcohol use, unsafe sex practices, or a thrill-seeking act that places the adolescent in danger. A psychiatrist may choose to work with the child or adolescent toward agreeing to share confidential information when it is determined by the treating psychiatrist that the probable outcome would be beneficial. The initial treatment contract, however, limits confidentiality to situations of “danger” to the child or others.

CHILD CUSTODY

Child custody evaluations by child and adolescent psychiatrists may be initiated by divorcing parents who cannot come to an agreement regarding custody of their children, or can be requested by an attorney. Attorneys are most likely to seek child custody evaluations when allegations are made of parental incompetence, or issues of alleged physical or sexual abuse arise. Comprehensive custody evaluations by mental health professionals may play a significant role in successful negotiations of custody by parents without the necessity of proceeding to a trial.

The evolution of child custody decision-making has been influenced by increasing awareness and recognition of the rights of children and women, as well as by a broadening perspective on the developmental and psychological needs of the children involved. Historically, children were considered to be their fathers’ property. At the beginning of the 20th century, the “tender years” doctrine became the standard for determining child custody. According to this doctrine, the relationship between mother and infant, later generalized to mother and child, is responsible for the optimal emotional development of the child; the doctrine thus supported custody decisions in the mother’s favor in most cases. With this doctrine as its guide, psychological issues in developing children became an acceptable dimension to consider in the determination of custody. In controversial and unclear cases, psychological expert testimony began to be accepted as a valuable part of child custody decision-making.

The “best interest of the child” standard replaced the “tender years” doctrine and expanded considerations of the optimal parent to include assessing issues of emotional climate, safety, and educational and social opportunities for the children. The “best interest of the child” grew from the movement to support legislation about the rights of children in the areas of compulsory education, child labor laws, and child abuse and neglect protection laws. Therefore, although “best interest” standards have broadened the dimensions considered in evaluating which parent is best able to serve the best interest of the child, how to measure these qualities in a parent remains vague. In view of the lack of clarity regarding what specific parameters in a parent best correspond to the interest of the child, child and adolescent psychiatrists have increasingly been asked to help make decisions by defining relevant psychological conditions in parents and in the relationships between parents and children.

Psychiatric evaluators may be asked to give an opinion about child custody at various points during the separation and divorce process. Sometimes, a psychiatric evaluation is requested by the parents before any legal action occurs. When the parents and an evaluator can agree on custody decisions before the legal process, a court is likely to go along with these decisions rather than launch an additional investigation. A psychiatric evaluation may be ordered by the court or by the attorneys representing the feuding parents. In such cases, an evaluator is faced with two disgruntled parents, who often are consumed by their mutual conflict to the point that neither is willing to compromise, even in the child’s interest. The advantage in such cases, however, is that evaluators represent the court and can act as advocate for the child without the same pressures that an evaluator hired by only one parent faces. A psychiatric evaluation also may be initiated by a guardian ad litem, an attorney who is appointed by the court to represent the child. Psychiatric evaluators also may be requested to give an opinion about custody during a mediation process. Mediation is a legal process that usually involves one attorney and one evaluator. Because mediation can occur outside the judicial system, some families may prefer it to going through a trial. In addition to custody, psychiatric evaluators often are asked to give opinions about visitation.

In undertaking a custody evaluation, an evaluator is expected to determine the best interests of the child while keeping in mind the standard elements that the court considers. These considerations include the wishes of the parents and the child; relationships with significant others in the child’s life; the child’s adjustment to the current home, school, and community; the psychiatric and physical health of all parties; and the level of conflict and potential danger to the child under the care of either parent. A psychiatric evaluator must maintain his or her role as an advocate for the best interest of the child and does not consider the fairest outcome for parents. The psychiatric evaluator conducts a series of interviews, often including at least one separate interview with each parent and the child alone and one interview with the child and both parents. The evaluator may obtain a written waiver of confidentiality from all parties because he or she may have made disclosures to opposing attorneys and in court before the judge. The evaluator uses direct questioning as well as observations of the relationships between the child and each parent. The age and developmental needs of the child are considered in making a judgment regarding which parent may better serve the child’s interests. As
part of the psychiatric assessment of the child custody evaluation, the evaluator determines the need for psychiatric treatment of any of the parties involved.

The child custody evaluation generally is provided in a written report. This document is not confidential and can be used in court. The report contains a description of the relationship between the child and parents, the capabilities of the parents, and finally, the custody recommendations. In view of data supporting the importance of continuing a relationship with both parents in most cases, it is recommended that joint custody be considered before other options. When sufficient cooperation exists to negotiate for joint custody, the best interests of the child often are served. Joint custody may not be the best option for a child when the relationship of the child with either parent is jeopardized and undermined by the other. The next most frequent choice when joint custody is not advisable is full custody by one parent with visitation rights for the other parent. The parent awarded full custody should be able to support the visitations and relationship with the noncustodial parent. In custody disputes involving a biological parent and a nonbiological parent, the biological parent generally has the right to custody unless he or she is shown to be unable to provide for the child. After the custody evaluation has been submitted in writing, the results must be communicated to the parents, the child, and possibly their respective attorneys. The evaluator may be called on to testify in court, and the parties can use the custody evaluation to mediate other areas of their dispute.

Many complications can occur in an ongoing bitter dispute between divorcing or divorced parents. Both true and false allegations of psychiatric illness, drug or alcohol abuse, or sexual or physical abuse are not uncommon during custody battles. The evaluator must be prepared to verify any allegations and to carefully discuss their effects on custody and visitation. Evidence suggests that markedly elevated numbers of unfounded allegations of child sexual abuse occur during the course of custody disputes.

Tremain, age 9 years, has been in a therapeutic foster home for 2 years, having been removed from his home along with his younger sister, due to profound neglect, as well as physical abuse. Although he is receiving cognitive-behavioral therapy, medication, and a social skills group, he remains volatile, and typically becomes more aggressive and regressed after weekly supervised visits with his mother. Tremain's sister has been reunited with their mother, and his guardian ad litem requests that a child psychiatrist perform a forensic evaluation to determine whether visits should continue. She reviews extensive records, evaluates each parent, obtains history from them and the foster parent, and then observes a visit. Tremain's little sister totally dominates the visit, and her mother is at a loss to control her aggressive and hyperactive behavior. Tremain is passive and clingy with his mother. According to the social work supervisor, this is a fairly typical visit. When the child and adolescent psychiatrist meets individually with Tremain, he expresses concern that his sister is probably being abused at home, and he likes to check on her during these visits. Tremain wants to go home, but he says that his mother has too many problems to take care of him. Tremain has developed a positive relationship with his foster father and, in contrast, has little to say about his biological mother. The child and adolescent psychiatrist recommends a psychiatric evaluation of the sister, but Tremain's mother does not follow through. The child and adolescent psychiatrist recommends cutting visits back to monthly, but Tremain's anxiety and aggressive behavior persist around these limited visits. It also becomes apparent that Tremain's mother is not up to the demands of caring for two special-needs children, as she is having difficulty containing her little daughter. The child and adolescent psychiatrist recommends delaying efforts at parental reunification however, maintaining contact between Tremain, his mother, and his sister. (Adapted from case material from Diane H. Schetky, M.D.)

JUVENILE OFFENDERS

According to the AACAP Practice Parameter for Child and Adolescent Forensic Evaluations, at least 2.7 million youth younger than 18 years are arrested each year in the U.S., and more than 1 million youth will have a formal interaction with the juvenile justice system. Historically, a separate juvenile court system in the United States occurred by statute in the state of Illinois in the late 1800s. Its mandate was to rehabilitate rather than to punish. Despite the protective intentions of the legal system, children and adolescents involved in the juvenile justice system are at high risk for multiple psychiatric disorders and suicidal thoughts and behavior. The omission of various constitutional safeguards, such as the rights to counsel, confrontation, and cross-examination of an accuser, eventually led to criticism and disillusionment with this system. Juvenile offenders of small and significant crimes often were sent to state-run residential programs that were criticized for being overcrowded, neglectful, and frankly abusive. Despite the strong sentiment to increase due process protection for juveniles rather than pretrial, trial, and sentencing, the juvenile court system includes intake, adjudication, and disposition. The intake is a determination of whether probable cause exists that the youth committed a crime. A youth who confesses may be diverted from the court system altogether at this time, and appropriate plans for rehabilitation can be made in a community setting. For more serious crimes or when juveniles deny perpetrating a crime, the process continues. Juveniles must be represented by counsel, and an attorney is provided if the family cannot afford to provide its own. Unlike adult court, in juvenile court, guilt or innocence is determined by a judge, not a jury. The case is argued by a prosecuting attorney and a defense attorney, and the judge is bound by the same standards as in adult court; that is, a judgment of delinquency requires proof beyond a reasonable doubt. When the charge is substantiated and the judgment is for delinquency, the juvenile is an “adjudicated delinquent.” Disposition must next be determined. Dispositions include a wide range of options, from placement in youth correctional facilities, to residential treatment settings, to psychiatric hospitalizations for further evaluation. Delinquent acts refer to ordinary crimes committed by juveniles; status offenses refer to behaviors that would not be criminal if perpetrated by adults, such as truancy, running away, or drinking alcohol. Sometimes, youths who are believed to have committed a serious crime are turned over (receive a waiver) to adult criminal court.
DEVELOPMENTAL IMMATURITY VERSUS
JUVENILE COMPETENCE TO STAND TRIAL

A growing body of research is elucidating the significance of "developmental immaturity" on the capacity of children and young adolescents' competency to stand trial. Starting in the 1960s, the Supreme Court mandated a series of due process rights in juvenile court proceedings including the rights to notice of charges, an adversarial hearing with representation by counsel, the ability to cross-examine witnesses, and a trial transcript. Furthermore, juveniles have the right to a hearing prior to being transferred to adult court, and use of the standard of proof beyond a reasonable doubt to sustain a delinquency petition; however, there is no mention of the right to be competent to stand trial in delinquency proceedings. In the 1960 landmark case *Dusky v. United States*, the Supreme Court established a minimum national standard for competency in criminal proceedings for adults. This standard mandates that in order for a defendant to be competent to stand trial, he or she must possess "sufficient present ability to consult with his lawyer with a reasonable degree of rational understanding and a rational as well as factual understanding of the proceedings against him." Thus, there is no legal requirement for juveniles to be competent to participate in delinquency proceedings; however, many states have adopted their own competency standards for their juvenile courts. This is critical insofar as research suggests that developmental level has a definite impact on a child or early adolescent's understanding and a rational as well as factual understanding required for juveniles to be competent to participate in delinquency proceedings; however, many states have adopted their own competency standards for their juvenile courts.

This is critical insofar as research suggests that developmental level has a definite impact on a child or early adolescent's understanding of legal concepts, and long-term implications associated with their decisions and were more likely than adults to accept plea agreements; whereas youths up to 15 years also demonstrated greater compliance with authority figures in their decision making, compared to adults. Researchers in this field have concluded that due to developmental status alone, young juveniles are at greater risk to make poor decisions on their own behalf in the context of working with their own attorneys. There are many factors that may influence a juvenile's competency, and several are essential in a competency evaluation of a juvenile, including: (1) age, with special consideration in any child of 12 years or younger; (2) developmental stage with respect to judgment, reasoning, responsibility, risk perception, suggestibility, temperament (seeking advice rather than acting without the facts), and future orientation; (3) assessment of mental disorder and intellectual level.

MENTAL HEALTH NEEDS OF YOUTH IN THE
JUVENILE JUSTICE SYSTEM

Youth in the juvenile justice system are at extremely high risk for psychiatric disturbance, and unmet mental health needs have reached such high proportions that they are of public health concern. Adolescents in juvenile justice residential facilities not only have higher rates of psychiatric disorders, including depression, substance use, and suicidal behavior, but they are also significantly more likely to have been victims of physical and sexual abuse, educational failure, and family conflict. A survey of 991 youth at an initial juvenile justice intake revealed high levels of suicidal ideation with recent attempts more common in females, and youth with major depression or substance use disorders, and those who were violent offenders. Few studies, however, have documented the needs of juveniles in residential facilities and the medical and psychiatric care available. A recent study collected data from the U.S. Department of Justice censuses of all public and private juvenile justice facilities in the United States: The Juvenile Residential Facilities Census (JRFC) and the Census of Juveniles in Residential Placement (CJRP) investigated data on death rates of youth under the age of 21 years who had been charged with, or adjudicated for, an offense and are housed in that facility because of the offense. In the 2-year period, a total of 62 deaths of youth occurred. The leading cause of death was from suicide (20 cases), followed by accidents (17 cases), illness (14 cases), and homicides by non-residents (6 cases). No deaths resulted from acquired immunodeficiency syndrome (AIDS), homicide by another resident, or an injury that occurred before placement. The risk for death of youth in juvenile justice facilities was found to be 8 percent higher than the death rate for the general population of adolescents aged 15 to 19 years. Above all, the risk for suicide is clearly increased in the juvenile justice facility compared with the general population, indicating a significant need for increased mental health evaluation and treatment in this population.

FORENSIC ASPECTS OF SCHOOL BULLYING

The forensic aspects of school bullying have increased over the last two decades, particularly in the wake of the serious incidents of school violence that took place in the mid-1990s such as the Columbine school shootings. The responsibilities of schools to protect students and safeguard against injury have extended from a duty to care, to a duty to protect. Bullying is typically observed in four different realms: physical, relational, verbal, and cyberbullying. Forensic evaluations often begin with a referral from an attorney, the court, or a family. After obtaining a comprehensive history of the youths involved in a reported bullying incident, the evaluator is tasked with determining if the alleged bullying has had a negative impact on the mental health and well-being of the victim. In some cases, investigators have reported findings of increased suicidality in the bully as well
as the victim. One study reported that victims of cyberbullying attempt suicide twice as often as other youth.

**THE RELATIONSHIPS BETWEEN TRAUMA, ABUSE, AND VIOLENT DELINQUENCY**

Child and adolescent psychiatrists are frequently sought out to evaluate children or adolescents who have been exposed to a traumatic or adverse life event and are exhibiting a variety of violent and delinquent behaviors. The child and adolescent psychiatrist may be asked to determine whether a child or adolescent is experiencing posttraumatic stress disorder or whether a given set of symptoms is likely to have been caused by exposure to the adverse life event. It is clear from surveys of delinquent adolescents that there is a relationship between posttraumatic stress disorder, previous histories of trauma and abuse, and aggressive behavior. Some researchers argue that evidence supports a trauma-related psychopathy in youth that evolves into aggressive behavior, and often into delinquency. It appears that brain circuits that monitor “threat response,” that is, circuits that run from the medial nucleus of the amygdala to the medial hypothalamus and to the peri-aqueductal gray matter, are overly reactive in reactive/affec­tive/defensive/impulsive aggression (RADI, also referred to as “hot” aggression), as well as in planned or predatory aggression (PIP, also referred to as “cold” aggression). Particularly in RADI, structures may have become dysregulated by traumatic emotional activation, resulting in a lack of subtle differentiation between emotions such as sadness, anger, and fear. The result is that any stress is perceived as a threat, and activates the “defense” system, leading to the flight or fight decisions. The final response seems to be “fight,” a response triggered during abusive or life-threatening situations in which escape seems impossible.

In another study, a cognitive mechanism for the link between abusive parenting and violent delinquency is offered. In this retrospective study of 112 adolescents (male 90; female 22), ages 12 to 19 years who were incarcerated in a juvenile detention facility pending criminal charges, participants completed questionnaires pertaining to exposure to abusive and nonabusive discipline, expressed and converted shame, and violent delinquency. The authors defined shame as a state in which negative attributions of the self and self-blame are made as a result of perceived failure in meeting their own expected standards. Higher levels of shame have been found among youth exposed to trauma. Converted shame is an expression of externalizing blame to others so that hostility is directed away from oneself, and decreases one’s own sense of responsibility for something negative, such as abuse. Converted shame can serve as a self-protective attribution. The findings of this study led to subjects’ responses, which fell into four groups: (1) Low shame, and low blaming of others; (2) Converters: low shame and high blaming of others; (3) Expressers: high shame, and low blaming of others; (4) High shame and high blaming of others. Subjects who were in group 2 (low shame and high blaming of others) had significantly more exposure to abusive parenting, and exhibited significantly more violent delinquent behaviors than those in group 3 (high shame, low blaming of others). Thus, although converting shame is “meant” to be self-protective, and a potentially adap­tive response to consistent abusive parenting, those adolescents who strongly blamed others appeared to develop more violent delinquency. The authors considered the violent delinquency a pathological response to trauma.

Dr. Sullivan is called by a defense attorney to review discovery material in a case that alleges perman­ent harm and suffering in 6-year-old Travis, who is alleged to have been sexually abused at age 3 in his day care center. Dr. Lane, the forensic expert for the plaintiff, has evaluated the child and performed psychological testing of him and concluded that the boy’s conduct problems are all related to the alleged abuse, which the child has difficulty recalling. His early history on the boy is cursory, however, and he has little information about the mother, who is a single parent, and he did not review medical records. In her thorough review of discovery material, Dr. Sullivan learns that Travis has witnessed extensive domestic violence and his mother’s rape, shown signs of hyperactivity since age 2, and has exhibited much anxiety related to his mother’s safety and several separations from her at times when she was unable to care for him owing to depression. Travis also has had delayed language development. Dr. Lane, at the time of his deposition, was asked why he had not asked about these matters. He said he considered the mother’s personal life a private matter and did not see its relevance to the litigation. Dr. Sullivan, when deposed, points out that many other factors beside the alleged abuse might account for Tony’s behavioral problems. (Adapted from case material from Diane H. Schetky, M.D.)

Hinduja S, Patchin JW. Bullying, cyberbullying, and suicide. *Arch Suicide Res.* 2010;14:206–221.

Roper V Simmons, 543 U.S. 551 (2005).

According to the U.S. Department of Health and Human Services, 408,425 children and adolescents were in foster care in the United States in 2010. Most children entering foster care have experienced multiple traumatic events including neglect, or abuse, which are typically the precipitant for their removal from their biological parents. One study estimated that 26 percent of children in the United States will experience a traumatic event by the age of 4 years. Over the last decade, specifically between the years of 2000 to 2010, the number of evaluations for suspected child maltreatment has increased by 17 percent, according to another study.

Foster care is intended to be temporary out-of-home care, provided by the welfare system, for children and adolescents whose immediate families are unable to care for them. Given the severity of the pathology of vulnerable parents; however, care is often needed for many months and years. In 1997, President Clinton signed the Adoption and Safe Families Act, a law designed to improve provisions for child safety, to decrease the length of time that a child remains in foster care without long-term planning, and to limit the amount of time in which a biological parent has to undergo rehabilitation to 12 months. An additional law was added to allocate federal funds for independent living assistance for adolescents and young adults aged 16 to 21 to assist them in transitioning to independent living.

Epidemiology and Demographics of Foster Care

The number of children entering foster care due to maltreatment has risen in the last decade by 19 percent. Of those children who entered foster care, there was an increase of 60 percent in the number who were identified as emotionally disturbed. In the United States, one of the most common scenarios of children being placed in foster care involves parental substance abuse, which leads to inability of the parent to care for their children. The National Center on Addiction and Substance Abuse of Columbia University reported that seven of ten abused or neglected children had parents with substance abuse. Furthermore, children in foster care were more often being raised by a single mother prior to placement compared to children in the community.

Minority children are overrepresented in the foster care population. In a study utilizing birth records and child protective service (CPS), black children were more than twice as likely to be referred due to maltreatment, be substantiated as victims of maltreatment, and enter the foster care system before age 5 years, compared to white children. However, low socioeconomic black children had a lower rate of referral, substantiation, and placement in foster care than socioeconomically similar white children. Among Latinos, children of U.S.-born mothers were significantly more likely to have involvement with CPS, compared to Latino children of foreign-born mothers. However, after adjusting for socioeconomic factors, the relative risk of referral, substantiation, and entry into the foster care system was significantly higher for all Latino children than for white children. Approximately 38 percent of children in the foster care system are African American, more than three times their representation in the general population. Whites make up approximately 48 percent, and Hispanics make up almost 15 percent of foster children; 55 to 69 percent are girls, and 83.4 percent enter foster care at a mean age of 3 years. Children placed in care as infants are more likely to stay in care. Those younger than 5 years of age currently comprise the fastest growing segment of the foster care population. Studies reveal that up to 62 percent of foster children had prenatal drug exposure.

Needs of Foster Care Children

Children entering foster care have enormous mental health needs; more than 80 percent of them have developmental, emotional, or behavioral problems. It is estimated that up to 70% of these children have diagnosable psychiatric disorders. In addition, according to one study, quality of life (QOL) is significantly poorer among children in the foster care system than children in the general community. Children and adolescents living in residential care rated their QOL as poorer than those living with foster families. Up to 50 percent of foster care children exhibit depressive symptoms, and self-reports of anxiety problems occur in about 36 percent. QOL is adversely affected by the presence of mental health problems, and those youth with greater mental health difficulties rated their QOL as poorer whether in residential facilities or foster placement. In a review of the literature, psychiatric disorders found with increased frequency in foster youth were attention-deficit/hyperactivity disorder (ADHD), posttraumatic stress disorder, conduct disorders, attachment disorders, substance abuse, depression, and eating disorders.

In addition to high rates of psychiatric disorders, foster care youth are referred to pediatric clinics more frequently due to multiple health problems compared to community youth. Growth abnormalities (including failure to thrive), neurological abnormalities, neuromuscular disorders, language disorders, cognitive delays, and asthma are prevalent. Health care costs in foster care youth are six to ten times that of matched non–foster-care peers. Among children 0 to 5 years of age, approximately 25 percent are seriously emotionally damaged; attachment disorders are increasingly diagnosed. Foster care children use the full range of mental health services: outpatient, acute inpatient, day treatment, partial hospitalization, and residential treatment. Adolescents in foster care are at increased risk for substance abuse, teenage pregnancies, and sexually transmitted diseases, including human immunodeficiency virus (HIV). With public health care increasingly adopting a managed health care system, which is designed to limit care, grave concern exists that the provision and delivery of services to this medically and psychiatrically vulnerable population may be seriously compromised.

Kinship Care for Foster Children

More states are recognizing kinship care as an alternative placement option and are authorizing licensing and reimbursement to kinship caregivers who are generally female (mostly maternal grandmothers), of low income, of low education, and of minority status. Currently, nationwide, approximately 23 percent of African American children are in foster kinship care. It is
unknown just how many children are in informal kinship care within the African American population, which has had a long cultural tradition of taking in children of family members who are unable to care for their offspring. The few studies available indicate that outcomes, although mixed, are somewhat more positive than for those children in nonkinship care. Children reportedly receive more positive regard from caregivers in kinship care, and a consistent outcome, when it works, is that it provides more stability than nonrelative foster care. Most foster children have consistently said that they would rather be with a family member than stay in the system. When foster children feel embraced by their families of origin, and the latter can provide appropriate nurturance and access to good therapeutic services, the foster children’s sense of identity and belonging is less disrupted. However, no demonstrable difference is seen in the need for mental health, medical, and special educational services for these children.

**THERAPEUTIC FOSTER CARE**

_Therapeutic foster care_ (TFC) has emerged as a cost-effective alternative to the more restrictive _residential treatment center_ (RTC). Therapeutic effectiveness is mixed. TFC is designed to provide nurturing family-based care with specialized treatment interventions from an interdisciplinary treatment team. Therapeutic foster parents are meant to be the agents of therapeutic change, functioning as _extenders_ of the clinical treatment team. Because of the child’s special needs, therapeutic foster parents must have more extensive training than other foster parents, receive a higher reimbursement, and receive more intensive monitoring, supervision, and support from the foster care agency. Although the concept of TFC is promising, good outcome data do not show consistent success. Several models exist, but implementation that shows fidelity to empirically tested models is often spotty. Some models have proved too expensive and complicated to implement in the real-world setting. The concept of professional therapeutic parents, who are paid competitive full-time wages to care for special needs foster children, holds promise as an alternative to current prevailing practice. Clinical practice demonstrates that, when adequate and appropriate intensive in-home services with good case management is provided in a well-managed foster care setting, children can show significant gains.

**CULTURAL COMPETENCE**

Anna McPhatter defines _cultural competence_ as the ability to use knowledge and cultural awareness to design psychosocial interventions that support and sustain healthy client–system functioning within a cultural context that is meaningful to the client. Because American society is still significantly encumbered by racial conflicts, some children have been denied placement with families of a different race, and have ended up in long-term foster care rather than in a permanent adoption placement. The Association of Black Social Workers went on record as opposing transracial placement of African American children. In 1978, the Indian Child Welfare Act transferred to Tribal Courts the power to make placement decisions about Native American children to reverse the practice of placement in non-Native American homes. Adoption studies have shown that it is not inherently harmful for children to be cross-racially adopted. Congress has passed legislation, the Multiethnic Placement Act of 1994, facilitating transracial adoptions, while maintaining the language of cultural awareness in placement decisions. The need for cultural sensitivity, respect, and a capacity to facilitate a foster child’s cultural development and identity are well acknowledged. These issues must be addressed in training providers of foster care services.

**PSYCHOLOGICAL ISSUES IN FOSTER CARE CHILDREN**

Family risk factors including alcohol and drug abuse in parents, parental neglect and abuse, and cognitive or mental or physical health problems in parents, as well as low socioeconomic status and low social support, are strongly associated with a child being placed out of the home. Psychiatric and behavior problems in the child may also contribute to being placed out of the home. Among children who return home, 40 percent reenter the foster care system. These children struggle with issues of abandonment, neglect, rejection, and physical, emotional, and sexual maltreatment. The child’s age, home environment, and the specific reasons for going into placement affect the emotional issues that the child must handle. Early abandonment and neglect can lead to ananicitic depression. Attachment issues are prevalent in this young population, because there has been no opportunity to form secure attachments with consistent nurturing figures in early life.

Foster children are often unprepared for separations, which can be abrupt and repeated in the current foster care climate. Early separation from the primary caretaker is considered a major trauma for a child and sets the stage for vulnerability to subsequent trauma. Those children who bounce from foster home to foster home have their capacity to form enduring emotional attachments compromised; trust becomes a lifelong challenge.

Children who have experienced traumatic physical and sexual abuse often become mistrustful, hypervigilant, aggressive, impulsive, oppositional, and avoidant as they attempt to negotiate a world that they experience as threatening, hostile, and uncaring. When a child’s early developmental period is spent in a psychosocial environment of trauma, aggression, and lack of empathy from adults, the psychological seeds are sown for later violence against the self and others. A wide range of behavior problems is likely to emerge in foster care children given their early family experiences. A pervasive problem is one of dysregulation: dysregulation of behavior, emotions and affect, attention, and sleep. The empirical data on the neurobiology of maltreatment on the developing brain reveals that stress hormones play an important role in adaptation and coping, and that these capacities are compromised in varying degrees of severity in abused and neglected children. The data also show that, because of the developmental plasticity of the brain, appropriate early intervention can induce remediation and repair at the neurobiological level.

Nick, a 5-year-old, was placed in foster care because of maternal substance abuse and inability to take care of her child. When seen for a psychiatric evaluation, it was noted that all of his primary teeth were full of dental cavities. The foster mother was asked about dental care, and she responded that the dentist
had said that he would wait until the teeth had fallen out, because they were his first set of teeth and did not require intervention. This response aroused suspicion that neglect in the foster family was exacerbating Nick’s hyperactive and aggressive behaviors. A neglect report was made and the investigation revealed that Nick was not only neglected, but was also being physically abused in that foster care placement. Subsequent to removal and placement with a nurturing and responsible foster family, Nick has shown considerable emotional stabilization, does well academically and socially, and is now being adopted by that family. (Adapted from case material Marilyn B. Benoit, M.D., Steven L. Nickman, M.D., and Alvin Rosenfeld, M.D.)

FAMILY PRESERVATION

Family preservation has come under increasing scrutiny in the last decade. Estimates on the percentage of children who are reportedly reunited vary from 66 to 90 percent. Philosophically, family reunification appears to be the right thing to do, yet approximately 40 percent of reunified children reenter out-of-home care. The field needs discriminating criteria that would identify psychosocial profiles of families that could best benefit from family preservation services. In 1996, the Child Welfare League of America (CWLA) acknowledged the failure of family preservation efforts and requested that child welfare policy makers rethink the current use of intensive family preservation. Recent research has validated poor outcomes with family preservation. Hopes are that the Adoption and Safe Families Act of 1997 will give child welfare agencies the opportunity to step back from the myopic view of family preservation and to consider the needs of the child as the major priority. The AACAP and the CWLA jointly launched a national effort to address the mental health needs of children in foster care. This effort is supported by a broad-based coalition of agencies that are all stakeholders in foster care. The coalition proposes that the foster care system be child focused, but inclusive of the biological and foster families in intervention planning on the child’s behalf if families are to be preserved.

One case of a 7-year-old boy who was in foster care for 2 years is illustrative of why some family preservation efforts fail. When James was returned to his biological mother, she was in a new marriage with a new baby. Her husband was new to parenting. The family was financially strapped and lived under harsh conditions. James’ mother completed the required parenting course for resuming custody of her child, and seemed pleased to have him back with her; however, no supports were put in place to assist this young couple financially or with any family therapy, psychoeducation, or case management interventions. Frequent and increasingly urgent calls to the child welfare family reunification services were made to seek respite and financial help, but this was not possible. The outcome for James was that he was reabused and had to reenter the foster care system.

This outcome represents a failure of the system, but also translates into a debilitated family, with a profound sense of failure. (Adapted from case material from Marilyn B. Benoit, M.D., Steven L. Nickman, M.D., and Alvin Rosenfeld, M.D.)

FOSTER CARE OUTCOMES AND RESEARCH INITIATIVES

The overall quality of available outcome studies is poor. Some patterns, however, recur across studies. Several studies reveal that 15 to 39 percent of the homeless are foster care graduates, who are also overrepresented among adult substance abusers and clients in the criminal justice system. It is likely that the reasons that initially precipitated the child’s foster care placement contributed to the negative adult outcomes. Studies indicate that children entering care who have been victimized, who have substance-abusing parents or parents with major mental illness or high criminality, or both, and who come from homes with a high degree of domestic violence are at greater risk of having poor outcomes. Research on early maltreatment indicates that the influence of maltreatment on brain development can be profound over the life span. Developmental disabilities occur in more than 50 percent of the foster care population. Children returned to their families of origin typically have fared worse than those who have remained in long-term placement.

Several studies report findings indicating that multiple placements and poor parental involvement consistently lead to negative outcomes. Federal mandate requires states to maintain a tracking system for children in foster care. New reporting systems, the Adoption and Foster Care Analysis and Reporting System (AFCARS) and the Statewide Automated Child Welfare Information System (SACWIS), are available nationwide. States are being monitored for compliance with their use, and continued federal funds are contingent on the implementation of these information systems. Because foster care placement is the result of psychosocial environmental failure, fixing the existing system requires more than good information systems. Integration of sound, theory-driven, child-focused, family-centered services, collaboratively funded by multiple governmental agencies, is essential. Through the use of longitudinal, research-based performance measures, reliable data are emerging. The National Institutes of Mental Health (NIMH) has funded some research focusing on foster care children and youth. The complexity of the impact of ever-changing psychosocial variables makes this type of research challenging. Despite that, it must be done if welfare dollars are to be spent doing the right thing for needy children and their families. In 2004, in a groundbreaking study, the Pew Commission on Children in Foster Care made sweeping recommendations to overhaul the system, stating that “children deserve more from our child welfare system.”

HISTORY OF ADOPTION

Adoption has existed in different forms throughout history. In ancient Babylonia, it provided for the transmission of property or artisan’s skills, whereas, in the Roman Empire, it was often used to elevate the status of an adult protégé. In some Pacific islands, adoption of young children formed part of an exchange system between related clans. Concerns expressed by adopted persons about not knowing their roots are as ancient as they are contemporary. Euripides’ Ion contains a touching dialogue between a woman in search of the child she had given up years before and a young priest of Apollo, who does not know that he is the woman’s son and says that the only mother he knows is Apollo’s priestess.

Historically, closed adoptions were common practice. That was done to ensure the sealed identities of birth and adoptive parents and was believed to be in the best interests of adopted
children. That practice is now considered flawed; contemporary, although still controversial, thinking is that most adoptees should grow up knowing of their adoption status, as well as the identities of their birth parents. Currently, adoptees, as well as many birth parents and adoptive parents, increasingly have shared interests in legislation that affects the open or closed status of birth records and the placement of children in families. The phrase adoption triad has come to stand for these shared interests. Several other organizations represent each of these three groups, and those organizations often have divergent agendas. Since the 1980s, adoption practice has been profoundly affected by federal legislation.

**EPIDEMIOLOGY OF ADOPTION**

Estimates suggest that between 2.5 and 3.5 percent of children in the United States are adopted, with more than 2 percent adopted by nonrelatives, and about 1.5 percent in relative adoptions, which include stepparents. Foster care children who are adopted account for about 15 percent of all adopted children. Approximately 125,000 children are adopted each year, in a variety of scenarios. Infants may be relinquished by their biological parents at birth and adopted through private agencies. These adoptions are increasingly “open,” with some continued contact with biological parents. About 50,000 babies are adopted in this manner each year. Another 50,000 children are adopted through the child welfare system, and these children have often been exposed to multiple foster home placements before they are adopted. These adoptees range in age, with more than half of them being older than 6 years of age, and the majority of them having experienced significant early abuse or neglect.

**INTERNATIONAL ADOPTION**

International adoptions have been growing over the last two decades. Each year more than 20,000 children are adopted from overseas, and many of these are transracial adoptions. More than 17,000 children were adopted from Guatemala, for example, in the last two decades. In the Guatemalan adoptees, the mean age was 1.5 years and the children had previously resided in orphanages, foster homes, or mixed-care settings. Investigation of the health records of international adoptees who were evaluated in an international adoption specialty clinic in the U.S. revealed that younger children at the time of adoption have better growth, language development, cognitive skills, and competence in activities of daily living compared to children who were older at time of adoption. Among children matched for age, gender, and time from adoption to evaluation, those who were previously living in foster care were observed to have higher cognitive scores and improved growth compared to children who had resided in orphanages. These findings support the priority of adoptive placement at younger ages and that foster care has benefits over orphanage care.

**EARLY CHILDHOOD VERSUS LATE ADOPTION**

Data suggest that earlier age adoption predicts better outcome than adoption in middle or late childhood. A recent prospective study examined factors related to successful outcome in public adoption of children ranging in age from 5 to 11 years of age. Prospective data were collected from domestic adoptions in the United Kingdom at the 1st year, and 6 years later on 108 adoptees who were placed primarily because of situations involving childhood abuse and neglect. Outcome was assessed by the disruption rate and measures of psychological adaptation. At the adolescent follow-up, 23 percent of the adoption placements had been disrupted, 49 percent were continuing with positive adaptations, and 28 percent were ongoing but with significant conflicts. Four factors contributed independently to the risk of disruptions: older age at placement, report of being singled out and rejected by siblings, time in care, and greater degree of behavioral problems. Given that almost half of the placements were ongoing, it is apparent that later childhood age of adoption can also be successful; assessment of the constellation of the adoptive families, and of the children’s behavioral problems, may determine the likelihood of positive outcome for school-aged child adoptees.

**BIRTH PARENTS: SEARCH AND REUNION**

The increasing trend toward open adoption allows the opportunity for adoptees to more easily search and successfully find their birth parents. Many adoptive parents choose open adoptions in the belief that they can experience a greater connection with the child if they have some relationship with the birth mother. Some adoptees want to develop an ongoing relationship with birth parents, but many who search are satisfied to meet birth parents without further correspondence. Outcomes of reunions with birth parents vary widely. In some cases, especially when the birth parents are well functioning and welcoming toward their child, the adoptee may experience a sense of relief and joy in knowing that their birth mother is no longer vulnerable.

**REFERENCES**

Child maltreatment includes all types of abuse and neglect and is a major public health concern in the United States. The Centers for Disease Control and Prevention (CDC) estimate that one in every five children in the United States has been a victim of child maltreatment. Among the CDC's estimates of maltreated children, 9 percent were victims of physical abuse, 1 percent were victims of sexual abuse, 4 percent were victims of neglect, and 12 percent experienced emotional abuse. Estimates of children maltreated in the United States each year are close to 1 million, and the annual number of deaths caused by abuse or neglect is reported to be about 1,500. A majority of child neglect and abuse occurs in infancy and early childhood, negatively impacting overall brain development, and disrupting time-sensitive developmental brain processes. A growing body of research suggests that child maltreatment potentially results in long-term damage in the neuroendocrine system, cell loss, and delays in myelination in the hippocampus and prefrontal cortex, as well as a chronic inflammatory state independent of clinical comorbidities.

The National Longitudinal Study on Adolescent Health investigated the prevalence, risk factors, and health consequences of maltreatment in 12,118 adolescents. Maltreated adolescents retrospectively reported the most common experiences were being left home alone as a child, (reported by 41.5 percent of the sample), physical assault (reported by 28.4 percent), physical neglect (reported by 11.8 percent), and sexual abuse (reported by 4.5 percent). Each type of maltreatment was associated with at least eight of the ten adolescent health risks examined, including self-report of depression, regular alcohol use, binge drinking, marijuana use, overweight status, generally “poor” health, inhalant use, and aggressive behaviors, including fighting and hurting others. Clearly, the effects of self-reported maltreatment had far ranging and long-lasting associations with multiple detrimental consequences.

The identification, management, and treatment of child maltreatment require cooperative efforts between professionals, including primary care physicians, emergency room staff, law enforcement, attorneys, social service staff, and mental health professionals. Perpetrators typically deny abuse or neglect and maltreated children often fear disclosure of their abuse or neglect.

DEFINITIONS

DSM-5

The Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) lists Child Maltreatment and Neglect in the section “Other Conditions That May Be a Focus of Clinical Attention.” The presence of Child physical abuse, Child sexual abuse, Child neglect, and Child psychological abuse can be coded as confirmed or suspected and as an Initial encounter or a Subsequent encounter. Under a subcategory of “other circumstances related to” each form of child maltreatment or neglect, five “V” coded clinical situations related to maltreatment can be coded. These include the following (1) Encounter for mental health services for victim of child maltreatment by parent, (2) Encounter for mental health services for victim of nonparental child maltreatment, (3) Personal history (past history) of childhood maltreatment, (4) Encounter for mental health services for perpetrator of parental child maltreatment, (5) Encounter for mental health services for perpetrator of nonparental child maltreatment.

Federal Law

The Child Abuse Prevention and Treatment Act was passed in 1974 and has been amended several times, most recently in 2003. In federal law, child abuse and neglect mean, at a minimum, any recent act or failure to act on the part of a parent or caretaker that results in death, serious physical or emotional harm, or sexual abuse or exploitation. It also includes an act or failure to act that presents an imminent risk of serious harm. In federal law, sexual abuse means the employment, use, persuasion, inducement, enticement, or coercion of any child to engage in or to assist any other person to engage in any sexually explicit conduct (or simulation of such conduct for the purpose of producing a visual depiction of such conduct) or the rape (and in cases of caretaker or interfamilial relationships, statutory rape), molestation, prostitution, or other forms of sexual exploitation of children or incest with children.

State Law

A large mass of legal definitions and guidelines exists at the state level. The legal definitions of terms related to the maltreatment of children vary from one jurisdiction to another, so clinicians should be aware of the definitions used in their own locale. The following generic definitions are used in this section.

Neglect

Neglect, the most prevalent form of child maltreatment, is the failure to provide adequate care and protection for children. Children can be harmed by malicious or ignorant withholding of physical, emotional, and educational necessities. Neglect includes failure to feed children adequately and to protect them from danger. Physical neglect includes abandonment, expulsion from home, disruptive custodial care, inadequate supervision, and reckless disregard for a child's safety and welfare. Medical neglect includes refusal, delay, or failure to provide medical
care. Educational neglect includes failure to enroll a child in school and allowing chronic truancy.

Physical Abuse

Physical abuse can be defined as any act that results in a nonaccidental physical injury, such as beating, punching, kicking, biting, burning, and poisoning. Some physical abuse is the result of reasonably severe corporal punishment or unjustifiable punishment. Physical abuse can be organized by damage to the site of injury: skin and surface tissue, the head, internal organs, and skeletal.

Emotional Abuse

Emotional or psychological abuse occurs when a person conveys to children that they are worthless, flawed, unloved, unwanted, or endangered. The perpetrator may spurn, terrorize, ignore, isolate, or berate the child. Emotional abuse includes verbal assaults (e.g., belittling, screaming, threats, blaming, or sarcasm), exposing the child to domestic violence, overpressurizing through excessively advanced expectations, and encouraging or instructing the child to engage in antisocial activities. The severity of emotional abuse depends on (1) whether the perpetrator actually intends to inflict harm on the child and (2) whether the abusive behaviors are likely to cause harm to the child. Some authors believe that the terms emotional or psychological abuse should not be used and that verbal abuse more accurately describes the pathological behavior of the caregiver.

Sexual Abuse

Sexual abuse of children refers to sexual behavior between a child and an adult or between two children when one of them is significantly older or uses coercion. The perpetrator and the victim may be of the same sex or the opposite sex. The sexual behaviors include touching breasts, buttocks, and genitals, whether the victim is dressed or undressed; exhibitionism; frottage; cunnilingus; and penetration of the vagina or anus with sexual organs or objects. Sexual abuse can involve behavior over an extended time or a single incident. Developmental factors must be considered in assessing whether sexual activities between two children are abusive or normative. In addition to the forms of inappropriate sexual touching, sexual abuse also refers to sexual exploitation of children, for instance, conduct or activities related to pornography depicting minors and promoting or trafficking in prostitution of minors.

Ritual Abuse

Cult-based ritual abuse, which includes satanic ritual abuse, is physical, sexual, or psychological abuse that involves bizarre or ceremonial activity that is religiously or spiritually motivated. Typically, multiple perpetrators abuse multiple victims over an extended period. Ritual abuse is a controversial concept; some professionals believed in the 1990s that ritual abuse was a common, horrible phenomenon in society, whereas others were skeptical about most allegations and descriptions of ritual abuse.

Perpetrators of Abuse

Some lack of consistency is seen in who may be defined as an abuse perpetrator. Usually, a person must be a parent or designated caregiver to be charged with neglect, physical abuse, or emotional abuse. Another adult (e.g., a stranger) who injures a child would be charged with battery, not with child abuse. On the other hand, a caretaker or any other person could be charged with child sexual abuse. State laws vary in this regard.

ETIOLOGY

Physical Abuse

Although child abuse occurs at all socioeconomic levels, it is highly associated with poverty and psychosocial stress, parental substance abuse, and mental illness. Child maltreatment is strongly correlated with less parental education, underemployment, poor housing, welfare reliance, and single parenting. Child abuse tends to occur more often in families characterized by domestic violence, social isolation, parental mental illness, and drug and alcohol abuse. The probability of maltreatment may be increased by risk factors in the child such as prematurity, intellectual disability, and physical handicap. In addition, the risk of child abuse increases in families with many children.

Sexual Abuse

Social, cultural, physiological, and psychological factors all contribute to the breakdown of the incest taboo. Incestuous behavior has been associated with alcohol abuse, overcrowding, increased physical proximity, and rural isolation that prevents adequate extrafamilial contacts. Some communities may be more tolerant of incestuous behavior. Major mental disorders and intellectual deficiency have been described in some perpetrators of incest and sexual abuse.

CLINICAL FEATURES

Maltreated children manifest a variety of emotional, behavioral, and somatic reactions. These psychological symptoms are neither specific nor pathognomonic: The same symptoms can occur without any history of abuse. The psychological symptoms manifested by abused children and the behaviors of abusive parents can be organized into clinical patterns. Although it may be helpful to note whether a particular case falls into one of these patterns, that in itself is not diagnostic of child abuse.

Physically Abused Children

In many cases, the physical examination and radiological evaluation show evidence of repeated suspicious injuries. Abused children display behaviors that should arouse the suspicions of the health professional. For example, these children may be unusually fearful, docile, distrustful, and guarded. On the other hand, they may be disruptive and aggressive. They may be wary of physical contact and show no expectation of being comforted by adults; they may be on the alert for danger and continually size up the environment, and they may be afraid to go home.
The literature regarding the psychological consequences of physical abuse and neglect indicates a wide range of effects: affect dysregulation, insecure and atypical attachment patterns, impaired peer relationships involving increased aggression or social withdrawal, and academic underachievement. Physically abused children exhibit a range of psychopathology, including depression, conduct disorder, ADHD, oppositional defiant disorder, dissociation, and posttraumatic stress disorder (PTSD).

Physically Abusive Parents

Abusive parents often feel significant guilt, and may delay seeking help for the child's injuries, fearful that the child will be taken away. Often the history of how a child sustained injuries given by the parents is implausible or incompatible with the physical findings. Parents may blame a sibling or claim that the child injured themselves. The characteristics of abusive parents often include a history of abuse in their own early lives, a lack of empathy for the child, unrealistic expectations of the child, and an impaired parent–child attachment.

Katie, 3 years of age, had been exhibiting new negative and aggressive behavior at preschool beginning 3 months after the birth of her brother. Katie's teacher observed her increased irritability and aggression, at times pushing other children, and she had recently hit a classmate with a wooden block, causing a laceration of the child's lip. When Katie's teacher took her aside to talk about her behavior, she noticed several bruises on Katie's arms and face. When her teacher asked Katie how she had gotten the bruises, Katie replied “my mommy's boyfriend gets mad at me and hits me with his belt.” The teacher reported suspected child abuse to Child Protective Services. Katie’s teacher also called her mother to let her know what was happening, and suggested that they take Katie for a psychiatric evaluation.

Katie's baby brother was colicky and slept only for short periods of time throughout the day and night. He stopped crying only when his mother held him. Her mother, therefore, had little time for Katie, and the mother's boyfriend was left to take care of Katie on evenings after day care and on weekends. He began to drink more than usual and became increasingly irritable. Katie's mother and her boyfriend often argued, and Katie had seen her mother physically pushed and threatened by her boyfriend. Katie, who was a bright, curious, and talkative child, had tried to be helpful by asking to hold the baby. When refused, however, Katie became upset and would lie on the floor and have a tantrum. Katie began to have difficulty falling asleep and awoke repeatedly during the night. Katie's mother's boyfriend would become extremely angry when Katie would wake him up, and often told her to shut up and slapped her when she told him that she couldn't go back to sleep. On many occasions, he responded to her tantrums or repeated demands for attention by hitting her with his belt.

Child Protective Services suggested that mother's boyfriend voluntarily move out, and no longer spend time alone with Katie caring for her, which he did begrudgingly, and Katie and her mother began a family therapy program that included parenting training for Katie's mother and, a behavioral program to help Katie with her tantrums. Katie’s mother's boyfriend attended Alcoholics Anonymous (AA) meetings and stopped drinking. He was able to control his anger, and was allowed to visit the home, as long as Katie's mother was present. Within the next three months, Katie’s aggressive behavior had ceased, and she was less irritable and was no longer having tantrums. She was doing well with peers, was sleeping through the night, and was no longer afraid to be at home. (Adapted from case material from William Bernet, M.D.)

Sexually Abused Children

A variety of symptoms, behavioral changes, and diagnoses sometimes occur in sexually abused children: anxiety symptoms, dissociative reactions and hysterical symptoms, depression, disturbances in sexual behaviors, and somatic complaints.

Anxiety Symptoms. Anxiety symptoms include fearfulness, phobias, insomnia, nightmares that directly portray the abuse, somatic complaints, and PTSD.

Dissociative Reactions and Hysterical Symptoms. The child may exhibit periods of amnesia, daydreaming, trancelike states, hysterical seizures, and symptoms of dissociative identity disorder.

Depression. Depression may be manifested by low self-esteem and suicidal and self-mutilative behaviors.

Disturbances in Sexual Behaviors. Some sexual behaviors are particularly suggestive of abuse, such as masturbating with an object, imitating intercourse, and inserting objects into the vagina or anus. Sexually abused children may display sexually aggressive behavior toward others. Other sexual behaviors are less specific, such as showing genitals to other children and touching the genitals of others. A younger child may manifest age-inappropriate sexual knowledge. In contrast to these overly sexualized behaviors, the child may avoid sexual stimuli through phobias and inhibitions.

Somatic Complaints. Somatic complaints include enuresis, encopresis, anal and vaginal itching, anorexia, bulimia, obesity, headache, and stomachache.

These symptoms are not pathognomonic. Nonabused children may exhibit any of these symptoms and behaviors. For example, normal, nonabused children commonly exhibit sexual behaviors, such as masturbating, displaying their genitals, and trying to look at people who are undressing.

Approximately one third of sexually abused children have no apparent symptoms. Many adults who were abused as children have no significant abuse-related symptoms. On the other hand, the following factors tend to be associated with more severe symptoms in the victims of sexual abuse: greater frequency and duration of abuse, sexual abuse that involved force or penetration, and sexual abuse perpetrated by the child's father or stepfather. Other factors associated with poorer prognosis are the child's perception of not being believed, family dysfunction, and lack of maternal support. Also, multiple investigatory interviews appear to increase symptoms.

Intrafamilial Sexual Abuse

Incest can be defined strictly as sexual relations between close blood relatives, that is, between a child and the father, uncle, or sibling. Because of increased reporting, sibling incest is an area of growing concern. In its broader sense, incest includes sexual intercourse between a child and a stepparent or stepsibling. Although father–daughter incest is the most common form, incest can also involve father and son, mother and daughter, and mother and son.

Intrafamilial sexual abuse and other sexual abuse that occurs over a period of time is characterized by a particular pattern or
sequence of steps. Victims of sexual abuse recount a gradual progression of boundary violations by the perpetrator, starting with tiny invasions and escalating to serious, overwhelming intrusions. Healthy, self-confident children rebuff the intrusions directly (via temper tantrums and verbal disagreements) or indirectly (through silence and distancing maneuvers) by adopting any strategy that causes the offender to refrain.

Sexual abuse that occurs over a period of time evolves through five phases: engagement, sexual interaction, secrecy, disclosure, and suppression.

**Engagement Phase.** The perpetrator induces the child into a special relationship. The daughter in father–daughter incest has frequently had a close relationship with her father throughout her childhood and may be pleased at first when he approaches her sexually.

**Sexual Interaction Phase.** The sexual behaviors progress from less to more intrusive forms of abuse. As the behavior continues, the abused daughter becomes confused and frightened, because she never knows whether her father will be parental or sexual. If the victim tells her mother about the abuse, the mother may not be supportive. The mother often refuses to believe her daughter's reports or refuses to confront her husband with her suspicions. Because the father provides special attention to a particular daughter, her brothers and sisters may distance themselves from her.

**Secrecy Phase.** The perpetrator threatens the victim not to tell. The father, fearful that his daughter may expose their relationship and often jealously possessive of her, interferes with the girl's development of normal peer relationships.

**Disclosure Phase.** The abuse is discovered accidentally (when another person walks into the room and sees it), through the child's reporting it to a responsible adult, or when the child is brought for medical attention and an alert clinician asks the right questions.

**Suppression Phase.** The child often retracts the statements of the disclosure because of family pressure or because of the child's own mental processes. That is, the child may perceive that violent or intrusive attention is synonymous with interest or affection. Many incest survivors rally around their perpetrators, seeking to capture any modicum of tenderness or interest. At times, affection for the perpetrator outweighs the facts of abuse, and children recant their statements about sexual assault, regardless of substantiated evidence of molestation.

**Extrafamilial Sexual Abuse**
Of course, sexual abuse is not limited to incest. Children can be abducted and sexually abused by strangers. A perpetrator may observe a playground and may identify a child who is not closely supervised. A pedophile may molest this child and hundreds of other children before he or she is apprehended. For the child, this is usually a single, isolated experience.

On the other hand, children can be repeatedly abused by trusted adults, such as teachers, counselors, family friends, and clergy. In this scenario, the pedophilic perpetrator grooms the child over a period of time. He or she gains the friendship of children through enjoyable activities and gifts, introduces sexual activities that may seem innocent and even pleasurable, and progresses to more intrusive activities. The pedophile encourages secrecy.

A solo sex ring is a form of child sexual abuse that involves one adult perpetrator and multiple child victims, who may know about each other's sexual activities with the perpetrator. A sex ring may also involve multiple perpetrators and multiple victims.

**Neurobiological and Health Consequences of Child Maltreatment**
Current data document long-term physical and mental health consequences of child physical abuse, sexual abuse, emotional abuse, and neglect. Severe physical abuse and repeated sexual abuse cause changes in the child's developing brain that persist into adulthood. A review of 20 studies concluded that child maltreatment is associated with future increased levels of inflammatory markers such as increased C-reactive protein (CRP), fibrinogen, and proinflammatory cytokines. The association of child maltreatment with an increased state of inflammatory markers in adulthood is a robust finding. However, it is not clear how this occurs, and how it impacts functioning. According to the CDC, and the Child Maltreatment Report, long-term consequences of child maltreatment lead to increased risk of multiple physical illnesses and high-risk behaviors such as alcoholism and drug abuse, which in turn can lead to depression, unemployment, and unstable relationships. Physical abuse, emotional abuse, and neglect are strongly related to future depressive disorders, anxiety disorders, eating disorders, suicidal behaviors, drug use, and risky sexual behavior. Child maltreatment is also associated with a host of physical conditions and illnesses, including ischemic heart disease, liver disease, adolescent pregnancy, chronic obstructive pulmonary disease, fetal death, and skeletal fractures. Studies have demonstrated that adults with childhood histories of maltreatment are at higher risk for abnormalities on magnetic resonance imaging (MRI) of the brain that indicate reduced size of the adult hippocampus. These abnormalities are more pronounced on the left side of the brain. Deficient integration exists between the left and right hemispheres, manifested by reduced size of the corpus callosum. These neurobiological effects of child maltreatment probably mediate the behavioral and psychological symptoms that follow abuse, such as increased aggressiveness, heightened autonomic arousal, depression, and memory problems.
**EVALUATION PROCESS**

The evaluation of a child or adolescent who may have been physically or sexually abused depends on its circumstances and context. Practitioners must consider whether they are conducting a forensic evaluation, which has legal implications and may ultimately be used in court, or a clinical evaluation, which is done for a therapeutic purpose. A forensic evaluation emphasizes collecting accurate and complete data to determine—as objectively as possible—what happened to the child. Was the injury an accident, was it self-inflicted, or was it a result of parental abuse? Was the child actually sexually abused, or was he or she indoctrinated to believe that he or she was abused? The data collected in a forensic evaluation must be preserved in a reliable manner through audiotape, videotape, or detailed notes. The results of the forensic evaluation are organized into a report that is read by attorneys, a judge, and others. The emphasis in a therapeutic evaluation is to assess psychological strengths and weaknesses, to make a clinical diagnosis, to develop a treatment plan, and to lay the foundation for continuing psychotherapy. The clinician is also interested in determining what happened to the child, but it is not as essential to distinguish facts from fantasies. Compared with the forensic evaluation, the psychotherapist does not need to keep such detailed records and ordinarily does not prepare a report for court.

In addition to distinguishing a forensic examination from a therapeutic consultation, a number of factors can affect the evaluation of a child who was abused or may have been abused: whether one is a pediatrician in an emergency department or a child psychiatrist in an office, whether a parent or another person is suspected of the abuse, the severity of the abuse and the victim’s relationship to the perpetrator, whether physical signs of abuse are obvious or absent, the age and gender of the child, and the degree of anxiety, defensiveness, anger, or mental disorganization that the child exhibits. Often, the examiner must be creative and persistent.

From the psychiatric perspective, the interview is usually the primary source of information, and the physical examination is secondary. In practice, children who may have been neglected or sexually abused are interviewed first and are later given a physical examination and other tests. A child who has been physically abused is more likely to have a physical examination that may be followed by a psychiatric interview.

When the child is brought to the emergency room, a detailed and spontaneous account of the injury should be obtained promptly from parents or other caregivers before secondary details and rationalizations cloud the information provided. The interviewer should allow the caregiver to explain, to expound, to derail, or to distort the story line. An abuser or codependent parent may claim to have happened on the injured child in a coma or bleeding from some unknown trauma or to have noticed significant bruising, burns, or a crooked extremity while bathing the child. Comparing the parents’ histories can provide valuable insight into how power is wielded in the family unit.

A one-month-old baby girl was transferred from a rural hospital to a university medical center because of a reported near sudden infant death syndrome (SIDS). The child was unresponsive and required mechanical ventilation. A nuclear magnetic resonance imaging (MRI) study revealed bilateral subdural hematomas, subarachnoid hemorrhage, and hemorrhage in the parenchyma of the brain. An X-ray skeletal survey showed two posterior rib fractures. An ophthalmologist observed extensive retinal hemorrhages. After the child was admitted to the Pediatric Intensive Care Unit, the child abuse consultant interviewed the parents separately. The mother, 28 years of age, said that she had recently started a new job. The baby was perfectly fine when she left her in the care of her live-in boyfriend, the child’s biological father. The father, 24 years of age, said that when he checked on the baby, he found her not breathing, blue, and unresponsive. He ran to report this to a neighbor and then called 911. The child abuse consultant suggested to the father that the baby must have been injured in some way and asked whether the father had any explanation for this injury. The father said, “I shook the baby after I found her not breathing.” The consultant concluded that severe child abuse had occurred in the form of shaken baby syndrome. The consultant notified child protective services and the local police department, so that they could initiate and coordinate their investigation. (Courtesy of William Bernet, M.D.)

**Suspected Sexual Abuse.** The examiner should consider the possibility that the parents are not telling the truth. This situation is more complex, however, than suspected physical abuse. For example, the mother may wish to avoid the discovery of father–daughter incest by blaming the child’s genital injury on another child or a stranger. In another scenario, the mother may concoct an allegation of incest when the child had never been abused at all. The first version protects a father who is guilty; the second version implicates a father who is innocent.

The examiner should determine how the allegation originally arose and what subsequent statements were made. Determine the emotional tone of the first disclosure (e.g., whether the disclosure arose in the context of a high level of suspicion of abuse). Determine the sequence of previous examinations, the techniques used, and what was reported. Try to determine whether the previous interviews may have distorted the child’s recollections. If possible, review transcripts, audiotapes, and videotapes of earlier interviews. Seek a history of oversubilitation, prior abuse, or other traumas. Consider other stressors that could account for the child’s symptoms. The examiner should also ask about exposure to other possible male and female perpetrators.

**In Either Case.** Whether physical or sexual abuse is involved, a pertinent psychosocial history should be collected and organized, including the following:

1. Symptoms and behavioral changes that sometimes occur in abused children
2. Confounding variables, such as psychiatric disorder or cognitive impairment, that may need to be considered
3. Family’s attitude toward discipline, sex, and modesty
4. Developmental history from birth through periods of possible trauma to the present
5. Family history, such as earlier abuse of or by the parents, substance abuse by the parents, spouse abuse, and psychiatric disorder in the parents
6. Underlying motivation and possible psychopathology of adults involved
Collateral Information

The evaluator should consider requesting collateral information from the following people, after obtaining authorizations: protective services, school personnel, other caregivers (e.g., babysitters), other family members (e.g., siblings), the pediatrician, and police reports.

Child Interview

Several structured and semistructured interview protocols have been developed that were designed to maximize the amount of accurate information and to minimize mistaken or false information provided by children. These approaches include the Cognitive Interview, which encourages witnesses to search their memories in various ways, such as recalling events forward and then backward. The Step-Wise Interview is a funnel approach that starts with open-ended questions and, if necessary, moves to more specific questions. The interview protocol developed at the National Institute of Child Health and Human Development (NICHD) includes a series of phases and makes use of detailed interview scripts.

Although these protocols may be particularly important in a forensic context, experienced clinicians endorse flexibility and consistent good-hearted behavior by the interviewer. As with seeing any patient, the evaluator must size up the situation and use techniques that are likely to help the youngster become comfortable and communicative. One victim might need a favorite object (e.g., a teddy bear or a toy truck); another might need to have a particular person included in the interview. Some children are comfortable talking; others prefer to draw pictures. An unrelated joke, a shared cookie, or a picture on the evaluator's wall may lead to a disclosure of abuse. Important comments might be made while chatting during the break time, instead of during the structured interviews.

GENOTYPE AND MALTREATMENT: RISK AND PROTECTIVE FACTORS

Two studies of Caucasian males have provided evidence that particular genotypes with high levels of monoamine oxidase A (MAOA) seem to protect against the malignant impact of childhood maltreatment on the development of conduct disorder and antisocial behavioral patterns. Subjects in a prospective cohort design involving court-substantiated cases of child abuse and neglect and matched comparison groups were followed into adulthood. A composite index of violent and antisocial behavior (VASB) was created based on arrest record, self-report, and diagnostic information. Genotypes associated with high levels of MAOA activity were correlated with less risk of violent and antisocial behavior in later life for Caucasians, but this effect was not found for non-Caucasians. This result was not replicated in a group of adolescents with respect to the development of adolescent conduct disorder. Further studies are needed to understand the possible links between genotypes of high levels of MAOA and potential behavioral outcomes.

TREATMENT AND PREVENTION STRATEGIES

The immediate strategic intervention is to ensure the child's safety, which may require the child's removal from an abusive or neglectful home environment. Physicians are among a group of professionals who are mandated by law to report suspected child abuse or neglect to the local protective services agency.

Several evidence-based psychotherapies now exist in the treatment of childhood abuse and neglect. These include Multisystemic Therapy for Child Abuse and Neglect (MST-CAN), Parent-Child Interaction Therapy (PCIT), adapted for children who have been physically abused, and Combined Parent-Child Cognitive Behavioral Therapy (CPC-CBT).

MST-CAN uses a home-based model in which therapists come to the home to involve families in a highly monitored positive interactional approach toward their physically abused children. Parents receive support and guidance to care for their children in a less harsh, nonneglectful manner. This approach has been shown to reduce behavioral problems in the children, while increasing parental understanding of meeting their children's needs in a safe environment.

PCIT consists of combined treatment for parents and children in which parenting is coached directly by the therapist and practiced in sessions with parents and children together. Typically, therapists observe parent–child interactions through a one-way mirror and coach parents during the live interaction using a radio earphone. This model is based on the premise that changing parent–child interaction patterns will break the cycle of parent and child behaviors that maintain abusive behavior, and replace it with more nurturing and supportive interactions. Although PCIT has been shown to be effective, additional treatments are likely to be needed for parents with mental health problems such as depression or substance use.

CPC-CBT is designed to help parents to develop more positive strategies with their children and to help children to cope more effectively with their past abuse and to learn more positive interactions with parents. Therapeutic techniques used with parents include motivational interviewing, psychoeducation, adaptive coping skills, and better problem solving when difficult situations arise. Therapeutic strategies used with children focus on the development of positive coping, anger management, and gradual exposure through the use of a developmentally appropriate trauma narrative. Parents and children participate together in sessions in which the parent is able to convey complete responsibility for their abusive behavior, and then, the parent and child collaborate on a new joint family plan that promotes safety and more positive relationships. Therapeutic sessions with the child and parent together appear to add to the effectiveness of treatment.

Children who have been maltreated are at increased risk for further maltreatment according to studies of child victims of abuse and maltreatment. Studies have shown that four factors were most consistently identified as predictors of future maltreatment: number of previous episodes of maltreatment; neglect as the form of maltreatment; parental conflict; and parental psychiatric illness. Maltreated children were found to be about six times more likely to experience recurrent maltreatment, and the risk of recurrence was highest within 30 days of the index experience. This underscores the importance of a careful examination of the protective factors in the home environment and the early initiation of therapeutic sessions.

31.19d Impact of Terrorism on Children

In recent years, exposure to mass trauma and terrorism has become an increasing concern regarding the well-being of youth. Mass trauma has occurred directly and by witness through highly publicized traumatic events globally and in the United States, pertaining to terrorism, war, mass killings, and natural disasters.

On April 15, 2013, the first major terrorist attack in the United States since 9/11 occurred at the finish line of the Boston Marathon in the mid-afternoon. Two “improvised explosive devices” (IEDs), that is, homemade bombs, detonated 8 minutes apart in the middle of a densely packed crowd of thousands of marathon runners and bystanders, killing three people and injuring about 264 others. Within moments after the blasts, the crowd’s panic and chaos turned to purposeful action. Courageously, bystanders ran toward others to give aid rather than dispersing away from the scene in all directions. Runners tore off their own shirts to apply pressure to fellow runners who were bleeding, or to use them as tourniquets. Boston’s emergency response medical teams worked quickly, efficiently, and tirelessly to transport injured runners to hospitals and into operating rooms in order to save limbs, and stop bleeding. The fact that almost all the injured were saved is a tribute to the emergency preparedness and collaboration of law enforcement, medical, and surgical teams carrying out an emergency plan that they had previously been briefed on, as a matter of course.

Additional situations in which youth are exposed to severe trauma and terror involve armed conflict around the world, multiple mass school shootings that have taken place across the United States in recent years, and hurricanes, devastating storms, and tsunamis. Of course, more than a decade ago, the youth in the United States experienced the large-scale domestic terrorist attack on September 11, 2001, on the World Trade Center in New York City and the Pentagon in Washington, DC.

There is an increasing body of literature on the impact of terrorism on children as well as a variety of other forms of trauma. One predominant and near universal symptom in children in response to these stimuli is anxiety. Young children may cling excessively to their parents, whereas older children may become preoccupied with fear about unrelated issues. Some youth express overt anger, and others experience a sense of hopelessness, lack of control, and/or depression. Severe traumas, such as experiencing a terrorist event, may be more likely to result in posttraumatic stress syndromes among exposed youth, compared to less severe forms of trauma. The number of traumas experienced by a child, degree of family support provided after the exposure, and the reactions of parents are all important factors in a child’s reaction.

According to a national survey after the terrorist attack of September 11th, stress reactions to that disaster were increased by watching repeated media coverage of those events. A similar study evaluating the impact of media versus direct exposure to collective trauma, on acute stress response was undertaken 2 to 4 weeks after the Boston Marathon bombings through surveying 846 people from Boston, 941 people from New York City, and 2,888 people through Internet means. Direct exposure, defined as being at or near the bombings, was compared to media exposure, including footage on television and bombing related stories on the radio, in print, online, and other social media coverage. Because acute stress responses appear within weeks of a traumatic event, this study was able to capture acute stress difference between the two groups. The study found that trauma related to media exposure was associated with acute stress reactions in people from all over the United States who were not directly exposed to the event in Boston. Furthermore, respondents reporting exposure to media coverage of the bombings for six or more hours daily in the week following the bombings were nine times more likely to report high acute stress than those who had minimal exposure to media coverage of the events. In fact, the group who engaged in extensive media coverage had higher levels of acute stress than respondents who had direct exposure in Boston, but who had minimal exposure to media coverage of the bombings. These findings suggest that prolonged media exposure to collective traumatic events may have a strong negative impact on psychological symptoms and acute stress syndromes. However, the study noted substantial resilience in the surveyed population. Researchers have suggested that the
effectiveness of Boston’s medical and law enforcement teams in response to the terrorist bombings may have promoted some degree of resilience in the population.

A unique aspect of exposure to terrorist-related trauma, as well as school shootings, is the psychological effects of knowing that the trauma was both consciously and purposely perpetrated, and yet also random. The random nature of terrorist attacks appears to lead to especially adverse reactions in children. School shootings are among the most tragic of traumatic events involving youth. On December 14, 2012, in the village of Sandy Hook, in Newtown, Connecticut, a 20-year-old male in black clothing carrying his mother’s rifle, shot his way through a glass window at the front of the Sandy Hook Elementary School, rampaged the school, shooting and killing 20 first-grade students from multiple classrooms and 6 school personnel, and then shot and killed himself. He had shot and killed his mother before arriving at the school. The psychological impact of this massacre on children who survived is moderated by age, gender, and family reactions. Younger children appear to be at higher risk for posttraumatic stress disorder, somatic symptoms, depression, and distress than older children and adolescents. Gender also has been found to influence behavioral symptoms after exposure to severe trauma or terrorism, with girls experiencing higher levels of posttraumatic stress syndromes and depression, while boys exhibit more external behavior problems.

Although the United States has launched a series of initiatives in response to the threats and consequences of terrorism in the form of an act of Congress in 2002 called the Public Health Security and Bioterrorism Preparedness and Response Act, children and adolescents continue to view media exposure to terrorist events throughout the world that reinforces a sense of danger.

The concept of terrorist acts is characterized by three distinct features: (1) They produce a societal atmosphere of extreme danger and fear, (2) they inflict significant personal harm and destruction, and (3) they undermine the expectation of citizens that the state is able to protect them.

Child and adolescent reactions to exposure to terrorism are mediated by numerous factors, including personal appraisal of persisting danger, the likelihood of recurrent attack, and the perception of the relative safety of one’s family and close friends. Children’s responses to terrorist exposure are influenced by how their parents cope with the trauma and resulting turmoil and how well they understand the situation. PTSD has been studied in adolescents, with and without learning disabilities, who have been exposed to terror attacks. Findings from this study revealed that personal exposure to terror, past personal life-threatening events, and history of anxiety all contributed to the development of posttraumatic stress reactions. In addition, adolescents with learning disabilities who had difficulties in cognitively processing the traumatic events were at higher risk of developing PTSD when this was combined with the other high risk factors, such as being personally exposed to the traumatic events.

Table 31.19d-1 identifies the relationship between objective features of danger and subjective features related to exposure to terrorist acts.

The following summarizes data collected after the terrorist attack of the World Trade Center on September 11, 2001.

SEPTEMBER 11, 2001 ATTACKS

The U.S. Department of Education, through Project SERV, supported the New York City Board of Education in conducting a needs assessment of New York City schoolchildren. A total of 8,000 randomly selected students were surveyed 6 months after the September 11, 2001 attacks. Striking differences were seen among students in the vicinity of Ground Zero as compared with students in the rest of the city, in exposure to smoke and dust, fleeing for safety, problems getting home, and smelling smoke in the days and weeks after September 11. Approximately 70 percent of all children, however, were exposed to one of these factors. Interpersonal exposure through direct victimization of a family member was greater among children attending schools outside the Ground Zero vicinity as compared with those attending school in this area. Media exposure was extensive and prolonged. Signs of heightened security were visible throughout the city. The study used several scales of the Diagnostic Interview Schedule for Children (DISC). Three sets of findings stand out from this study. First a significant degree of persistent separation anxiety was seen, especially among school-age children, but also among adolescents. Second, reflecting an age-related vulnerability to incident-specific new fears (e.g., subways and buses) and avoidance behavior of school-age children, a nearly 25 percent rate of agoraphobia was reported among 4th- and 5th-graders. Care must be taken, however, not to misrepresent incident-specific new fears as agoraphobia, because the course of recovery and intervention strategies may differ. Third, an enormous reservoir of prior traumatic experiences (more than one half of the total sample) was
associated with severity of current PTSD symptoms, emphasizing the need to attend to prior trauma in conducting needs assessments, surveillance, and intervention strategies. Other risk factors, in addition to younger age, included female gender and Hispanic ethnicity. The finding of age-related increases in rates of conduct disorder also needs to be interpreted in light of adolescent response to an ecology of danger in which overly aggressive, reckless, and risk-taking behaviors are well documented and associated with posttraumatic stress reactions. A major strength of this study was the inclusion of self-reported impairment as well as symptoms, setting an important standard for future studies.

J. Stuber and colleagues conducted a telephone survey of a random sample of adult residents of Manhattan 1 to 2 months after the September 11th attacks. The sample included more than 100 parents who were asked to describe the experiences and reactions of their children. Not surprisingly, given the time of the incident, most children were at school or day care when the disaster occurred. Many of the parents recalled concern about their children's safety at the time, and most were not reunited with their children for more than 4 hours. More than 20 percent of the parents studied reported that their children had received counseling related to the disaster. Receiving counseling was associated with male gender, parental posttraumatic stress, and having at least one sibling living in the household.

Also using parent report in a New York City telephone survey, researchers assessed predictors of posttraumatic stress reactions in children between the ages of 4 and 17 years, 4 to 5 months after the attacks. Almost 20 percent of children were reported by their parents to have experienced severe or very severe posttraumatic stress reactions, and approximately two thirds had moderate posttraumatic stress reactions. Parental reactions and viewing three or more graphic images of the disaster on television were associated with severe or very severe posttraumatic stress reactions in children. Another study reported that 27 percent of children with severe or very severe posttraumatic stress reactions received some mental health care 4 to 5 months after September 11th.

Two surveys of representative samples of adults were conducted after the September 11th attacks; the first between 4 and 5 months and the second between 6 and 9 months after the attacks. Behavior problems were related to the child's race or ethnicity, family income, living in a single-parent household, disaster event experiences, and parental reactions to the attacks. The results of these surveys were examined in light of findings from a representative survey conducted before September 11th. The rate of behavior problems was lower in the first post-September 11th survey (4 to 6 months after the attacks) than rates in the pre-September 11th survey, but problems returned to pre-September 11th levels by the second post-September 11th study (6 to 9 months after the attacks). Consistent with findings in studies of Hurricane Andrew, these results suggest that behavior problems may decrease in the months after a disaster or that parents may be insensitive to them, but that they return to pre-disaster levels over time.

Media coverage of the September 11th attacks brought renewed debate about its impact, especially on children, even children with no direct exposure. One study reported extensive exposure to television coverage in children throughout the nation, using a representative survey of adults conducted in the first days after the attacks. Approximately one third of the parents surveyed attempted to limit or to prevent their children's viewing, but, among those whose parents made no attempt to restrict viewing, the number of hours of disaster coverage watched was related to the number of reported stress symptoms.

Using a Web-based, nationally representative sample of adults, another study examined distress in children 1 to 2 months after the attacks by asking parents if their children were upset by the events. Among the children perceived as most upset, 20 percent had trouble sleeping, 30 percent were irritable or easily upset, and 27 percent feared separation from their parents. The mean age of children perceived as most upset was 11 years, with no statistically significant gender differences. The proportion of parents reporting at least one child upset did not differ by community in analysis of data from the New York City metropolitan area, Washington, DC, other major metropolitan areas, and the rest of the country.

A strength of these surveys was their examination of representative samples, but earlier work points to concern about assessing children by interviewing their parents. Furthermore, as with the Oklahoma City studies, the samples were composed mainly of indirectly exposed children, and the clinical significance of the findings is unclear.

Nine-year-old Jason endured the traumatic loss of his father on the first plane into the World Trade Center. Jason's father was on board American Airlines Flight No. 11 on a business trip. Jason and his siblings were preparing to leave for school when he, his mother, and his siblings learned of the event. Jason watched his mother nearly collapse when she confirmed the presence of his father aboard the aircraft. Jason observed the recurring video segments of the second plane crashing into the second tower several times that morning before his mother limited television access. Jason, the oldest child in his family, had enjoyed an exceptionally close relationship with his father.

Almost immediately after the terrorist attacks, Jason's mother became worried that he was despondent, suicidal and unable to function, just preoccupied with the grisly nature of his father's death. He was becoming increasingly agitated as he talked constantly about the gruesome way that his father had died. Jason's mother sought immediate psychological treatment for him, during which he began to ask a continual series of questions about his father's death, including aspects of burning, fragmentation, pain, blood, and the exact moment of his father's deaths in comparison with what he had initially observed on television. This became the main theme of Jason's early treatment, in which he ruminated (i.e., whether this father had been "blown up in a thousand pieces" and the sequence of fire, burning, pain, and death). Jason developed nightmares within days in which he awakened and called for his mother at least three times a night. Jason was unwilling to discuss the content of his dreams with his mother, given his observations of her own serious distress. Jason began to express fears that the "hijackers" would hurt his mother and siblings. He became focused on the concept that "half our freedom is gone," and he was concerned that one half of New York City was destroyed. He was becoming increasingly agitated as he talked constantly about the gruesome way that his father had died. Jason's mother had to constantly reassure him that the war in Afghanistan, and his mother had to constantly reassure him that the war was not near their home.

Jason told his therapist of his wish that could find a time machine and be transported back in time on board his father's flight.
before it crashed. While his therapist could fly the plane, he would overpower the “hijackers” and throw them off the plane, and then the plane would land safely in Boston. Jason continued his wish that after landing, his father and the other passengers tell him “thank you,” and be very happy. After expressing his wish verbally, he appeared to be somewhat comforted and he began to recall many positive activities with his father, and a series of happy, highly detailed memories of his father, which then caused him to suddenly become tearful with profound sadness at the realization that these would be no more.

In therapy, Jason alternately expressed rage and anger and confusion about the actions of “Osama Bin Laden.” Over many months, Jason was able to remember and speak about the good things he remembered about his father without immediately breaking down in tears. Jason become a helpful big brother, who often tried to care for his younger siblings, and his mother often told him how proud she was of him. (Adapted from Robert S. Pynoos, M.D. M.P.H., Merritt D. Schreiber, Ph.D., Alan M. Steinberg Ph.D., Betty Pfefferbaum, M.D., and J.D.)

To respond to the mental health needs of children and adolescents who have been exposed to terrorism either through personal experience or through exposure to media depicting world-wide terrorism, the adverse psychological reactions listed in Table 31.19d-2 must be considered.

**COMPONENTS OF MECHANISMS FOR RECOVERY FROM EXPOSURE TO TERRORISM**

In order to begin the process of recovery from exposure to mass trauma, an assessment of a child’s current coping must be done. Numerous instruments to measure coping exist. These include COPE, a self-report questionnaire which has 52 items that can be used with children, adolescents and adults; Children’s Coping Strategies Checklist (CCSC), a self-report questionnaire with 45 general coping items used with children 9 to 13 years of age; and How I Coped Under Pressure (HICIPS), which has 45 event specific questions for children in the 4th to 6th grade. Once this assessment has been determined, the next steps can be taken to begin the road to recovery.

**Perception of Safety**

The notion of perceived safety is an important protective factor as well as a component of recovery for a child, adolescent, or adult who has been exposed to terrorism. A recent report of symptoms of PTSD, depression, and perceived safety in disaster workers 2 weeks after the September 11th terrorist attacks found that lower perceived safety was associated with increased symptoms of hyperarousal and intrusive fearful thoughts, but not avoidance. An expected diminished sense of safety was found in those individuals who had personally been in greater physical danger, or who had worked with dead bodies compared with others who were physically less exposed. To regain a sense of security, reestablishment of a perception of safety is a necessary first step.

**Reestablishment or Maintenance of Daily Routines**

Although it is clearly not always possible to maintain usual daily routines amidst war or exposure to terrorism, a study of Israeli adolescents found that those whose families were able to maintain their usual activities, such as attending school and family functions, were at lower risk for the development of posttraumatic reactions.

**Proactive Interventions to Enhance Resilience**

Perceived personal resilience has been shown to be protective against symptoms of posttraumatic stress development. Proactive interventions aimed at enhancing a sense of personal resilience and an ability to cope with the stressful situation may serve to decrease the risk of psychiatric symptoms after exposure to terrorism. Interventions may include regaining a sense of perceived safety through reestablishing routines, altruistic tasks, family preparedness planning, and parental expression of security.

Adulthood

For most of the history of developmental psychology, the pre-dominant theory held that development ended with childhood and adolescence. Adults were considered to be finished products in whom the ultimate developmental states had been reached. Beyond adolescence, the developmental point of view was relevant only insofar as success or failure to reach adult levels or to maintain them determined the maturity or immaturity of the adult personality.

In contradistinction were the long-recognized ideas that adult experiences, such as pregnancy, marriage, parenthood, and aging, had an obvious and significant impact on mental processes and experience in the adult years. This view of adulthood suggests that the patient, of any age, is still in the process of ongoing development, as opposed to merely being in possession of a past that influences mental processes and is the primary determinant of current behavior. Although the debate continues, the idea that development continues throughout life is increasingly accepted.

Development in adulthood, as in childhood, is always the result of the interaction among body, mind, and environment, never exclusively the result of any one of the three variables. Most adults are forced to confront and adapt to similar circumstances: establishing an independent identity, forming a marriage or other partnership, raising children, building and maintaining careers, and accepting the disability and death of one’s parents.

In modern Western societies, adulthood is the longest phase of human life. Although the exact age of consent varies from person to person, adulthood can be divided into three main parts: young or early adulthood (ages 20 to 40), middle adulthood (ages 40 to 65), and late adulthood or old age.

**YOUNG ADULTHOOD (20 TO 40 YEARS OF AGE)**

Usually considered to begin at the end of adolescence (about age 20) and to end at age 40, early adulthood is characterized by peaking biological development, the assumption of major social roles, and the evolution of an adult self and life structure. The successful passage into adulthood depends on satisfactory resolution of childhood and adolescent crises.

During late adolescence, young persons generally leave home and begin to function independently. Sexual relationships become serious, and the quest for intimacy begins. The 20s are spent, for the most part, exploring options for occupation and marriage or alternative relationships and making commitments in various areas.

Early adulthood requires choosing new roles (e.g., husband, father) and establishing an identity congruent with those new roles. It involves asking and answering the questions “Who am I?” and “Where am I going?” The choices made during this time may be tentative; young adults may make several false starts.

**Transition from Adolescence to Young Adulthood**

The transition from adolescence to young adulthood is characterized by real and intrapsychic separation from the family of origin and the engagement of new, phase-specific tasks (Table 32–1). It involves many important events, such as graduating from high school, starting a job or entering college, and living independently. During these years, the individual resolves the issue of childhood dependency sufficiently to establish self-reliance and begins to formulate new, young-adult goals that eventually result in creation of new life structures that promote stability and continuity.

**Developmental Tasks**

Establishing a self that is separate from parents is a major task of young adulthood. For most individuals, the emotional detachment from parents that takes place in adolescence and young adulthood is followed by a new inner definition of themselves as comfortably alone and competent, able to care for themselves in the real world. This shift away from the parents continues long after marriage, and parenthood results in the formation of new relationships that replace the progenitors as the most important individuals in the young adult’s life.

Psychological separation from the parents is followed by synthesis of mental representations from the childhood past and the young-adult present. The psychological separation from parents in adolescence has been called the second individuation, and the continued elaboration of these themes in young adulthood has been called the third individuation. The continuous process of elaboration of self and differentiation from others that occurs in the developmental phases of young (20 to 40 years of age) and middle (40 to 65 years of age) adulthood is influenced by all important adult relationships.

A number of different models have been proposed for understanding adult development. They are all theoretical and somewhat idealized. They all use metaphors to describe complex social, psychological, and interpersonal interactions. The models are heuristic: They provide a conceptual framework for thinking about common important experiences. They are descriptive rather than prescriptive; that is, they provide a
useful way of looking at what many persons do, not a formula for what all persons should do. Some of the terms and concepts commonly used are explained in Table 32-2. These periods involve individuation, that is, leaving the family of origin and becoming one's own man or woman, passing through midlife, and preparing in middle adulthood for the transition into late adulthood.

Work Identity. The transition from learning and play to work may be gradual or abrupt. Socioeconomic group, gender, and race affect the pursuit and development of particular occupational choices. Blue-collar workers generally enter the workforce directly after high school; white-collar workers and professionals usually enter the workforce after college or professional school. Depending on choice of career and opportunity, work may become a source of ongoing frustration or an activity that enhances self-esteem. Symptoms of job dissatisfaction are a high rate of job changes, absenteeism, mistakes at work, accident proneness, and even sabotage.

UNEMPLOYMENT. The effects of unemployment transcend those of loss of income; the psychological and physical tolls are enormous. The incidence of alcohol dependence, homicide, violence, suicide, and mental illness rises with unemployment. One's core identity, which is often tied to occupation and work, is seriously damaged when a job is lost, whether through firing, attrition, or early or sometimes even regular retirement.

Developing Adult Friendships. In late adolescence and young adulthood, before marriage and parenthood, friendships are often the primary source of emotional sustenance. Roommates, apartment mates, sorority sisters, and fraternity brothers, as indicated by the names used to describe them, are substitutes for parents and siblings, temporary stand-ins until more permanent replacements are found.

The emotional needs for closeness and confidentiality are largely met by friendships. All major developmental issues are discussed with friends, particularly those in similar circumstances. As marriages occur and children are born, the central emotional importance of friendships diminishes. Some friendships are abandoned at this point, because the spouse objects to the friend, recognizing at some level that they are competitors. Gradually, there is movement toward a new form of friendship, couples friendships. They reflect the newly committed status but are more difficult to form and to maintain, because four individuals must be compatible, not just two.

As children begin to move out of the family into the community, parents follow. Dance classes and Little League games provide the progenitors with a new focus and the opportunity to make friends with others who are at the same point developmentally and who are receptive to the formation of relationships that help explain, and cushion, the pressures of young adult life.

Sexuality and Marriage. The developmental shift from sexual experimentation to the desire for intimacy is experienced in young adulthood as an intense loneliness, resulting from the awareness of an absence of committed love similar to that experienced in childhood with their parents. Brief sexual encounters in short-lived relationships no longer significantly boost self-esteem. Increasingly, the desire is for emotional involvement in a sexual context. The young adult who fails to develop the capacity for intimate relationships runs the risk of living in isolation and self-absorption in midlife.

For most individuals in Western culture, the experience of intimacy increases the desire for marriage. Most persons in the United States marry for the first time in their mid- to late 20s. The median age of first marriage has been rising steadily since 1950 for both men and women, and the number of persons who never marry has been increasing. Today, approximately 50 percent of all adults ages 18 and older are not married, compared with only 28 percent in 1960. The proportion of 30- to 34-year-olds who never married has almost tripled, and the proportion of never-married 35- to 39-year-olds doubled.
INTERRACIAL MARRIAGE. Mixed-race marriages were banned in 19 states until a U.S. Supreme Court decision in 1967. In 1970, such marriages accounted for only 2 percent of all marriages. The trend has been steadily upward. Currently, interracial marriages account for about 1.5 million marriages in the United States.

Despite the trend toward more interracial marriages, they still remain a small proportion of all marriages. Most persons are more likely to marry someone from the same racial and ethnic background. Marriages between Hispanic whites and non-Hispanic whites and between Asians and whites are more common than those between blacks and whites.

SAME-SEX MARRIAGE. Same-sex marriage is recognized as legal by many states in the United States and by the U.S. Supreme Court, as well as in several countries around the world (e.g., France and Denmark). It differs from same-sex civil unions granted by states, which do not provide the same federal protection or benefits as marriage. No reliable estimates are available for the number of same-sex marriages in the United States; however, in 2013 it was estimated to be about 80,000. There is growing consensus in the United States and around the world that homosexual persons should be allowed the same marital rights and privileges as heterosexuals. Same-sex marriage can be subject to more stress than heterosexual marriage because of continued prejudice toward such unions among certain conservative political or religious groups who oppose such unions.

MARITAL PROBLEMS. Although marriage tends to be regarded as a permanent tie, unsuccessful unions can be terminated, as indeed they are in most societies. Nevertheless, many marriages that do not end in separation or divorce are disturbed. In considering marital problems, clinicians are concerned with both the persons involved and with the marital unit itself. How any marriage works relates to the partner selected, the personality organization or disorganization of each, the interaction between them, and the original reasons for the union. Persons marry for a variety of reasons—emotional, social, economic, and political, among others. One person may look to the spouse to meet unfulfilled childhood needs for good parenting. Another may see the spouse as someone to be saved from an otherwise unhappy life. Irrational expectations between spouses increase the risk of marital problems.

MARRIAGE AND COUPLES THERAPY. When families consist of grandparents, parents, children, and other relatives living under the same roof, assistance for marital problems can sometimes be obtained from a member of the extended family with whom one or both partners have rapport. With the contraction of the extended family in recent times, however, this source of informal help is no longer as accessible as it once was. Similarly, religion once played a more important role than it does now in the maintenance of family stability. Wise religious leaders are available to provide counseling, but they are not sought out to the extent they once were, which reflects the decline in religious influence among large segments of the population. Formerly, both the extended family and religion provided guidance for couples in distress and also prevented dissolution of marriages by virtue of the social pressures that the extended family and religion exerted on couples to stay together. As family, religious, and societal pressures have been relaxed, legal procedures for relatively easy separation and divorce have expanded. Concurrently, the need for formalized marriage counseling services has developed.

Marital therapy is a form of psychotherapy for married persons in conflict with each other. A trained person establishes a professional contract with the patient-couple and, through definite types of communication, attempts to alleviate the disturbance, to reverse or change maladaptive patterns of behavior, and to encourage personality growth and development.

In marriage counseling, only a particular conflict related to the immediate concerns of the family is discussed; marriage counseling is conducted much more superficially by persons with less psychotherapeutic training than is marital therapy. Marital therapy places greater emphasis on restructuring the interaction between the couple, including, at times, exploration of the psychodynamics of each partner. Both therapy and counseling emphasize helping marital partners cope effectively with their problems.

Parenthood. Parenthood intensifies the relationship between the new parents. Through their physical and emotional union, the couple has produced a fragile, dependent being that needs them in the interlocking roles of father and mother. This recognition expands their internal images of each other to include thoughts and feelings emanating from the role of parent. As they live together as a family, the lovers' relationship to each other changes. They become parents relating to one another and to their children.

Parent–child problems do arise, however. In addition to the economic burden of raising a child (estimated to be $250,000 for a middle-class family whose child goes to college), there are emotional costs. Children may reawaken conflicts that parents themselves had as children, or children may have chronic illnesses that challenge families' emotional resources. In general, men have been more concerned with their work and occupational advancement than with child rearing, and women have been more concerned about their role as mothers than with advancement in their occupation, but this emphasis is changing dramatically for both sexes. A small, but growing, number of couples are choosing to split a job (or work at two part-time jobs) and share child-rearing duties.

Parenting has been described as a continuing process of letting go. Children must be allowed to separate from parents and, in some cases, must be encouraged to do so. Letting go involves separation from children who are starting school. School phobias and school refusal syndromes that are accompanied by extreme separation anxiety may have to be dealt with. Often, a parent who cannot let go of a child accounts for this situation; some parents want their children to remain tightly bound to them emotionally. Family therapy that explores these dynamics may be needed to resolve such problems.

As children get older and enter adolescence, the process of establishing identity assumes great importance. Peer relationships become crucial to a child's development, and overprotective parents who keep a child from developing friendships or having the freedom to experiment with friends that the parents disapprove of can interfere with the child's passage through adolescence. Parents need not refrain from exerting influence over their children; guidance and involvement are crucial. But they must recognize that adolescents especially need parental
approval; although rebellious on the surface, adolescents are much more tractable than they appear, provided parents are not overbearing or generally punitive.

**SINGLE-PARENT FAMILIES.** More than 10 million single-parent families exist with one or more children under the age of 18; of these families, 20 percent are single-parent homes in which a woman is the sole head of the household. The increase in number of single-parent families has risen almost 200 percent since 1980.

**ALTERNATIVE LIFESTYLE PARENTING.** Single, partnered and married homosexual men and women are choosing to raise children. In most cases, such children are obtained through adoption. Some, however, may be born to a lesbian woman through artificial insemination or obtained from a willing mother surrogate. The number of such family units is increasing. The data about the development of children in these homes indicate that they are at no greater risk for emotional problems (or for a homosexual orientation) than children raised in conventional households.

**ADOPTION.** Since the turn of the century, adoption or foster placement has replaced institutional care as the preferred way to raise children who are neglected, unwanted, or abandoned. Many couples who are unable to conceive (and some couples who already have children) turn to adoption.

In addition to the full range of normal parent-child developmental issues, adoptive parents face special problems. They must decide how and when to tell the child about the adoption. They must deal with the child’s possible desire for information about his or her biological parents. Adopted children are more likely to develop conduct disorders, problems with drug abuse, and antisocial personality traits. It is unclear whether these problems result from the process of adoption or whether parents who give up children for adoption are more likely to pass along a genetic predisposition for these behaviors.

With widespread use of birth control and access to safe abortions, the number of infants available for adoption has declined steeply. Wealthy parents may prefer to arrange for private adoption rather than wait many uncertain years for an institutional adoption. (In private adoptions, a biological mother is paid for her legal and medical expenses but not for the baby. Baby selling is a felony in all states.) International adoptions (especially from Bosnia, Latin America, eastern Europe, and China) have also become more common. Questionable regulation in these countries has raised concern that some infants put up for adoption in poor countries may not be orphans but are being sold by destitute mothers.

**MIDDLE ADULTHOOD (40 TO 65 YEARS OF AGE)**

Middle adulthood is the golden age of adulthood, similar to the latency years in childhood, but much longer. Physical health, emotional maturity, competence and power in the work situation, and gratifying relationships with spouse, children, parents, friends, and colleagues all contribute to a normative sense of satisfaction and well-being. With regard to occupation, many persons begin to experience the gap between early aspirations and current achievements. They may wonder whether the lifestyle and the commitments they chose in early adulthood are worth continuing; they may feel that they would like to live their remaining years in a different, more satisfying way, without knowing exactly how. As children grow up and leave home, parental roles change, and persons redefine their roles as husbands and wives.

Important gender-specific changes occur in middle adulthood. Many women who no longer need to nurture young children can release their energy into independent pursuits that require assertiveness and a competitive spirit, traits that were traditionally considered masculine. Alternatively, men in middle adulthood may develop qualities that enable them to express their emotions and recognize their dependency needs, traits that were traditionally considered feminine. With the new balance of the masculine and the feminine, a person may now be able to relate more effectively to someone of the other sex than in the past. For a further discussion of adoption see Section 31.19b.

**Transition from Young to Middle Adulthood**

The transition from young adulthood to middle adulthood is slow and gradual, with no sharp physical or psychological demarcation. The aging process picks up speed and becomes a powerful organizing influence on intrapsychic life, but the change is gradual, unlike during adolescence. Mental change is experienced in a similar fashion, slow and imperceptible, without a sense of disruption.

Development in young adulthood is embedded in close relationships. Intimacy, love, and commitment are related to the mastery of the relationships most immediate to personal experience. The transition from young adulthood to middle age includes widening concern for the larger social system and differentiation of one’s own social, political, and historical system from others. Authors have described middle adulthood in terms of generativity, self-actualization, and wisdom.

**Developmental Theorists**

Robert Butler described several underlying themes in middle adulthood that appear to be present regardless of marital and family status, gender, or economic level (Table 32-3). These themes include aging (as changes in bodily functions are noticed in middle adulthood); taking stock of accomplishments and setting goals for the future; reassessing commitments to family, work, and marriage; dealing with parental illness and death; and attending to all the developmental tasks without losing the capacity to experience pleasure or to engage in playful activity.

**Erik Erikson.** Erikson described middle adulthood as characterized either by generativity or by stagnation. Erikson defined generativity as the process by which persons guide the oncoming generation or improve society. This stage includes having and raising children, but wanting or having children does not ensure generativity. A childless person can be generative by (1) helping others, (2) being creative, and (3) contributing to society. Parents must be secure in their own identities to raise children successfully: They cannot be preoccupied with themselves and act as if they were, or wished to be, the child in the family.
To be stagnant means that a person stops developing. For Erikson, stagnation was anathema, and he referred to adults without any impulses to guide the new generation or to those who produce children but don’t care for them as being “within a cocoon of self-concern and isolation.” Such persons are in great danger. Because they are unable to negotiate the developmental tasks of middle adulthood, they are unprepared for the next stage of the life cycle, old age, which places more demands on the psychological and physical capacities than all the preceding stages.

George Vaillant. In his longitudinal study of 173 men who were interviewed at 5-year intervals after they graduated from Harvard, Vaillant found a strong correlation between physical and emotional health in middle age. In addition, those with the poorest psychological adjustment during college years had a high incidence of physical illness in middle age. No single factor in childhood accounted for adult mental health, but an overall sense of stability in the parental home predicted a well-adjusted adulthood. A close sibling relationship during college years was correlated with emotional and physical well-being in middle age. In another study, Vaillant found that childhood and adult work habits were correlated, and that adult mental health and good interpersonal relationships were associated with the capacity to work in childhood. Vaillant’s studies are ongoing and represent the longest continuous study of adulthood ever performed.

Calvin Colarusso and Robert Nemiroff. On the basis of their experience as clinicians and psychoanalysts, Calvin Colarusso and Robert Nemiroff propose a broad theoretical foundation for adult development by suggesting that the developmental process is basically the same in the adult as in the child because, like the child, the adult is always in the midst of an ongoing dynamic process, continually influenced by a constantly changing environment, body, and mind. Whereas child development focuses primarily on the formation of psychic structure, adult development is concerned with the continuing evolution of existing psychic structure and with its use. Although the fundamental issues of childhood continue in altered form as central aspects of adult life, attempts to explain all adult behavior and pathology in terms of the experiences of childhood are considered reductionistic. The adult past must be taken into account in understanding adult behavior in the same way that the childhood past is considered. The aging body is understood to have a profound influence on psychological development in adulthood, as is the growing midlife recognition and acceptance of the finiteness of time and the inevitability of personal death.

Developing Midlife Friendships

Unlike friendships in latency and adolescence and, to some extent, in young adulthood, midlife friendships do not usually have the sense of urgency or the need for frequent or nearly constant physical presence of the friend. Midlife individuals have neither the need to build new psychic structure (as do latency-age children and adolescents) nor the pressing need to find new relationships (as do young adults). They may have many sources of gratification available through relationships with spouse, children, and colleagues.

As their firstborn sons progressed through high school, two women in their mid-40s became fast friends. In addition to raising money for the school activities in which their sons were involved, thus maintaining a close involvement with the boys, they spent many hours talking about the boys’ activities, girlfriends, and plans for college. Their husbands, who liked each other, became acquaintances, not friends. They directed their own feelings about their sons into other relationships. After the boys left for college, the intensity of the friendship diminished, tending to peak again during vacation periods. (Courtesy of Calvin Colarusso, M.D.)

Because of their unique position in the life cycle, midlife adults are easily able to initiate and sustain friendships with individuals of different ages, as well as chronological peers. In the face of a disrupted marriage or intimacy or the pressure of other midlife developmental themes, friendships may quickly become vehicles for the direct expression of impulses.

Reappraising Relationships. Midlife is a time of serious reappraisal of marriage and committed relationships. In the
process, individuals struggle with the question of whether to settle for what they have or to search for greater perfection with a new partner. For some, the conflict rages internally and is kept from others; others express it through actions that take the form of affairs, trial separations, and divorce.

Recent research on happy marriage indicates that these couples, despite internal and real conflict, have found or achieved a special goodness-of-fit between their individual needs, wishes, and expectations. In the eyes of these couples, marital success is based on the ongoing, successful engagement of a number of psychological tasks. Among the most important are providing a safe place for conflict and difference, holding a double vision of the other, and maintaining a satisfying sexual life.

The decision to leave a long-standing, committed relationship has great consequences, not only for the two individuals involved, but also for their friends and loved ones. The effect on children, in particular, is especially profound, extending far beyond childhood. The effects on the abandoned spouse, parents, and close relatives may be nearly as severe.

Various forms of therapeutic intervention, such as marital counseling, individual psychotherapy, and psychoanalysis, can be extremely effective in helping uncertain individuals decide what to do or in helping those who leave deal with the consequences of their decision on the abandoned partner, children, and other loved ones. Problems relating to intimacy, love, and sex can occupy a prominent position in an outpatient practice.

The four case studies presented here by Calvin Colarusso, M.D., illustrate some of the issues described above.

A 43-year-old patient, Mr. S, was continually preoccupied with his marriage during this 4-year psychoanalysis. Sexually inhibited during adolescence, he “married the only girl in the world who knew less about sex than I did.” Both were virgins on their wedding night. As the marriage progressed, the couple gradually developed a “satisfactory” sex life, but the patient always wondered what he had missed. As his sexual inhibitions were explored Mr. S’s sense of having “missed out on a lot of opportunities” lead to visits to massage parlors and prostitutes. Eventually such behavior ceased because of the recognition that his wife was a wonderful mother and loving wife and not the cause of the lack of sexual experience that he brought into the marriage. “I’ll always feel that I missed out when I was young, but I’ve got so much going for me now, I’m not going to mess it up over something that I can’t change.”

A 38-year-old woman entered therapy after her husband discovered that she was having sexual relations with men in their early and middle 20s. She explained that she loved her husband but he seemed to take her for granted. He no longer made her feel attractive and wanted. As the therapy progressed it became clear that she felt that as long as she could attract younger men she was still young and sexually desirable. Struggling with the early signs of physical aging, the realization that the young men were only using her to satisfy their own sexual needs was sobering and distressing. As she began to see that such behavior was self-destructive, she approached her husband about starting marital therapy.

Fifty-year-old Mrs. T left her “wonderful” husband because “I’ve missed something. I just have to get out on my own.” Married at 18 years of age, “after going from my parents’ home to his home,” she recognized that her rage at her husband for “not being all the other men I could have married, for closing off all the living I could have done” was irrational but uncontrollable. “I have to live on my own for a while, to see if I can do it, before it’s too late.” Fully intending to return to her husband, she continued exploring the infantile and adult issues that precipitated the separation, leaving the future of the marriage in doubt.

**Sexuality**

Whereas the young adult is preoccupied with developing the capacity for intimacy, the midlife individual is focused on maintaining intimacy in the face of deterring physical, psychological, and environmental pressures. In a long-standing relationship, these pressures include real and imaginary concerns about diminished sexual capability, emotional withdrawal because of preoccupation with developmental tasks, and the realistic pressures related to work and providing for dependent children and, sometimes, elderly parents as well. In relationships that begin in midlife, the maintenance of intimacy can be compromised by the absence of a common past, age and generational differences in interests and activities, and the difficulties involved in forming a stepfamily.

For sexual intimacy to continue, the participants must (1) accept the appearance of the partner’s middle-aged body, (2) continue to find it sexually stimulating, and (3) accept the normative changes that occur in sexual functioning. For those who master these developmental issues, the partner’s body remains sexually stimulating. Diminished sexual ability is compensated for by feelings of love and tenderness generated over the years by a satisfying relationship. Those who cannot accept the changes in the partner’s body or their own stop having sex, begin affairs, or leave the relationship, usually in search of a younger partner.

Normative changes in midlife sexual functioning include diminished sexual drive and an increase in mechanical problems. Men have greater difficulty getting and sustaining erections and experience a longer refractory period after ejaculation. Because of diminished estrogen production, women experience a thinning of the vaginal mucosa, a decrease in secretions, and fewer contractions at the time of orgasm. Women do not reach
their sexual prime until their mid-30s; consequently, they have a greater capacity for orgasm in middle adulthood than in young adulthood. Women, however, are more vulnerable than men to narcissistic blows to their self-esteem as they lose their youthful appearance, which is overvalued in today's society. During middle adulthood, they may feel less sexually desirable than in early adulthood and, thus, feel less entitled to an adequate sex life. An inability to deal with changes in body image prompts many women and men to undergo cosmetic surgery in an effort to maintain their youthful appearance.

The demands of raising children interfere with the privacy and emotional equilibrium required for intimacy, as do the pressures and responsibilities of work. Fatigue and diminished interest are common denominators in these circumstances. Patients with deeply rooted problems with sexuality or relationships may use aging, work, and relationships with children or elderly parents as a means of rationalizing their conflicts and refusing to analyze them.

**Climacterium**

Middle adulthood is the time of the male and female climacterium, the period in life characterized by decreased biological and physiological functioning. For women, the menopausal period is considered the climacterium, and it may start anywhere from the 40s to the early 50s. Bernice Neugarten studied this period and found that more than 50 percent of women described menopause as an unpleasant experience, but a significant portion believed that their lives had not changed in any significant way, and many women experienced no adverse effects. Because they no longer had to worry about becoming pregnant, some women report feeling sexually freer after menopause than before its onset. Generally, the female climacterium has been stereotyped as a sudden or radical psychophysiological experience, but it is more often a gradual experience as estrogen secretion decreases with changes in the flow, timing, and eventual cessation of the menses. Vasomotor instability (hot flashes) can occur, and menopause can extend over several years. Some women experience anxiety and depression, but women who have a history of poor adaptation to stress are more predisposed to the menopausal syndrome. (Chapter 27 on reproductive medicine provides further discussion of menopause and its management.)

For men, the climacterium has no clear demarcation; male hormones stay fairly constant through the 40s and 50s and then begin to decline. Nevertheless, men must adapt to a decline in biological functioning and overall physical vigor. About age 50, a slight decrease in healthy sperm and seminal fluid occurs; not sufficient, however, to preclude insemination. Coincident with the decreased testosterone level may be fewer and less firm erections and decreased sexual activity generally. Some men experience a so-called midlife crisis during this period. The crisis can be mild or severe, characterized by a sudden drastic change in work or marital relationships, severe depression, increased use of alcohol or drugs, or a shift to an alternate lifestyle.

**Midlife Transition and Crisis**

The *midlife transition* has been defined as an intense reappraisal of all aspects of life precipitated by the growing recognition that life is finite and approaching an end. It is characterized by mental turmoil, not action. For most people, the reappraisal results in decisions to keep most life structures, such as marriages and careers, which have been painstakingly built over time. When major changes are made, they are thoughtful and considered, even when they include major shifts, such as divorce or a job change. The developmentally aware clinician recognizes that every patient in this age group is engaged in a midlife transition (whether the patient is talking about it or not) and facilitates the process by making it conscious and verbal.

A true *midlife crisis* is a major, revolutionary turning point in life, involving changes in commitments to career or spouse, or both, and accompanied by significant, ongoing emotional turmoil for the individual and others. It is an upheaval of major proportions. A period of internal agitation is followed by a flurry of impulsive actions; for example, leaving spouse and children, becoming involved with a new sexual partner, and quitting a job, all within days or weeks of each other. Although unrecognized warning signs may have existed, those who are left behind are often shocked by the suddenness and abruptness of the change.

Efforts by family members or therapists to get the individual to stop and to reconsider usually fall on deaf ears. The overwhelming need is to avoid anyone who counsels restraint and to ignore therapists who recommend examining motivations and feelings before making such major decisions. Usually, in the midst of the crisis, the therapist is left with the painful job of helping those who have been left to deal with their shock and grief.

**Empty-Nest Syndrome.** Another phenomenon described in middle adulthood has been called the *empty-nest syndrome,* a depression that occurs in some men and women when their youngest child is about to leave home. Most parents, however, perceive the departure of the youngest child as a relief rather than a stress. If no compensating activities have been developed, particularly by the mother, some parents become depressed. This is especially true of women whose predominant role in life has been mothering or of couples who decided to stay in an otherwise unhappy marriage “for the sake of the children.”

**Other Tasks of Middle Adulthood**

As persons approach the age of 50, they clearly define what they want from work, family, and leisure. Men who have reached their highest level of advancement in work may experience disillusionment or frustration when they realize they can no longer anticipate new work challenges. For women who have invested themselves completely in mothering, this period leaves them with no suitable identity after the children leave home. Sometimes, social rules become rigidly established; lack of freedom in lifestyle and a sense of entrapment can lead to depression and a loss of confidence. Also unique financial burdens can occur in middle age, produced by pressures to care for aged parents at one end of the spectrum and children at the other end.

Daniel Levinson described a transitional period between the ages of 50 and 55 during which a developmental crisis may occur when persons feel incapable of changing an intolerable life structure. Although no single event characterizes the transition, the physiological changes that begin to appear may have a dramatic effect on a person's sense of self. For example, a person may experience a decrease in cardiovascular efficiency that accompanies aging. Chronological age and physical infirmity
are not linear, however; those who exercise regularly, who do not smoke, and who eat and drink in moderation can maintain their physical health and emotional well-being.

Middle adulthood is when persons frequently feel overwhelmed by too many obligations and duties, but it is also a time of great satisfaction for most persons. They have developed a wide array of acquaintances, friendships, and relationships, and the satisfaction they express about their network of friends predicts positive mental health. Some social ties, however, may be a source of stress when demands either cannot be met or assault a person's self-esteem. Power, leadership, wisdom, and understanding are most generally possessed by persons who are middle aged, and if their health and vitality remain intact, it is truly the prime of life.

DIVORCE

Divorce is a major crisis of life. Spouses often grow, develop, and change at different rates; one spouse may discover that the other is not the same as when they first married. In truth, both partners have changed and evolved, not necessarily in complementary directions. Frequently, one spouse blames a third person for alienation of affections and refuses to examine his or her own role in the marital problems. Certain aspects of marital deterioration and divorce seem to be related to specific qualities of middle life—need for change, weariness with acting responsibly, fear of facing up to oneself.

Types of Separation

Paul Bohannan, an anthropologist with expertise in marriage and divorce, described the types of separations that take place at the time of divorce.

Psychic Divorce. In psychic divorce, the love object is given up, and a grief reaction about the death of the relationship occurs. Sometimes a period of anticipatory mourning sets in before the divorce. Separating from a spouse forces a person to become autonomous, to change from a position of dependence. The separation may be difficult to achieve, especially if both are used to being dependent on each other (as normally happens in marriage) or if one was so dependent as to be afraid or incapable of becoming independent. Most persons report such feelings as depression, ambivalence, and mood swings at the time of divorce. Studies indicate that recovery from divorce takes about 2 years; by then, the ex-spouse may be viewed neutrally, and each spouse accepts his or her new identity as a single person.

Legal Divorce. Legal divorce involves going through the courts so that each of the parties is remarriagable. Of divorced women and divorced men, 75 percent and 80 percent, respectively, remarry within 3 years of divorce. No-fault divorce, in which neither person is judged to be the guilty party, has become the most widely used legal mechanism for divorce.

Economic Divorce. Economic divorce involves major concerns to the division of the couple's property between them and economic support for the wife. Many men who are ordered by the courts to pay alimony or child support flout the law and create a major social problem.

Community Divorce. The social network of the divorced couple changes markedly. A few relatives and friends are retained from the community and new ones are added. The task of meeting new friends is often difficult for divorced persons, who may realize how dependent they were on their spouses for social exchanges.

Coparental Divorce. Coparental divorce is the separation of a parent from the child's other parent. Being a single parent differs from being a married parent.

Custody

The parental right doctrine is a legal concept that awards custody to the more fit natural parent and attempts to ensure that the best interests of the child are served. In the past, mothers were almost always awarded custody, but custody is now given to fathers in about 15 percent of cases. Custodial fathers are likely to be white, married, older, and better educated than custodial mothers. Women who are granted custody have a better chance of being awarded child support and of actually receiving payment than do men who are granted custody. Nevertheless, women who receive payments still have lower incomes than men who receive payment.

The types of custody include joint custody, in which a child spends equal time with each parent, an increasingly common practice; split custody, in which siblings are separated and each parent has custody of one or more of the children; and single custody, in which the children live solely with one parent and the other parent has rights of visitation that may be limited in some way by the court. Child support payments are more likely to be made when parents have joint custody or when the noncustodial parent is given visitation rights.

Problems can surface in the parent–child relationship with the custodial or the noncustodial parent. The absence of the noncustodial parent in the home represents the reality of the divorce, and the custodial parent may become the target of the child's anger about the divorce. The parent under such stress may not be able to deal with the child's increased needs and emotional demands.

The noncustodial parent must cope with limits placed on time spent with the child. This parent loses the day-to-day gratification and the responsibilities involved with parenting. Emotional distress is common in parent and child. Joint custody offers a solution with some advantages, but it requires substantial maturity on the part of the parents and can present some problems. Parents must separate their child-rearing practices from their postdivorce resentments, and they must develop a spirit of cooperation about rearing the child. They must also be able to tolerate frequent communication with the ex-spouse.

Reasons for Divorce

Divorce tends to run in families and rates are highest in couples who marry as teenagers or come from different socioeconomic backgrounds. Every marriage is psychologically unique and so is each divorce. If a person's parents were divorced, he or she may choose to resolve a marital problem in the same way, through divorce. Expectations of the spouse may be unrealistic:
One partner may expect the other to act as an all-giving mother or a magically protective father. The parenting experience places the greatest strain on a marriage. In surveys of couples with and without children, those without children reported getting more pleasure from their spouse than those with children. Illness in the child creates the greatest strain of all, and more than 50 percent of marriages in which a child has died through illness or accident end in divorce.

Other causes of marital distress are problems about sex and money. Both areas may be used as a means of control, and withholding sex or money is a means of expressing aggression. Also, less social pressure to remain married currently exists. As discussed above, the easing of divorce laws and the declining influence of religion and the extended family may make divorce an acceptable course of action today.

**Intercourse Outside of Marriage.** Adultery is defined as voluntary sexual intercourse between a married person and someone other than his or her spouse. For men, the first extramarital affair is often associated with the wife’s pregnancy, when coitus may be interrupted. Most of these incidents are kept secret from the spouse and, if known, rarely account for divorce. Nevertheless, the infidelity can serve as the catalyst for basic dissatisfaction in the marriage to surface, and these problems may then lead to its dissolution. Adultery may decline, as potentially fatal sexually transmitted diseases such as acquired immune deficiency syndrome (AIDS) serve as sobering deterrents.

**ADULT MATURITY**

Success and happiness in adulthood are made possible by achieving a modicum of maturity—a mental state, not an age. The capacity for maturity, however, is a direct outgrowth of the engagement and mastery of the developmental tasks of young and middle adulthood. From a developmental perspective, maturity can be defined as a mental state found in healthy adults that is characterized by detailed knowledge of the parameters of human existence, a sophisticated level of self-awareness based on an honest appraisal of one’s own experience within those basic parameters, and the ability to use this intellectual and emotional knowledge and insight carefully in relation to one’s self and others.

The achievement of maturity in midlife leads to emergence of the capacity for wisdom. Those who possess wisdom have learned from the past and are fully engaged in life in the present. Just as important, they anticipate the future and make the necessary decisions to enhance prospects for health and happiness. In other words, a philosophy of life has been developed that includes understanding and acceptance of the person’s place in the order of human existence. Unfortunately, the joys of midlife do not last forever. Old age lies ahead. Although the hope and statistical expectation is for many years of mental competence and independence, physical and mental decline, increased dependence, and, eventually, death must be anticipated. Late adulthood has its own great pleasure, when there is a focus on continued mental and physical activity, a dominant preoccupation with the present and the future, and involvement with and facilitation of the young. Then, death can be met with feelings of satisfaction and acceptance, the natural end point of human existence that follows a life lived and well loved.

**References**

For many individuals, the passage from youth to old age is mirrored by a shift from the pursuit of wealth to the maintenance of health. In late adulthood, the aging body increasingly becomes a central concern, replacing the midlife preoccupations with career and relationships. This is so because of normal diminution in function, altered physical appearance, and the increased incidence of physical illness. Despite these occurrences, the body in late adulthood can still be a source of considerable pleasure and can convey a sense of competence, particularly if attention is paid to regular exercise, healthy diet, adequate rest, and preventive maintenance medical care. The normal state in the aged is physical and mental health, not illness and debilitation. The developmental tasks of late adulthood that lead to mental health are listed in Table 33-1.

Old age, or late adulthood, usually refers to the stage of the life cycle that begins at age 65. Gerontologists—those who study the aging process—divide older adults into two groups: young-old, ages 65 to 74; and old-old, ages 75 and beyond. Some use the term oldest old to refer to those over 85. Older adults can also be described as well-old (persons who are healthy) and sick-old (persons who have an infirmity that interferes with functioning and requires medical or psychiatric attention). The health needs of older adults have grown enormously as the population ages, and geriatric physicians and psychiatrists play major roles in treating this population.

DEMOGRAPHICS

The number of individuals over age 65 is rapidly expanding. In 1900, for example, 4 percent of the US population was older than 65 years. By 2012 it was 13.7 percent, and by 2050, it is projected to be about 20 percent. That increase far exceeds the threefold between 1900 and 2000—and is projected to continue (e.g., 2.5 times vs. just over 1.5 times between 1990 and 2050) (Table 33-2).

The life expectancy for women at birth is projected to continue to exceed that for men by 7 years until 2050. By 2050, it is projected to be about 20 percent. That increase far exceeds the general population growth—tenfold compared with just over threefold between 1900 and 2000—and is projected to continue (e.g., 2.5 times vs. just over 1.5 times between 1990 and 2050) (Table 33-2).

The life expectancy for women at birth is projected to continue to exceed that for men by 7 years until 2050. By 2050, it is projected to be about 20 percent. That increase far exceeds the general population growth—tenfold compared with just over threefold between 1900 and 2000—and is projected to continue (e.g., 2.5 times vs. just over 1.5 times between 1990 and 2050) (Table 33-2).

BIOLOGY OF AGING

The aging process, or senescence (from the Latin senescere, “to grow old”), is characterized by a gradual decline in the functioning of all of the body’s systems—cardiovascular, respiratory, genitourinary, endocrine, and immune, among others. But the belief that old age is invariably associated with profound intellectual and physical infirmity is a myth. Many older persons retain their cognitive abilities and physical capacities to a remarkable degree.

An overview of the biological changes that accompany old age is given in Table 33-4. The various decrements listed do not occur in a linear fashion in all systems. Not all organ systems deteriorate at the same rate, nor do they follow a similar pattern of decline for all persons. Each person is genetically endowed with one or more vulnerable systems, or a system may become vulnerable because of environmental stressors or intentional misuse, such as excessive ultraviolet exposure, smoking, or alcohol use. Moreover, not all organ systems deteriorate at the same time. Any one of a number of organ systems begins to deteriorate, and this deterioration then leads to illness or death.

Aging generally means the aging of cells. In the most commonly held theory, each cell has a genetically determined life span during which it can replicate itself a limited number of times before it dies. Structural changes occur in cells with age. In the central nervous system, for example, age-related cell changes occur in neurons, which show signs of degeneration. In senility (characterized by severe memory loss and a loss of intellectual functioning), signs of degeneration are much more severe. An example is the neurofibrillary degeneration seen most commonly in dementia of the Alzheimer’s type.

Structural changes and mutations in deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) are also found in aging cells; these have been attributed to genotypic programming, X-rays, chemicals, and food products, among others. Probably no single cause of aging exists, and all areas of the body are affected to some degree. Genetic factors have been implicated in disorders that commonly occur in older persons, such as hypertension, coronary artery disease, atherosclerosis, and neoplastic disease. Family studies indicate inheritance factors for breast and stomach cancer, colon polyps, and certain mental disorders of old age. Huntington’s disease shows an autosomal dominant mode of inheritance with complete penetrance. The average age of onset is between 35 and 40 years, but cases have occurred as late as 70 years.
Table 33-1
Developmental Tasks of Late Adulthood

To maintain the body image and physical integrity
To conduct the life review
To maintain sexual interests and activities
To deal with the death of significant loved ones
To accept the implications of retirement
To accept the genetically programmed failure of organ systems
To divest oneself of the attachment to possessions
To accept changes in the relationship with grandchildren

Longevity

Longevity has been studied since the beginning of recorded history and has always been a topic of great interest. The research about longevity reveals that a family history of longevity is the best indicator of a long life; of persons who live past 80, half of their fathers also lived past 80. Nevertheless, many conditions leading to a shortened life can be prevented, ameliorated, or delayed with effective intervention. Heredity is but one factor—one beyond a person’s control. Predictors of longevity that are within a person’s control include regular medical checkups, minimal or no caffeine or alcohol consumption, work gratification, and a perceived sense of the self as being socially useful in an altruistic role, such as spouse, teacher, mentor, parent, or grandparent. Healthy eating and adequate exercise are also associated with health and longevity.

Life Expectancy

In the United States, the average life expectancy of both sexes has increased in every decade—from 48 years in 1900 to 77.4 years for men and 82.2 years for women in 2013. The projected life expectancy at birth and at age 65 is indicated in Table 33-5. Changes in morbidity and mortality have also occurred. Over the past 30 years, for example, a 60 percent decline has occurred in mortality from cerebrovascular disease and a 30

Table 33-3
Demographic Highlights of the Aged

- The older population (65+) numbered 4.04 million in 2010, an increase of 5.4 million for 15.3 since 2000.
- The number of Americans aged 45 to 64—who will reach 65 over the next two decades—increased by 31% during this decade.
- Over one in every eight, or 13.1%, of the population is an older American.
- Persons reaching age 65 have an average life expectancy of an additional 18.8 years (20 years for females and 17.3 for males).
- Older women outnumber older men at 23 million older women to 17.5 million older men.
- In 2010, 20% of persons 65+ were minorities—8.4% were African-American.* Persons of Hispanic origin (who may be of any race) represented 6.9% of the older population. About 3.5% were Asian or Pacific Islanders,* and less than 1% were American Indian or Native Alaskan.* In addition, 0.8% of persons 65+ identified themselves as being of two or more races.
- Older men were much more likely to be married than older women—72% of men vs. 42% of women. In 2010, 40% older women were widows.
- About 29% (11.3 million) of noninstitutionalized older persons live alone (8.1 million women, 3.2 million men).
- Almost half of older women (47%) age 75+ live alone.
- About 485,000 grandparents aged 65 or more had the primary responsibility for their grandchildren who lived with them.
- The population 65 and over has increased from 35 million in 2000 to 40 million in 2010 (a 15% increase) and is projected to increase up to 55 million in 2020 (a 36% increase for that decade).
- The 85+ population is projected to increase from 5.5 million in 2010 and then 6.6 million in 2020 (19%) for that decade.
- Minority populations have increased from 5.7 million in 2000 (16.3% of the elderly population) to 8.1 million in 2010 (20% of the elderly) and are projected to increase to 13.1 million in 2020 (24% of the elderly).
- The median income of older persons in 2010 was $25,704 for males and $15,072 for females. Median income (after adjusting for inflation) of all households headed by older people fell 1.5% (not statistically significant) from 2009 to 2010. Households containing families headed by person 65+ reported a median income in 2010 of $45,763.
- The major sources of income as reported by older persons in 2009 were Social Security (reported by 87% of older persons), income from assets (reported by 53%), private pensions (reported by 28%), government employee pensions (reported by 14%), and earnings (reported by 26%).
- Social Security constituted 90% or more of the income received by 35% of beneficiaries in 2009 (22% married couples and 43% of nonmarried beneficiaries).
- Almost 3.5 million elderly persons (9.0%) were below the poverty level in 2010. This poverty rate is not statistically different from the poverty rate in 2009 (8.9%). During 2011, the U.S. Census Bureau also released a new Supplemental Poverty Measure (SPM) that takes into account regional variations in the living costs, noncash benefits received, and nondiscretionary expenditures but does not replace the official poverty measure. The SPM shows a poverty level for older persons of 15.9%, an increase of over 75% over the official rate of 9% mainly due to medical out-of-pocket expenses.
- About 11% (3.7 million) of older Medicare enrollees received personal care from a paid or unpaid source in 1999.

*Principle source data for the profile are from the U.S. Census Bureau, the National Center for Health Statistics, and the Bureau of Labor Statistics. The profile incorporates the latest data (2010) available but not all items are updated on an annual basis.

</table>
percent decline in mortality from coronary artery disease. In contrast, mortality from cancer, which rises steeply with age, has increased, especially cancer of the lung, colon, stomach, skin, and prostate.

The oldest old, persons over 85 years of age, is the most rapidly growing segment of the older population. Over the past 25 years, the population of all older persons increased by 100 percent, compared with 45 percent for the entire US population, but the increase for the 85 and older group exceeded 275 percent. It is expected that by 2050, the oldest old will make up about 25 percent of the elderly population and 5 percent of the total population in the United States. Figure 33-1 gives projected percentages for the average annual growth rate of the elderly population to 2050.

The leading causes of death among older persons are heart disease, cancer, and stroke. Accidents are among the leading causes of death of persons over 65. Most fatal accidents are caused by falls, pedestrian incidents, and burns. Falls are most commonly the result of cardiac arrhythmias and hypotensive episodes.

Some gerontologists consider death in very old persons (over 85) to result from an aging syndrome characterized by diminished elastic-mechanical properties of the heart, arteries, lungs, and other organs. Death results from trivial tissue injuries that would not be fatal to a younger person; accordingly, senescence is viewed as the cause of death.

### Ethnicity and Race

The proportion of older persons in the black, Hispanic, and Asian populations is smaller than that in the white population, but it is increasing rapidly. By 2050, 20 percent of older persons will be nonwhite. The proportion of older persons who are Hispanic will increase from 4 percent to approximately 14 percent over the same period. According to the U.S. Census Bureau, Hispanic refers to persons “whose origins are Mexican, Puerto Rican, Cuban, Central or South American, and other Hispanic or Latino, regardless of race” (Fig. 33-2).

### Sex Ratios

On average, women live longer than men and are more likely than men to live alone. The number of men per 100 women decreases sharply from age 65 to 85 (Fig. 33-3).

### Geographic Distribution

The most populous states have the largest number of older persons. California has the most (3.3 million), followed by New York, Pennsylvania, Texas, Michigan, Illinois, Florida, and Ohio, each with more than 1 million. States with high proportions of older persons include Pennsylvania, Florida, Nebraska, and North Dakota. The high proportion in Florida is owing to those who move into the state for retirement; in the others because of young persons moving out.

### Exercise, Diet, and Health

Diet and exercise play a role in preventing or ameliorating chronic diseases of older persons, such as arteriosclerosis and hypertension. Hyperlipidemia, which correlates with coronary artery disease, can be controlled by reducing body weight, decreasing the intake of saturated fat, and limiting the intake of cholesterol. Increasing the daily intake of dietary fiber can also help decrease serum lipoprotein levels. A daily intake of 1 ounce

(about 30 mL) of alcohol has been correlated with longevity and elevated high-density lipoproteins (HDL). Studies have also clearly demonstrated that statin drugs that reduce cholesterol have a dramatic effect on reducing cardiovascular disease in persons with diet-resistant or exercise-resistant hyperlipidemia.

Low salt intake (less than 3 g a day) is associated with a lowered risk of hypertension. Hypertensive geriatric patients can often correct their condition by moderate exercise and decreased salt intake without the addition of drugs.

A regimen of daily moderate exercise (walking for 30 minutes a day) has been associated with a reduction in cardiovascular disease, decreased incidence of osteoporosis, improved respiratory function, the maintenance of ideal weight, and a general sense of well-being. Exercise has been shown to improve strength and function even among the very old. In many cases, a disease process has been reversed and even cured by diet and exercise, without additional medical or surgical intervention.

Table 33-6 lists the biological changes associated with diet and exercise. A comparison with Table 33-2 reveals that almost every biological change associated with aging is positively affected by diet and exercise.

**STAGE THEORIES OF PERSONALITY DEVELOPMENT**

Early personality theorists proposed that development was completed by the end of childhood or adolescence. One of the first

development theorists to propose that personality continues to develop and grow over the life span was Erik Erikson. Erikson believed that development proceeded through a series of psychosocial stages, each with its own conflict that is resolved by the individual with greater or lesser success. Erikson termed the crises of the last epoch of life integrity versus despair and believed that successful resolution of this crisis involved a process of life review and achieving a sense of peace and wisdom through coming to terms with how one's life was lived. For example, Erikson proposed that successful resolution of this crisis would be characterized by a sense of having lived one's life well, whereas a less successful resolution would be characterized by feeling that life was too short, that one did not choose wisely, and bitterness that one will not have a chance to live life over.

Several studies have attempted to validate aspects of Erikson's theory. In one study, a sample of more than 400 men was studied prospectively, and the highest Eriksonian life stage each achieved was rated according to data gathered on the circumstances of his life. For example, if a man had achieved independence from his family of origin and was self-sufficient but was unable to develop an intimate relationship, the highest life stage achieved would be the identity stage, not the intimacy stage. This study found that Eriksonian stages are passed through in sequential order, although often not at the same age for every individual, and that the stages are surprisingly universal in populations that are ethnically and socioeconomically diverse.

A longitudinal study of approximately 500 subjects from two age cohorts found that the earlier age cohort scored significantly higher on integrity than the later age cohort, and scores for both age cohorts on integrity had declined significantly by the final time of testing. These data suggest that the conflict of integrity versus despair may have a more favorable outcome in earlier age cohorts than in later ones, raising the possibility that changing societal values have had a negative impact on the struggle for integrity. Another study found that wisdom, a construct related to integrity, bore a stronger relation to life satisfaction in elderly adults than other variables, including finances, health, and living situation.

A survey of theories of development in old age is given in Table 33-7.

</tr>
</tbody>
</table>

Is the fact that personality appears to have considerable stability over time inconsistent with the basic tenets of stage theories? Perhaps not. It may be that although individuals are consistent over time in their basic personality structure, the themes and conflicts with which they struggle change considerably over the life span, from concerns about developing identity and a stable sense of self, to finding a life partner, to issues related to life review, as hypothesized by the stage theories. In addition, in developing theories about personality change, few studies have examined the impact of significant historical events on personality; thus, the ways in which these events may result in personality change have not been studied systematically.

### PSYCHOSOCIAL ASPECTS OF AGING

#### Social Activity

Healthy older persons usually maintain a level of social activity that is only slightly changed from that of earlier years. For many, old age is a period of continued intellectual, emotional, and psychological growth. In some cases, however, physical illness or the death of friends and relatives may preclude continued social interaction. Moreover, as persons experience an increased sense of isolation, they may become vulnerable to depression. Growing evidence indicates that maintaining social activities is valuable for physical and emotional well-being. Contact with younger persons is also important. Old persons can pass on cultural values and provide care services to the younger generation and thereby maintain a sense of usefulness that contributes to self-esteem.
Ageism

Ageism, a term coined by Robert Butler, refers to discrimination toward old persons and to the negative stereotypes about old age that are held by younger adults. Old persons may themselves resent and fear other old persons and discriminate against them. In Butler’s scheme, persons often associate old age with loneliness, poor health, senility, and general weakness or infirmity. The experience of older persons, however, does not consistently support this attitude. For example, although 50 percent of young adults expect poor health to be a problem for those over 65 years old, 75 percent of persons 65 to 74 years of age describe their health as good. Two thirds of persons 75 and older feel the same way. Health problems, when they do exist, more often involve chronic than acute conditions. More than four of five persons over the age of 65 have at least one chronic condition (Table 33-8).

Good health, however, is not the sole determinant of a good quality of life in old age. Surveys of old persons show that social contacts are at least as highly valued. In fact, the factors affecting good aging appear to be multidimensional. Aging “robustly” means considering aging in terms of productive involvement, affective status, functional status, and cognitive status. These four indicators are only minimally correlated. The most robustly aging individuals report greater social contact, better health and vision, and fewer significant life events in the past 3 years than their less robustly aging counterparts. A linear, age-related decrease occurs in robustness, but it can still be found among the oldest old.

George Vaillant followed up a group of Harvard freshmen into old age and found the following about emotional health at age 65: Having been close to brothers and sisters during college correlated with emotional well-being; undergoing early traumatic life experiences, such as the death of a parent or parental divorce, did not correlate with poor adaptation in old age; being depressed at some point between ages 21 and 50 predicted emotional problems at age 65; and possessing the personality traits of pragmatism and dependability as a young adult was associated with a sense of well-being at age 65.

Transference

Several forms of transference, some of them unique to adulthood, are present in older adults. First is the well-recognized parental transference, in which the patient reacts to the therapist as a child to a parent. Peer or sibling transference, expressions of experiences from a variety of nonparental relationships, is also common. In this form of transference, the patient looks to the therapist to share experiences with siblings, spouses, friends, and associates. At first, therapists may be surprised by older patients’ ability to ignore their age in creating such transferences.

In son or daughter transference, quite common in middle-aged individuals and the elderly, the therapist is cast in the role of the patient’s child, grandchild, or son-in-law or daughter-in-law. The themes expressed in this form of transference are multiple and often center on defenses against dependency feelings, activity and dominance versus passivity and submission, and attempts to rework unsatisfying aspects of relationships with children before time runs out. Finally, sexual transferences in older individuals are frequent and intense, and the therapist needs to be able to accept them and manage his or her countertransference responses.

Countertransference

Older individuals are dealing with illness and signs of aging, the loss of spouses and friends, and the constant awareness of time limitation and the nearness of death. These are painful issues that are just beginning to come into focus for younger therapists who would prefer not to confront them with great intensity on a daily basis.

A second source of countertransference responses centers on the older patient’s sexuality. The presence of a vivid fantasy life, masturbation, and intercourse are disconcerting in and of themselves if the therapist has not had much experience in working with individuals who are the same age as their parents and grandparents. Consider the experience presented in the case study of a 31-year-old female therapist who was treating a 62-year-old man.

Early in the treatment process, Mr. E’s sexual feelings emerged. His well-groomed appearance and adolescent-like nervousness caused the therapist discomfort. Her concern was how to engender respect and develop a therapeutic alliance with a patient who

approached each session as a date, particularly because he was old enough to be her grandfather. At first shocked by his open expression of sexual interest in her, with the help of supervision and her own therapy, she was able to recognize that she and the patient had similar conflicts to resolve, despite the 30-year age difference between them. She had hoped that Mr. E would be “all grown up,” devoid of issues that she was grappling with also. She came to recognize that failure to help him understand the relation between his past and still vibrant sexuality would do the patient a great disservice and would spring from her a lack of understanding of late-life sexual development and her countertransference reaction to him based on her conflicted attitudes toward the sexuality of her parents and grandparents. (Courtesy of Calvin A. Colarusso, M.D.)

Socioeconomics

The economics of old age is of paramount importance to older persons themselves and to society at large. The past 30 years have seen a dramatic decline in the proportion of the US elderly population who are poor, primarily as a result of the availability of Medicare, Social Security, and private pensions. In 1959, 35.2 percent of persons over 65 lived below the poverty line, but by 2012 this figure had declined to 9.1 percent. Persons over age 65 make up 12 percent of the population, but they include only 9 percent of those living at low socioeconomic levels. Women are more likely than men to be poor. Income sources vary for persons age 65 and older. Despite overall economic gains, many older persons are so preoccupied by money worries that their enjoyment of life is lessened. Obtaining proper medical care may be especially difficult when personal funds are not available or are insufficient.

Medicare (Title 18) provides both hospital and medical insurance for those over age 65. About 150 million medical bills are reimbursed under the Medicare program each year; but only about 40 percent of all medical expenses incurred by older persons are covered under Medicare. The rest is paid by private insurance, state insurance, or personal funds. Some services—such as outpatient psychiatric treatment, skilled nursing care, physical rehabilitation, and preventive physical examinations—are covered minimally or not at all.

In addition to Medicare, the Social Security program pays benefits to persons over age 65 (over age 67 in 2027) and pays benefits at reduced rates from age 62 on. To qualify for benefits, a person must have worked long enough to become insured: A worker must have worked for 10 years to be eligible for benefits. Benefits are also paid to widows, widowers, and dependent children if those receiving benefits or contributing to Social Security die (survivor benefits). Social Security is not a pension scheme but a pay-as-you-go income supplement to prevent mass destitution among older persons. Benefits are paid by those currently working to those who are retired. Serious difficulties for Social Security are forecast for the next three decades, when the number of baby boomers reaching old age will greatly exceed the number of younger workers paying into the plan.

Retirement

For many older persons, retirement is a time for the pursuit of leisure and for freedom from the responsibility of previous working commitments. For others, it is a time of stress, especially when retirement results in economic problems or a loss of self-esteem. Ideally, employment after age 65 should be a matter of choice. With the passage of the Age Discrimination in Employment Act of 1967 and its amendments, forced retirement at age 70 has been virtually eliminated in the private sector, and it is not legal in federal employment.

Most of those who retire voluntarily reenter the workforce within 2 years, for a variety of reasons, including negative reactions to being retired, feelings of being unproductive, economic hardship, and loneliness. The amount of time spent in retirement has increased as the life span has nearly doubled since 1900. Currently, the number of years spent in retirement is almost equal to the number of years spent working.

Sexual Activity

The frequency of orgasm, from coitus or masturbation, decreases with age in men and women. The most important factors in determining the level of sexual activity with age are the health and survival of the spouse, one’s own health, and the level of past sexual activity. Although some degree of declining sexual interest and function is inevitable with age, social and cultural factors appear to be more responsible for the sexual changes observed than for the psychological changes of aging per se. Although satisfying sexual activity is possible for the reasonably healthy elderly, many do not actualize this potential. The widely held notion that the elderly are essentially asexual is often a self-fulfilling prophecy.

Long-Term Care

Many older persons who are infirm require institutional care. Although only 5 percent are institutionalized in nursing homes at any one time, about 35 percent of older persons require care in a long-term facility at some time during their lives (Fig. 33-4). Older nursing home residents are mainly widowed women, and about 50 percent are over age 85.

Nursing home care costs are not covered by Medicare; they range from $20,000 to $1 million a year. About 20,000 long-term nursing care institutions are available in the United States, this is not enough to meet the need. Those older persons who do not require skilled nursing care can be managed in other types of health-related facilities, such as centers they attend during the daytime hours, but the need for care far exceeds the availability of such centers.

Outside institutions, care for older persons is provided by their children (primarily their daughters and daughters-in-law), their wives, and other women (Fig. 33-5). More than 50 percent of these women caregivers also work in jobs outside the home, and about 40 percent also care for their own children. In general, women end up as caregivers more often than men because of cultural and societal expectations. According to the American Association of Retired Persons, daughters with jobs spend an average of 12 hours a week providing care and currently spend about $150 a month for travel, telephone calls, special foods, and medication for older persons.

PSYCHIATRIC PROBLEMS OF OLDER PERSONS

Despite the ubiquity of loss in old age, the prevalence of major depressive disorder and dysthymia is actually less than in younger age groups. Several explanations for this phenomenon have been
proposed: rarity of late-onset depression, higher mortality among persons with depression, and a general decrease in disorders caused by emotional upheavals or substance abuse in older persons. Depression in old persons is often accompanied by physical symptoms or cognitive changes that may mimic dementia.

The incidence of suicide among older persons is high (40 per 100,000 population) and is highest for older white men. The suicide of older persons is perceived differently by surviving friends and family members on the basis of gender: Men are thought to have been physically ill, and women are thought to have been mentally ill.

The relation between good mental and good physical health is clear in older persons. Adverse effects on the course of chronic medical illness are correlated with emotional problems. The following section will discuss the psychiatric problems in older persons.

**Psychiatric Examination of the Older Patient**

Psychiatric history taking and the mental status examination of older adults follow the same format as for younger adults; however, because of the high prevalence of cognitive disorders in older persons, psychiatrists must determine whether a patient understands the nature and purpose of the examination. When a patient is cognitively impaired, an independent history should be obtained from a family member or caretaker. The patient still should be seen alone—even in cases of clear evidence of impairment—to preserve the privacy of the doctor–patient relationship and to elicit any suicidal thoughts or paranoid ideation, which may not be voiced in the presence of a relative or nurse.

When approaching the examination of the older patient, it is important to remember that older adults differ markedly from one another. The approach to examining the older patient must take into account whether the person is a healthy 75-year-old who recently retired from a second career or a frail 96-year-old who just lost the only surviving relative with the death of the 75-year-old care-giving daughter.

**Psychiatric History**

A complete psychiatric history includes preliminary identification (name, age, sex, marital status), chief complaint, history of the present illness, history of previous illnesses, personal history, and family history. A review of medications (including over-the-counter medications) that the patient is currently using or has used in the recent past is also important.

Patients older than age 65 often have subjective complaints of minor memory impairments, such as forgetting persons’ names and misplacing objects. Minor cognitive problems also can occur because of anxiety in the interview situation. These age-associated memory impairments are of no significance; the term *benign senescent forgetfulness* has been used to describe them.

A patient’s childhood and adolescent history can provide information about personality organization and give important clues about coping strategies and defense mechanisms used under stress. A history of learning disability or minimal cerebral dysfunction is significant. The psychiatrist should inquire about friends, sports, hobbies, social activity, and work. The occupational history should include the patient’s feelings about work, relationships with peers, problems with authority, and attitudes toward retirement. The patient also should be questioned about plans for the future. What are the patient’s hopes and fears?
The family history should include a patient's description of parents' attitudes and adaptation to their old age and, if applicable, information about the causes of their deaths. Alzheimer's disease is transmitted as an autosomal-dominant trait in 10 to 30 percent of the offspring of parents with Alzheimer's disease; depression and alcohol dependence also run in families. The patient's current social situation should be evaluated. Who cares for the patient? Does the patient have children? What are the characteristics of the patient's parent–child relationships? A financial history helps the psychiatrist evaluate the role of economic hardship in the patient's illness and to make realistic treatment recommendations.

The marital history includes a description of the spouse and the characteristics of the relationship. If the patient is a widow or a widower, the psychiatrist should explore how grieving was handled. If the loss of the spouse occurred within the past year, the patient is at high risk for an adverse physical or psychological event.

The patient's sexual history includes sexual activity, orientation, libido, masturbation, extramarital affairs, and sexual symptoms (e.g., impotence and anorgasmia). Young clinicians may have to overcome their own biases about taking a sexual history: Sexuality is an area of concern for many geriatric patients, who welcome the chance to talk about their sexual feelings and attitudes.

**Mental Status Examination**

The mental status examination offers a cross-sectional view of how a patient thinks, feels, and behaves during the examination. With older adults, a psychiatrist may not be able to rely on a single examination to answer all of the diagnostic questions. Repeat mental status examinations may be needed because of fluctuating changes in the patient's family.

**General Description.** A general description of the patient includes appearance, psychomotor activity, attitude toward the examiner, and speech activity.

Motor disturbances (e.g., shuffling gait, stooped posture, "pill rolling" movements of the fingers, tremors, and body asymmetry) should be noted. Involuntary movements of the mouth or tongue may be adverse effects of phenothiazine medication. Many depressed patients seem to be slow in speech and movement. A mask-like facies occurs in Parkinson's disease.

The patient's speech may be pressured in agitated, manic, and anxious states. Tearfulness and overt crying occur in depressive and cognitive disorders, especially if the patient feels frustrated about being unable to answer one of the examiner's questions. The presence of a hearing aid or another indication that the patient has a hearing problem (e.g., requesting repetition of questions) should be noted.

The patient's attitude toward the examiner—cooperative, suspicious, guarded, ingratiating—can give clues about possible transference reactions. Because of transference, older adults can react to younger physicians as if the physicians were parent figures, despite the age difference.

**Functional Assessment.** Patients older than 65 years of age should be evaluated for their capacity to maintain independence and to perform the activities of daily life, which include toileting, preparing meals, dressing, grooming, and eating. The degree of functional competence in their everyday behaviors is an important consideration in formulating a treatment plan for these patients.

**Mood, Feelings, and Affect.** Suicide is a leading cause of death of older persons, and an evaluation of a patient's suicidal ideation is essential. Loneliness is the most common reason cited by older adults who consider suicide. Feelings of loneliness, worthlessness, helplessness, and hopelessness are symptoms of depression, which carries a high risk for suicide. Nearly 75 percent of all suicide victims suffer from depression, alcohol abuse, or both. The examiner should specifically ask the patient about any thoughts of suicide: Does the patient feel life is no longer worth living? Does the patient think he or she would be better off dead or, when dead, would no longer be a burden to others? Such thoughts—especially when associated with alcohol abuse, living alone, recent death of a spouse, physical illness, and somatic pain—indicate a high suicidal risk.

Disorders in mood states, most notably depression and anxiety, can interfere with memory functioning. An expansive or euphoric mood may indicate a manic episode or may signal a dementing disorder. Frontal lobe dysfunction often produces witzelsucht, which is the tendency to make puns and jokes and then laugh aloud at them.

The patient's affect may be flat, blunted, constricted, shallow, or inappropriate, all of which can indicate a depressive disorder, schizophrenia, or brain dysfunction. Such affects are important abnormal findings, although they are not pathognomonic of a specific disorder. Dominant lobe dysfunction causes dysprosody: an inability to express emotional feelings through speech intonation.

**Perceptual Disturbances.** Hallucinations and illusions by older adults can be transitory phenomena resulting from decreased sensory acuity. The examiner should note whether the patient is confused about time or place during the hallucinatory episode; confusion points to an organic condition. It is particularly important to ask the patient about distorted body perceptions. Because hallucinations can be caused by brain tumors and other focal pathology, a diagnostic workup may be indicated. Brain diseases cause perceptive impairments; agnosia, the inability to recognize and interpret the significance of sensory impressions, is associated with organic brain diseases. The examiner should note the type of agnosia—the denial of illness (anosognosia), the denial of a body part (atopognosia), or the inability to recognize objects (visual agnosia) or faces (prosopagnosia).

**Language Output.** The language output category of the geriatric mental status examination covers the aphasias, which are disorders of language output related to organic lesions of the brain. The best described are nonfluent or Broca's aphasia, fluent or Wernicke's aphasia, and global aphasia, a combination of fluent and nonfluent aphasias. In nonfluent or Broca's aphasia, the patient's understanding remains intact, but the ability to speak is impaired. The patient cannot pronounce "Methodist Episcopalian." Words are generally mispronounced and speech may be telegraphic. A simple test for Wernicke's aphasia is to point to some common objects—such as a pen or a pencil, a doorknob, and a light switch—and ask the patient to name them. The patient also may be unable to demonstrate the use of simple objects, such as a key and a match (ideomotor apraxia).

**Visuospatial Functioning.** Some decline in visuospatial capability is normal with aging. Asking a patient to copy figures or a drawing may be helpful in assessing the function. A neuropsychological assessment should be performed when visuospatial functioning is obviously impaired.

**Thought.** Disturbances in thinking include neologisms, word salad, circumstantiality, tangentiality, loosening of associations, flight of ideas, clang associations, and blocking. The loss of the ability to appreciate nuances of meaning (abstract thinking) may be an early sign of dementia. Thinking is then described as concrete or literal.

Thought content should be examined for phobias, obsessions, somatic preocupations, and compulsions. Ideas about suicide or homicide should be discussed. The examiner should determine whether delusions are present and how such delusions affect the patient's life. Delusions may be present in nursing home patients and may have been a reason for admission. Ideas of reference or of influence should be described. Patients who are hard of hearing can be classified mistakenly as paranoid or suspicious.
Sensorium and Cognition. Sensorium concerns the functioning of the special senses; cognition concerns information processing and intellect. The survey of both areas, known as the neuropsychiatric examination, consists of the clinician's assessment and a comprehensive battery of psychological tests.

CONSCIOUSNESS. A sensitive indicator of brain dysfunction is an altered state of consciousness in which the patient does not seem to be alert, shows fluctuations in levels of awareness, or seems to be lethargic. In severe cases, the patient is somnolent or stuporous.

ORIENTATION. Impairment in orientation to time, place, and person is associated with cognitive disorders. Cognitive impairment often is observed in mood disorders, anxiety disorders, factitious disorders, conversion disorder, and personality disorders, especially during periods of severe physical or environmental stress. The examiner should test for orientation to place by asking the patient to describe his or her present location. Orientation to person may be approached in two ways: Does the patient know his or her own name, and are nurses and doctors identified as such? Time is tested by asking the patient the date, the year, the month, and the day of the week. The patient also should be asked about the length of time spent in a hospital, during what season of the year, and how the patient knows these facts. Greater significance is given to difficulties concerning person than to difficulties of time and place, and more significance is given to orientation to place than to orientation to time.

MEMORY. Memory usually is evaluated in terms of immediate, recent, and remote memory. Immediate retention and recall are tested by giving the patient six digits to repeat forward and backward. The examiner should record the result of the patient's capacity to remember. Persons with unimpaired memory usually can recall six digits forward and five or six digits backward. The clinician should be aware that the ability to do well on digit-span tests is impaired in extremely anxious patients. Remote memory can be tested by asking for the patient's place and date of birth, the patient's mother's name before she was married, and names and birthdays of the patient's children.

In cognitive disorders, recent memory deteriorates first. Recent memory assessment can be approached in several ways. Some examiners give the patient the names of three items early in the interview and ask for recall later. Others prefer to tell a brief story and ask the patient to repeat it verbatim. Memory of the recent past also can be tested by asking for the patient's place of residence, including the street number, the method of transportation to the hospital, and some current events. If the patient has a memory deficit, such as amnesia, careful testing should be performed to determine whether it is retrograde amnesia (loss of memory before an event) or anterograde amnesia (loss of memory after the event). Retention and recall also can be tested by having the patient retell a simple story. Patients who confabulate make up new material in retelling the story.

INTELLECTUAL TASKS, INFORMATION, AND INTELLIGENCE. Various intellectual tasks can be presented to estimate the patient's fund of general knowledge and intellectual functioning. Counting and calculation can be tested by asking the patient to subtract 7 from 100 and to continue subtracting 7 from the result until the number 2 is reached. The examiner records the responses as a baseline for future testing. The examiner can also ask the patient to count backward from 20 to 1 and can record the time necessary to complete the exercise.

The patient's fund of general knowledge is related to intelligence. The patient can be asked to name the president of the United States, to name the three largest cities in the United States, to give the population of the United States, and to give the distance from New York to Paris. The examiner must take into account the patient's educational level, socioeconomic status, and general life experience in assessing the results of some of these tests.

RECALL AND RETENTION. Retention and recall also can be tested by having the patient read a simple story aloud or write a short sentence to test for a reading or writing disorder. Whether the patient is right handed or left handed should be noted.

JUDGMENT. Judgment is the capacity to act appropriately in various situations. Does the patient show impaired judgment? What would the patient do on finding a stamped, sealed, addressed envelope in the street? What would the patient do if he or she smelled smoke in a theater? Can the patient discriminate? What is the difference between a dwarf and a boy? Why are couples required to get a marriage license?

Neuropsychological Evaluation

A thorough neuropsychological examination includes a comprehensive battery of tests that can be replicated by various examiners and can be repeated over time to assess the course of a specific illness. The most widely used test of current cognitive functioning is the Mini-Mental State Examination (MMSE), which assesses orientation, attention, calculation, immediate and short-term recall, language, and the ability to follow simple commands. The MMSE is used to detect impairments, follow the course of an illness, and monitor the patient's treatment responses. It is not used to make a formal diagnosis. The maximal MMSE score is 30. Age and educational level influence cognitive performance as measured by the MMSE.

The assessment of intellectual abilities is performed with the Wechsler Adult Intelligence Scale-Revised (WAIS-R), which gives verbal, performance, and full-scale intelligence quotient (IQ) scores. Some test results, such as those of vocabulary tests, hold up as aging progresses; results of other tests, such as tests of similarities and digit-symbol substitution, do not. The performance part of the WAIS-R is a more sensitive indicator of brain damage than the verbal part.

Visuospatial functions are sensitive to the normal aging process. The Bender Gestalt Test is one of a large number of instruments used to test visuospatial functions; another is the Halstead-Reitan Battery, which is the most complex battery of tests covering the entire spectrum of information processing and cognition. Depression, even in the absence of dementia, often impairs psychomotor performance, especially visuospatial functioning and timed motor performance. The Geriatric Depression Scale is a useful screening instrument that excludes somatic complaints from its list of items. The presence of somatic complaints on a rating scale tends to confound the diagnosis of a depressive disorder.

Medical History. Elderly patients have more concomitant, chronic, and multiple medical problems and take more medications than younger adults; many of these medications can influence their mental status. The medical history includes all major illnesses, trauma, hospitalizations, and treatment interventions. The psychiatrist should also be alert to underlying medical illness. Infections, metabolic and electrolyte disturbances, and myocardial infarction and stroke may first be manifested by psychiatric symptoms. Depressed mood, delusions, and hallucinations may precede other symptoms of Parkinson's disease by many months. On the other hand, a psychiatric disorder can also cause such somatic symptoms as weight loss, malnutrition, and inanition of severe depression.
Careful review of medications (including over-the-counter medications, laxatives, vitamins, tonics, and lotions) and even substances recently discontinued is extremely important. Drug effects can be long lasting and may induce depression (e.g., antidepressives), cognitive impairment (e.g., sedatives), delirium (e.g., anticholinergics), and seizures (e.g., neuroleptics). The review of medications must include sufficient detail to identify misuse (overdose, underuse) and relate medication use to special diets. A dietary history is also important; deficiencies and excesses (e.g., protein, vitamins) can influence physiological function and mental status.

EARLY DETECTION AND PREVENTION STRATEGIES

Many age-related illnesses develop insidiously and gradually progress over the years. The most common cause of late-life cognitive impairment, Alzheimer's disease, is characterized neuropathologically by a gradual accumulation of neuritic plaques and neurofibrillary tangles in the brain. Clinically, a progression of cognitive decline is seen, which begins with mild memory loss and ends with severe cognitive and behavioral deterioration. Because it will likely be easier to prevent neural damage than to repair it once it occurs, investigators are developing strategies for early detection and prevention of age-related illnesses, such as Alzheimer's disease. Considerable progress has been made in the detection component of this strategy, using brain imaging technologies, such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), in combination with genetic risk measures. With these approaches, subtle brain changes can now be detected that progress and can be followed over time. Such surrogate markers allow clinical scientists to track disease progression and to test novel treatments designed to decelerate brain aging. Clinical trials of cholinesterase inhibitor drugs, anticholesterol drugs, anti-inflammatory drugs, and others (e.g., vitamin E) are in progress to determine if such treatments delay the onset of Alzheimer's disease or the progression of brain metabolic or cognitive decline.

Novel approaches to measuring the physical evidence of Alzheimer's disease, the plaques and tangles in the cerebral cortex, have been successful in initial studies and will likely facilitate the testing of innovative treatments designed to rid the brain of these pathognomonic lesions. Scientists may not be able to cure Alzheimer's disease in its advanced stages, but they may be able to delay its onset effectively, thus helping patients live longer without the debilitating manifestations of the disease, including cognitive decline.

MENTAL DISORDERS OF OLD AGE

The National Institute of Mental Health's Epidemiologic Catchment Area (ECA) program has found that the most common mental disorders of old age are depressive disorders, cognitive disorders, phobias, and alcohol use disorders. Older adults also have a high risk for suicide and drug-induced psychiatric symptoms. Many mental disorders of old age can be prevented, ameliorated, or even reversed. Of special importance are the reversible causes of delirium and dementia; if not diagnosed accurately and treated in a timely fashion, however, these conditions can progress to an irreversible state requiring a patient's institutionalization. Table 33-9 lists the general cognitive domains assessed in a neuropsychological evaluation, with the tests used to measure that skill and a description of the specific behaviors measured by each test. The tests listed in the table constitute a comprehensive test battery generally appropriate for use with a geriatric population. Use of a comprehensive battery is preferable for confident determination of the presence and type of dementia or other cognitive disorder in elderly persons; in some circumstances, however, administering a several-hour battery is not possible.

![Table 33-9: Cognitive Domains](image)

**Gross cognitive functioning**

- Mini-Mental State Examination: orientation, repetition, following commands, naming, constructional skill, written expression, memory, mental flexibility, and calculations

**Intelligence**

- Wechsler Adult Intelligence Scale-Revised (WAIS-R) or Wechsler Intelligence Scale-III (WAIS-III): verbal and nonverbal intelligence

**Basic attention**

- WAIS-R or WAIS-III Digit Span: repetition of digits forward and backward

**Information-processing speed**

- WAIS-R or WAIS-III Digit Symbol: rapid graphomotor tracking
- Trailmaking Part A: rapid graphomotor tracking
- Stroop A and B: rapid word reading and color naming

**Motor dexterity**

- Finger tapping: right and left index finger dexterity

**Language**

- Boston Naming Test: word retrieval
- WAIS-R or WAIS-III Vocabulary: vocabulary range

**Visual perceptual/spatial**

- WAIS-R or WAIS-III Picture Completion: visual perception
- WAIS-R or WAIS-III Block Design: constructional ability
- Rey-Osterrieth Complex Figure: paper-and-pencil copy of complex design
- Beery Developmental Test of Visual Motor Integration: paper-and-pencil copy of simple-to-complex designs

**Learning and memory**

- An 8- to 10-item word list learning task: learning and recall of rote verbal information
- Wechsler Memory Scale-Revised (WMS-R) or Wechsler Memory Scale-III (WMS-III)
- Logical Memory subtest: immediate and delayed recall of paragraph information
- Visual Reproduction subtest: immediate and delayed recall of visual designs
- Rey-Osterrieth Complex Figure 3-minute delayed recall: delayed recall of complex design

**Executive functions**

- Trailmaking Part B: rapid alternation between tasks
- Stroop C: inhibition of an overlearned response
- Wisconsin Card Sorting Test: categorization and mental flexibility
- Verbal fluency (FAS and category): rapid word generation
- Design fluency: rapid generation of novel designs

(Courtesy of Kyle Brauer Boone, Ph.D.)
Several psychosocial risk factors also predispose older persons to mental disorders. These risk factors include loss of social roles, loss of autonomy, the deaths of friends and relatives, declining health, increased isolation, financial constraints, and decreased cognitive functioning.

Many drugs can cause psychiatric symptoms in older adults. These symptoms can result from age-related alterations in drug absorption, a prescribed dosage that is too large, not following instructions and taking too large a dose, sensitivity to the medication, and conflicting regimens presented by several physicians. Almost the entire spectrum of mental disorders can be caused by drugs.

**Dementing Disorders**

Only arthritis is a more common cause of disability among adults age 65 and older than dementia, a generally progressive and irreversible impairment of the intellect, the prevalence of which increases with age. About 5 percent of persons in the United States older than age 65 have severe dementia, and 15 percent have mild dementia. Of persons older than age 80, about 20 percent have severe dementia. Known risk factors for dementia are age, family history, and female sex.

In contrast to intellectual disability, the intellectual impairment of dementia develops over time—that is, previously achieved mental functions are lost gradually. The characteristic changes of dementia involve cognition, memory, language, and visuospatial functions, but behavioral disturbances are common as well and include agitation, restlessness, wandering, rage, violence, shouting, social and sexual disinhibition, impulsiveness, sleep disturbances, and delusions. Delusions and hallucinations occur during the course of the dementias in nearly 75 percent of patients.

Cognition is impaired by many conditions, including brain injuries, cerebral tumors, acquired immune deficiency syndrome (AIDS), alcohol, medications, infections, chronic pulmonary diseases, and inflammatory diseases. Although dementias associated with advanced age typically are caused by primary degenerative central nervous system (CNS) disease and vascular disease, many factors contribute to cognitive impairment; in older persons, mixed causes of dementia are common.

About 10 to 15 percent of all patients who exhibit symptoms of dementia have potentially treatable conditions. The treatable conditions include systemic disorders, such as heart disease, renal disease, and congestive heart failure; endocrine disorders, such as hypothyroidism; vitamin deficiency; medication misuse; and primary mental disorders, most notably depressive disorders.

Depending on the site of the cerebral lesion, dementias are classified as cortical and subcortical. A subcortical dementia occurs in Huntington’s disease, Parkinson’s disease, normal pressure hydrocephalus, vascular dementia, and Wilson’s disease. The subcortical dementias are associated with movement disorders, gait apraxia, psychomotor retardation, apathy, and akinesis, which can be confused with catatonia. Table 33-10 lists some potentially reversible conditions that may resemble dementia. The cortical dementias occur in dementias of the Alzheimer’s type, Creutzfeldt-Jakob disease (CJD), and Pick’s disease, which frequently manifest aphasia, agnosia, and apraxia. In clinical practice, the two types of dementias overlap and, in most cases, an accurate diagnosis can be made only by autopsy. Human prion diseases result from coding mutations in the prion protein gene (PRNP) and may be inherited, acquired, or sporadic. They include familial CJD, Gerstmann-Sträussler-Scheinker syndrome, and fatal familial insomnia. These are inherited as autosomal-dominant mutations. The acquired diseases include kuru and iatrogenic CJD. Kuru was an epidemic prion disease of the Fore people of Papua, New Guinea, caused by cannibalistic funeral rituals, which peaked in incidence in the 1950s. Iatrogenic disease is rare and is caused, for example, by the use of contaminated dura mater and corneal grafts and treatment with human cadaveric pituitary-derived growth hormone and gonadotropin. Sporadic CJD accounts for 85 percent of the human prion diseases and occurs worldwide, with a uniform distribution and an incidence of about 1 in 1 million per annum, with a mean age at onset of 65 years. It is exceedingly rare in individuals under 30 years of age.

**Depressive Disorders**

Depressive symptoms are present in about 15 percent of all older adult community residents and nursing home patients. Age itself is not a risk factor for the development of depression, but being widowed and having a chronic medical illness are associated with vulnerability to depressive disorders. Late-onset depression is characterized by high rates of recurrence.

The common signs and symptoms of depressive disorders include reduced energy and concentration, sleep problems (especially early
morning awakening and multiple awakenings), decreased appetite, weight loss, and somatic complaints. The presenting symptoms may be different in older depressed patients from those seen in younger adults because of an increased emphasis on somatic complaints in older persons. Older persons are particularly vulnerable to major depressive episodes with melancholic features, characterized by depression, hypochondriasis, low self-esteem, feelings of worthlessness, and self-accusatory trends (especially about sex and sinfulness) with paranoid and suicidal ideation. A geriatric depression scale is given in Table 33-11.

Cognitive impairment in depressed geriatric patients is referred to as the dementia syndrome of depression (pseudodementia), which can be confused easily with true dementia. In true dementia, intellectual performance usually is global, and impairment is consistently poor; in pseudodementia, deficits in attention and concentration are variable. Compared with patients who have true dementia, patients with pseudodementia are less likely to have language impairment and to confabulate; when uncertain, they are more likely to say ‘I don’t know’; and their memory difficulties are more limited to free recall than to recognition on cued recall tests. Pseudodementia occurs in about 15 percent of depressed older patients, and 25 to 50 percent of patients with dementia are depressed.

Schizophrenia

Schizophrenia usually begins in late adolescence or young adulthood and persists throughout life. Although first episodes diagnosed after age 65 are rare, a late-onset type beginning after age 45 has been described. Women are more likely to have a late onset of schizophrenia than men. Another difference between early-onset and late-onset schizophrenia is the greater prevalence of paranoid schizophrenia in the late-onset type. About 20 percent of persons with schizophrenia show no active symptoms by age 65; 80 percent show varying degrees of impairment. Psychopathology becomes less marked as patients age.

The residual type of schizophrenia occurs in about 30 percent of persons with schizophrenia. Its signs and symptoms include emotional blunting, social withdrawal, eccentric behavior, and illogical thinking. Delusions and hallucinations are uncommon. Because most persons with residual schizophrenia cannot care for themselves, long-term hospitalization is required.

Older persons with schizophrenic symptoms respond well to antipsychotic drugs. Medication must be administered judiciously, and lower-than-usual dosages often are effective for older adults.

Delusional Disorder

The age of onset of delusional disorder usually is between ages 40 and 55, but it can occur at any time during the geriatric period. Delusions can take many forms; the most common are persecutory—patients believe that they are being spied on, followed, poisoned, or harassed in some way. Persons with delusional disorder may become violent toward their supposed persecutors. Some persons lock themselves in their rooms and live reclusive lives. Somatic delusions, in which persons believe they have a fatal illness, also can occur in older persons. In one study of persons older than 65 years of age, pervasive persecutory ideation was present in 4 percent of persons sampled.

Among those who are vulnerable, delusional disorder can occur under physical or psychological stress and can be precipitated by the death of a spouse, loss of a job, retirement, social isolation, adverse financial circumstances, debilitating medical illness or surgery, visual impairment, and deafness. Delusions also can accompany other disorders—such as dementia of the Alzheimer’s type, alcohol use disorders, schizophrenia, depressive disorders, and bipolar I disorder—which need to be ruled out. Delusional syndromes also can result from prescribed medications or be early signs of a brain tumor. The prognosis is fair to good in most cases; best results are achieved through a combination of psychotherapy and pharmacotherapy.

A late-onset delusional disorder called paraphrenia is characterized by persecutory delusions. It develops over several years and is not associated with dementia. Some workers believe that the disorder is a variant of schizophrenia that first becomes manifest after age 60. Patients with a family history of schizophrenia show an increased rate of paraphrenia.

Anxiety Disorders

Anxiety disorders usually begin in early or middle adulthood, but some appear for the first time after age 60. An initial onset of panic disorder in older persons is rare but can occur. The ECA study determined that the 1-month prevalence of anxiety disorders in persons age 65 and older is 5.5 percent. By far the most common disorders are phobias (4 to 8 percent). The rate for panic disorder is 1 percent.

The signs and symptoms of phobia in older adults are less severe than those that occur in younger persons, but the effects are equally, if not more, debilitating for older patients. Existential theories help explain anxiety when no specifically identifiable
stimulus exists for a chronically anxious feeling. Older persons must come to grips with death. The person may deal with the thought of death with a sense of despair and anxiety, rather than with equanimity and Erikson's "sense of integrity." The fragility of the autonomic nervous system in older persons may account for the development of anxiety after a major stressor. Because of concurrent physical disability, older persons react more severely to PTSD than younger persons.

**Obsessive-Compulsive Disorders**

Obsessions and compulsions may appear for the first time in older adults, although older adults with obsessive-compulsive disorder (OCD) usually had demonstrated evidence of the disorder (e.g., being orderly, perfectionistic, punctual, and parsimonious) when they were younger. When symptomatic, patients become excessive in their desire for orderliness, rituals, and sameness. They may become generally inflexible and rigid and have compulsions to check things again and again. OCD (in contrast to obsessive-compulsive personality disorder) is characterized by ego-dystonic rituals and obsessions and may begin late in life.

**Somatic Symptom Disorders**

Disorders characterized by physical symptoms resembling medical diseases are relevant to geriatric psychiatry because somatic complaints are common among older adults. More than 80 percent of persons over 65 years of age have at least one chronic disease—usually arthritis or cardiovascular problems. After age 75, 20 percent have diabetes and an average of four diagnosable chronic illnesses that require medical attention.

Hypochondriasis is common in persons over 60 years of age, although the peak incidence is in those 40 to 50 years of age. The disorder usually is chronic, and the prognosis guarded. Repeated physical examinations help reassure patients that they do not have a fatal illness, but invasive and high-risk diagnostic procedures should be avoided unless medically indicated.

Telling patients that their symptoms are imaginary is counterproductive and usually engenders resentment. Clinicians should acknowledge that the complaint is real, that the pain is really there and perceived as such by the patient, and that a psychological or pharmacological approach to the problem is indicated.

**Alcohol and Other Substance Use Disorder**

Older adults with alcohol dependence usually give a history of excessive drinking that began in young or middle adulthood. They usually are medically ill, primarily with liver disease, and are either divorced, widowed, or are men who never married. Many have arrest records and are numbered among the homeless persons. A large number have chronic dementing illness, such as Wernicke's encephalopathy or Korsakoff's syndrome. Of nursing home patients, 20 percent have alcohol dependence.

Over all, alcohol and other substance use disorders account for 10 percent of all emotional problems in older persons, and dependence on such substances as hypnotics, anxiolytics, and narcotics is more common in old age than is generally recognized. Substance-seeking behavior characterized by crime, manipulativeness, and antisocial behavior is rarer in older than in younger adults. Older patients may abuse anxiolytics to allay chronic anxiety or to ensure sleep. The maintenance of chronically ill cancer patients with narcotics prescribed by a physician produces dependence, but the need to provide pain relief takes precedence over the possibility of narcotic dependence and is entirely justified.

The clinical presentation of older patients with alcohol and other substance use disorders varies and includes confusion, poor personal hygiene, depression, malnutrition, and the effects of exposure and falls. The sudden onset of delirium in older persons hospitalized for medical illness is most often caused by alcohol withdrawal. Alcohol abuse also should be considered in older adults with chronic gastrointestinal problems.

Older persons may misuse over-the-counter substances, including nicotine and caffeine. Over-the-counter analgesics are used by 35 percent of older persons, and 30 percent use laxatives. Unexplained gastrointestinal, psychological, and metabolic problems should alert clinicians to over-the-counter substance abuse.

**Sleep Disorders**

Advanced age is the single most important factor associated with the increased prevalence of sleep disorders. Sleep-related phenomena reported more frequently by older than by younger adults are sleeping problems, daytime sleepiness, daytime napping, and the use of hypnotic drugs. Clinically, older persons experience higher rates of breathing-related sleep disorder and medication-induced movement disorders than younger adults.

In addition to altered regulatory and physiological systems, the causes of sleep disturbances in older persons include primary sleep disorders, other mental disorders, general medical disorders, and social and environmental factors. Among the primary sleep disorders, dyssomnias are the most frequent, especially primary insomnia, nocturnal myoclonus, restless legs syndrome, and sleep apnea. Of the parasomnias, rapid eye movement (REM) sleep behavior disorder occurs almost exclusively among elderly men. The conditions that commonly interfere with sleep in older adults also include pain, nocturia, dyspnea, and heartburn. The lack of a daily structure and of social or vocational responsibilities contributes to poor sleep.

As a result of the decreased length of their daily sleep-wake cycle, older persons without daily routines, especially patients in nursing homes, may experience an advanced sleep phase, in which they go to sleep early and awaken during the night.

Even modest amounts of alcohol can interfere with the quality of sleep and can cause sleep fragmentation and early morning awakening. Alcohol can also precipitate or aggravate obstructive sleep apnea. Many older persons use alcohol, hypnotics, and other CNS depressants to help them fall asleep, but data show that these persons experience more early morning awakening than trouble falling asleep. When prescribing sedative-hypnotic drugs for older persons, clinicians must monitor the patients for unwanted cognitive, behavioral, and psychomotor effects, including memory impairment (anterograde amnesia), residual sedation, rebound insomnia, daytime withdrawal, and unsteady gait.

Changes in sleep structure among persons over 65 years of age involve both REM sleep and nonrapid eye movement (NREM) sleep. The REM changes include the redistribution of REM sleep throughout the night, more REM episodes, shorter REM episodes, and less total REM sleep. The NREM changes include the decreased amplitude of delta waves, a lower percentage of stages 3 and 4 sleep, and a higher
percent of stages 1 and 2 sleep. In addition, older persons experience increased awakening after sleep onset.

Much of the observed deterioration in the quality of sleep in older persons is caused by the altered timing and consolidation of sleep. For example, with advanced age, persons have a lower amplitude of circadian rhythms, a 12-hour sleep-propensity rhythm, and shorter circadian cycles.

**SUICIDE RISK**

Elderly persons have a higher risk for suicide than any other population. The suicide rate for white men over the age of 65 is five times higher than that of the general population. One third of elderly persons report loneliness as the principal reason for considering suicide. Approximately 10 percent of elderly individuals with suicidal ideation report financial problems, poor medical health, or depression as reasons for suicidal thoughts. Suicide victims differ demographically from individuals who attempt suicide. About 60 percent of those who commit suicide are men; 75 percent of those who attempt suicide are women. Suicide victims, as a rule, use guns or hang themselves, whereas 70 percent of suicide attempters take a drug overdose, and 20 percent cut or slash themselves. Psychological autopsy studies suggest that most elderly persons who commit suicide have had a psychiatric disorder, most commonly depression. Psychiatric disorders of suicide victims, however, often do not receive medical or psychiatric attention. More elderly suicide victims are widowed and fewer are single, separated, or divorced than is true of younger adults. Violent methods of suicide are more common in the elderly, and alcohol use and psychiatric histories appear to be less frequent. The most common precipitants of suicide in older individuals are physical illness and loss, whereas problems with employment, finances, and family relationships are more frequent precipitants in younger adults. Most elderly persons who commit suicide communicate their suicidal thoughts to family or friends before the act of suicide.

Older patients with major medical illnesses or a recent loss should be evaluated for depressive symptomatology and suicidal ideation or plans. Thoughts and fantasies about the meaning of suicide and life after death may reveal information that the patient cannot share directly. There should be no reluctance to question patients about suicide, because no evidence indicates that such questions increase the likelihood of suicidal behavior.

**OTHER CONDITIONS OF OLD AGE**

**Vertigo**

Feelings of vertigo or dizziness, a common complaint of older adults, cause many older adults to become inactive because they fear falling. The causes of vertigo vary and include anemia, hypotension, cardiac arrhythmia, cerebrovascular disease, basilar artery insufficiency, middle ear disease, acoustic neuroma, benign postural vertigo, and Ménière's disease. Most cases of vertigo have a strong psychological component, and clinicians should ascertain any secondary gain from the symptom. The overuse of anxiolytics can cause dizziness and daytime somnolence. Treatment with meclizine (Antivert), 25 to 100 mg daily, has been successful in many patients with vertigo.

**Syncope**

The sudden loss of consciousness associated with syncope results from a reduction of cerebral blood flow and brain hypoxia. A thorough medical workup is required to rule out the potential causes. Causes of syncope are listed in Table 33-12.

**Hearing Loss**

About 30 percent of persons over age 65 have significant hearing loss (presbycusis). After age 75, that figure rises to 50 percent. The causes vary. Clinicians should be sensitive to hearing loss in patients who complain they can hear but cannot understand what is being said or who ask that questions be repeated. Most elderly persons with hearing loss can be treated with hearing aids.

**Elder Abuse**

An estimated 10 percent of persons above 65 years of age are abused. Elder abuse is defined by the American Medical Association as "an act or omission which results in harm or threatened harm to the health or welfare of an elderly person." Mistreatment includes abuse and neglect—physically, psychologically, financially, and materially. Sexual abuse does occur. Acts of omission include withholding food, medicine, clothing, and other necessities.
Family conflicts and other problems often underlie elder abuse. The victims tend to be very old and frail. They often live with their assailants, who may be financially dependent on the victims. Both the victim and the perpetrator tend to deny or minimize the presence of abuse. Interventions include providing legal services, housing, and medical, psychiatric, and social services.

SPOUSAL BEREAVEMENT

Demographic data suggest that 51 percent of women and 14 percent of men over the age of 65 will be widowed at least once. Spousal loss is among the most stressful of all life experiences. As a group, older adults appear to have a more favorable outcome than expected following the death of a spouse. Depressive symptoms peak within the first few months after a death, but decline significantly within a year. A relationship exists between spousal loss and subsequent mortality. Elderly survivors of spouses who committed suicide are especially vulnerable, as are those with psychiatric illness.

PSYCHOPHARMACOLOGICAL TREATMENT OF GERIATRIC DISORDERS

Certain guidelines should be followed regarding the use of all drugs in older adults. A pretreatment medical evaluation is essential, including an electrocardiogram (ECG). It is especially useful to have the patient or a family member bring in all currently used medications, because multiple drug use could be contributing to the symptoms.

Most psychotropic drugs should be given in equally divided doses three or four times over a 24-hour period. Older patients may not be able to tolerate a sudden rise in drug blood level resulting from one large dose. Any changes in blood pressure and pulse rate and other side effects should be watched. For patients with insomnia, however, giving the major portion of an antipsychotic or antidepressant at bedtime takes advantage of its sedating and soporific effects. Liquid preparations are useful for older patients who cannot, or will not, swallow tablets. Clinicians should frequently reassess all patients to determine the need for maintenance medication, changes in dosage, and development of adverse effects. If a patient is taking psychotropic drugs at the time of the evaluation, the clinician should discontinue these medications, if possible, and, after a washout period, reevaluate the patient during a drug-free baseline state.

Adults over 65 years of age use the greatest number of medications of any age group; 25 percent of all prescriptions are written for them. Adverse drug reactions caused by medications result in the hospitalization of nearly 250,000 persons in the United States each year. Psychotropic drugs are among the most commonly prescribed, along with cardiovascular and diuretic medications; 40 percent of all hypnotics dispensed in the United States each year. Psychotropic drugs are among the most prescribed, along with cardiovascular and diuretic medications; 40 percent of all hypnotics dispensed in the United States each year. Psychotropic drugs are distributed more widely in fat than in lean tissue, so a drug's action can be unexpectedly prolonged in older persons. Similarly, changes in end-organ or receptor-site sensitivity must be taken into account. In older persons, the increased risk of orthostatic hypotension from psychotropic drugs is related to reduced functioning of blood pressure–regulating mechanisms.

As a general rule, the lowest possible dose should be used to achieve the desired therapeutic response. Clinicians must know the pharmacodynamics, pharmacokinetics, and biotransformation of each drug prescribed and the effects of the interaction of the drug with other drugs that a patient is taking. An adage in geriatric medicine regarding the use of drugs is: Start low, go slow.

PSYCHOTHERAPY FOR GERIATRIC PATIENTS

The standard psychotherapeutic interventions—such as insight-oriented psychotherapy, supportive psychotherapy, cognitive therapy, group therapy, and family therapy—should be available to geriatric patients. According to Sigmund Freud, persons older than 50 years are not suited for psychoanalysis because their mental processes lack elasticity. In the view of many who followed Freud, however, psychoanalysis is possible after age 50. Advanced age certainly limits plasticity of the personality, but as Otto Fenichel stated, "It does so in varying degrees and at very different ages so that no general rule can be given." Insight-oriented psychotherapy may help remove a specific symptom, even in older persons. It is of most benefit when patients have possibilities for libidinal and narcissistic gratification, but it is contraindicated if it would bring only the insight that life has been a failure and that the patient has no opportunity to make up for it.

Common age-related issues in therapy involve the need to adapt to recurrent and diverse losses (e.g., the deaths of friends and loved ones), the need to assume new roles (e.g., the adjustment to retirement and the disengagement from previously defined roles), and the need to accept mortality. Psychotherapy helps older persons to deal with these issues and the emotional problems surrounding them and to understand their behavior and the effects of their behavior on others. In addition to improving interpersonal relationships, psychotherapy increases self-esteem and self-confidence, decreases feelings of helplessness and anger, and improves the quality of life.

Psychotherapy helps relieve tensions of biological and cultural origins and helps older persons work and play within the limits of their functional status and as determined by their past training, activities, and self-concept in society. In patients with impaired cognition, psychotherapy can produce remarkable gains in both physical and mental symptoms. In one study conducted in an old-age home, 43 percent of the patients receiving psychotherapy showed less urinary incontinence, improved gait,
greater mental alertness, improved memory, and better hearing than before psychotherapy.

Therapists must be more active, supportive, and flexible in conducting therapy with older than with younger adults, and they must be prepared to act decisively at the first sign of an incapacity that requires the active involvement of another physician, such as an internist, or that requires consulting with, or enlisting the aid of, a family member.

Older persons usually seek therapy for a therapist’s unqualified and unlimited support, reassurance, and approval. Patients often expect a therapist to be all powerful, all knowing, and able to effect a magical cure. Most patients eventually recognize that the therapist is human and that they are engaged in a collaborative effort. In some cases, however, the therapist may have to assume the idealized role, especially when the patient is unable or unwilling to test reality effectively. With the help of the therapist, the patient deals with problems that had been avoided previously. As the therapist offers direct encouragement, reassurance, and advice, the patient’s self-confidence increases as conflicts are resolved.

DEATH AND DYING

Definitions

The terms death and dying require definition: Whereas death may be considered the absolute cessation of vital functions, dying is the process of losing these functions. Dying may also be seen as a developmental concomitant of living, a part of the birth-to-death continuum. Living may entail numerous mini-deaths—the end of growth and its potential, health-compromising illnesses, multiple losses, decreasing vitality and growing dependency with aging, and dying. Dying, and the individual’s awareness of it, imbues humans with values, passions, wishes, and the impetus to make the most of time.

Two terms that have been used with increased frequency in recent years refer to the quality of living as death comes near. A good death is one that is free from avoidable distress and suffering for patients, families, and caregivers and is reasonably consistent with clinical, cultural, and ethical standards. A bad death, in contrast, is characterized by needless suffering, a dishonoring of the patient or family’s wishes or values, and a sense among participants or observers that norms of decency have been offended.

Uniform Determination of Death Act. The President’s Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research published its definition of death in 1981. Working with the American Bar Association, the American Medical Association (AMA), and the National Conference of Commissioners on Uniform State Laws, the Commission established that one who has sustained either (1) irretrievable cessation of circulatory and respiratory functions or (2) irretrievable cessation of all functions of the entire brain, including the brainstem, is dead. Determination of death must be in accordance with accepted medical standards.

Generally accepted criteria for determining brain death require a series of neurological and other assessments. For children, special guidelines apply. They generally specify two assessments separated by an interval of at least 48 hours for those between the ages of 1 week and 2 months, 24 hours for those between the ages of 2 months and 1 year, and 12 hours for older children; additional confirmatory tests may also be advisable under some circumstances. Brain death criteria are normally not applied to infants younger than 7 days. Table 34.1-1 lists the clinical criteria for brain death in adults and children.

Legal Aspects of Death

According to law, physicians must sign the death certificate, which attests to the cause of death (e.g., congestive heart failure or pneumonia). They must also attribute the death to natural, accidental, suicidal, homicidal, or unknown causes. A medical examiner, coroner, or pathologist must examine anyone who dies unattended by a physician and perform an autopsy to determine the cause of death. In some cases, a psychological autopsy is performed: A person’s sociocultural and psychological background is examined retrospectively by interviewing friends, relatives, and doctors to determine whether a mental illness, such as a depressive disorder, was present. For example, a determination can be made that a person died because he or she was pushed (murder) or because he or she jumped (suicide) from a high building. Each situation has clear medical and legal implications.

Stages of Death and Dying

Elisabeth Kübler-Ross, a psychiatrist and thanatologist, made a comprehensive and useful organization of reactions to impending death. A dying patient seldom follows a regular series of responses that can be clearly identified; no established sequence is applicable to all patients. Nevertheless, the following five stages proposed by Kübler-Ross are widely encountered.

Stage 1: Shock and Denial. On being told that they are dying, persons initially react with shock. They may appear dazed at first and then may refuse to believe the diagnosis; they may deny that anything is wrong. Some persons never pass beyond this stage and may go from doctor to doctor until they find one who supports their position. The degree to which denial is adaptive or maladaptive appears to depend on whether a patient continues to obtain treatment even while denying the prognosis. In such cases, physicians must communicate to patients and their families, respectfully and directly, basic information about the illness, its prognosis, and the options for treatment. For effective communication, physicians must allow for patients’ emotional responses and reassure them that they will not be abandoned.

Stage 2: Anger. Persons become frustrated, irritable, and angry at being ill. They commonly ask, “Why me?” They may become angry at God, their fate, a friend, or a family member;
they may even blame themselves. They may displace their anger onto the hospital staff members and the doctor, whom they blame for the illness. Patients in the stage of anger are difficult to treat. Doctors who have difficulty understanding that anger is a predictable reaction and is really a displacement may withdraw from patients or transfer them to other doctors’ care.

Physicians treating angry patients must realize that the anger being expressed cannot be taken personally. An empathic, nondefensive response can help defuse patients’ anger and can help them refocus on their own deep feelings (e.g., grief, fear, loneliness) that underlie the anger. Physicians should also recognize that anger may represent patients’ desire for control in a situation in which they feel completely out of control.

**Stage 3: Bargaining.** Patients may attempt to negotiate with physicians, friends, or even God; in return for a cure, they promise to fulfill one or many pledges, such as giving to charity and attending church regularly. Some patients believe that if they are good (compliant, nonquestioning, cheerful), the doctor will make them better. The treatment of such patients involves making it clear that they will be taken care of to the best of the doctor’s abilities and that everything that can be done will be done, regardless of any action or behavior on the patients’ part. Patients must also be encouraged to participate as partners in their treatment and to understand that being a good patient means being as honest and straightforward as possible.

**Stage 4: Depression.** In the fourth stage, patients show clinical signs of depression—withdrawal, psychomotor retardation, sleep disturbances, hopelessness, and, possibly, suicidal ideation. The depression may be a reaction to the effects of the illness on their lives (e.g., loss of a job, economic hardship, helplessness, hopelessness, and isolation from friends and family), or it may be in anticipation of the loss of life that will eventually occur. A major depressive disorder with vegetative signs and suicidal ideation may require treatment with antidepressant medication or electroconvulsive therapy (ECT). All persons feel some sadness at the prospect of their own death, and normal sadness does not require biological intervention. But major depressive disorder and active suicidal ideation can be alleviated and should not be accepted as normal reactions to impending death. A person who suffers from major depressive disorder may be unable to sustain hope, which can enhance the dignity and quality of life and even prolong longevity. Studies have shown that some terminally ill patients can delay their death until after a loved one’s significant event, such as graduation of a grandson from college.

**Stage 5: Acceptance.** In the stage of acceptance, patients realize that death is inevitable, and they accept the universality of the experience. Their feelings can range from a neutral to a euphoric mood. Under ideal circumstances, patients resolve their feelings about the inevitability of death and can talk about facing the unknown. Those with strong religious beliefs and a conviction of life after death sometimes find comfort in the ecclesiastical maxim, “Fear not death; remember those who have gone before you and those who will come after.”

### Near-Death Experiences

Near-death descriptions are often strikingly similar, involving an out-of-body experience of viewing one’s body and overhearing conversations, feelings of peace and quiet, hearing a distant noise, entering a dark tunnel, leaving the body behind, meeting dead loved ones, witnessing beings of light, returning to life to complete unfinished business, and a deep sadness on leaving this new dimension. This pattern of sensations and perceptions is usually described as peaceful and loving; it feels real to participants, who distinguish it from dreams or hallucinations. These experiences provoke sweeping lifestyle changes, such as fewer material concerns, a heightened sense of purpose, a belief in God, joy of life, compassion, less fear of death, an enhanced approach to life, and intense feelings of love. In a similar vein, hospice nurses have described experiences among terminally ill patients of visions that may include a sense of presence of departed loved ones, of spiritual beings, of a bright light, or of being in a particular place, often described with a sense of warmth and love. Although such “visions” do not readily lend themselves to scientific investigation and thus are not legitimized, patients may benefit from discussing them with clinicians. A term to describe this experience is *unio mystica*, which refers to an oceanic feeling of mystical unity with an infinite power.

### Life Cycle Considerations about Death and Dying

The clinical diversity of death-related attitudes and behaviors between children and adults has its roots in developmental factors and age-dependent differences in causes of death. As opposed to adults, who usually die from chronic illness, children are apt to die from sudden, unexpected causes. Almost half
of the children who die between the ages of 1 and 14 years and nearly 75 percent of those who die in late adolescence and early adulthood die from accidents, homicides, and suicides. With their characteristics of violence, suddenness, and mutilation, such unnatural causes of death are special stressors for grieving survivors. Bereaved parents and siblings of dead young children and teenagers often feel victimized and traumatized by their losses; their grief reactions resemble posttraumatic stress disorder (PTSD). Devastating family disruptions can occur, and surviving siblings risk having their emotional needs put on the back burner, ignored, or completely unnoticed.

Children. Children's attitudes toward death mirror their attitudes toward life. Although they share with adolescents, adults, and elderly adults similar fears, anxieties, beliefs, and attitudes about dying, some of their interpretations and reactions are age specific. None welcome it without ambivalence, and all temper their acceptance with healthy doses of denial and avoidance. Dying children are often aware of their condition and want to discuss it. They often have more sophisticated views about dying than their medically well counterparts, engendered by their own failing health, separations from parents, subjection to painful procedures, and the deaths of hospital chums.

At the preschool, preoperational stage of cognitive development, death is seen as a temporary absence, incomplete and reversible, like departure or sleep. Separation from the primary caretaker(s) is the main fear of preschool-age children. This fear surfaces as an increase in nightmares, more aggressive play, or concern about the deaths of others rather than in direct discourse. Terminally ill children may assume responsibility for their death, feeling guilty for dying. Preschool children may be unable to relate the treatment to the illness, instead viewing treatment as punishment and family separation as rejection. They need reassurance that they are loved, have done nothing wrong, are not responsible for their illness, and will not be abandoned.

School-age children manifest concrete-operational thinking and recognize death as a final reality. They, however, view death as something that happens to old people, not to them. Between the ages of 6 and 12 years, children have active fantasies of violence and aggression, often dominated by themes of death and killing. School-age children ask questions about serious illness and death if encouraged to do so; however, if they receive cues that the subject is taboo, they may withdraw and participate less fully in their care. Facilitating open discussion and updating children with important information, including prognostic changes, can be very helpful. In addition, children may need help coping with peers and school demands. Teachers should be informed and updated. Classmates may need education and assistance to help them understand the situation and respond appropriately.

Adolescents. Capable of formal cognitive operations, adolescents understand that death is inevitable and final but may not accept that their own death is possible. The major fears of dying teenagers parallel those of all teenagers—losing control, being imperfect, and being different. Concerns about body image, hair loss, or loss of bodily control can generate great resistance to continuing treatment. Alternating emotions of despair, rage, grief, bitterness, numbness, terror, and joy are common. The potential for withdrawal and isolation is great because teenagers may equate parental support with loss of independence or may deny their fears of abandonment by actually repulsing friendly gestures. Teenagers must be included in all decision-making processes surrounding their deaths. Many are capable of great courage, grace, and dignity in facing death.

Adults. Some of the most often expressed fears of adult patients entering hospice care, listed in the approximate order of frequency, include fears of (1) separation from loved ones, homes, and jobs; (2) becoming a burden to others; (3) losing control; (4) what will happen to dependents; (5) pain or other worsening symptoms; (6) being unable to complete life tasks or responsibilities; (7) dying; (8) being dead; (9) the fears of others (reflected fears); (10) the fate of the body; and (11) the afterlife. Problems in communication arise out of trepidation, making it important for those involved in health care to provide environments of trust and safety in which people can begin to talk about uncertainties, anxieties, and concerns.

Late-age adults often accept that their time has come. Their main fears include long, painful, and disfiguring deaths; prolonged vegetative states; isolation; and loss of control or dignity. Elderly patients may talk or joke openly about dying and sometimes welcome it. In their 70s and beyond, they rarely harbor illusions of indestructibility—most have already had several close calls: Their parents have died, and they have gone to funerals for friends and relatives. Although they may not be happy to die, they can be reconciled to it.

According to Erik Erikson, the eighth and final stage in the life cycle brings a sense of either integrity or despair. As elderly adults enter the last phase of their lives, they reflect on their pasts. When they have taken care of their affairs, have been relatively successful, and have adapted to the triumphs and disappointments of life, they can look back with satisfaction and only a few regrets. Integrity of the self allows people to accept inevitable disease and death without fear of succumbing helplessly. If elderly individuals look back on life as a series of missed opportunities or personal misfortunes, however, they feel a sense of bitter despair, a preoccupation with what might have been if only this or that had happened. Then death is fearsome because it symbolizes emptiness and failure.

Management

Caring for a dying patient is highly individual. Caretakers need to deal with death honestly, tolerate wide ranges of affects, connect with suffering patients and bereaved loved ones, and resolve routine issues as they arise. Although each therapeutic relationship between a patient and health provider has a uniqueness derived from the patient’s and health provider’s gender, constitution, life experience, age, stage of life, resources, faith, culture, and other considerations, major themes confront all health providers caring for dying patients. End-of-life care and palliative medicine are discussed in Section 34.2.

BEREAVEMENT, GRIEF, AND MOURNING

Bereavement, grief, and mourning are terms that apply to the psychological reactions of those who survive a significant loss. Grief is the subjective feeling precipitated by the death of a loved one. The term is used synonymously with mourning, although, in the strictest sense, mourning is the process
by which grief is resolved; it is the societal expression of post-
bereavement behavior and practices. Bereavement literally
means the state of being deprived of someone by death and
refers to being in the state of mourning. Regardless of the fine
points that differentiate these terms, the experiences of grief
and bereavement have sufficient similarities to warrant a syn-
drome that has signs, symptoms, a demonstrable course, and an
expected resolution.

Normal Bereavement Reactions
The first response to loss, protest, is followed by a longer period
of searching behavior. As hope to reestablish the attachment
bond diminishes, searching behaviors give way to despair and
detachment before bereaved individuals eventually reorganize
themselves around the recognition that the lost person will not
return. Although the bereaved ultimately learn to accept the real-
ity of the death, they also find psychological and symbolic ways
of keeping the memory of the deceased person very much alive.
Grief work allows the survivor to redefine his or her relationship
to the deceased person and to form new but enduring ties.

Duration of Grief. Most societies mandate modes of
bereavement and time for grieving. In contemporary America,
bereaved individuals are expected to return to work or school in
a few weeks, to establish equilibrium within a few months, and
to be capable of pursuing new relationships within 6 months to
1 year. Ample evidence suggests that the bereavement process
does not end within a prescribed interval; certain aspects per-
sist indefinitely for many otherwise high-functioning, normal
individuals.

The most lasting manifestation of grief, especially after
spousal bereavement, is loneliness. Often present for years
after the death of a spouse, loneliness may, for some, be a daily
reminder of the loss. Other common manifestations of pro-
tracted grief occur intermittently. For example, a man who has
lost his wife may experience elements of acute grief every time
he hears her name or sees her picture on the nightstand. Usually,
these reactions become increasingly short lived over time, dis-
sipating within minutes, and become tinged with positive and
pleasant affects. Such bittersweet memories may last a lifetime.
Thus, most grief does not fully resolve or permanently disap-
pear; rather, grief becomes circumscribed and submerged only
to reemerge in response to certain triggers.

Anticipatory Grief
In anticipatory grief, grief reactions are brought on by the slow
dying process of a loved one through injury, illness, or high-
risk activity. Although anticipatory grief may soften the blow of
the eventual death, it can also lead to premature separation and
withdrawal while not necessarily mitigating later bereavement.
At times, the intensification of intimacy during this period may
heighten the actual sense of loss even though it prepares the
survivor in other ways.

Anniversary Reactions. When the trigger for an acute
grief reaction is a special occasion, such as a holiday or birth-
day, the rekindled grief is called an anniversary reaction. It is
not unusual for anniversary reactions to occur each year on the
same day the person died or, in some cases, when the bereaved
individual becomes the same age the deceased person was at
the time of death. Although these anniversary reactions tend to
become relatively mild and brief over time, they can be experi-
enced as the reliving of one’s original grief and prevail for hours
or days.

Mourning
From earliest history, every culture records its own beliefs,
customs, and behaviors related to bereavement. Specific pat-
terns include rituals for mourning (e.g., wakes or Shiva), for
disposing of the body, for invocation of religious ceremonies,
and for periodic official remembrances. The funeral is the pre-
vailing public display of bereavement in contemporary North
America. The funeral and burial service acknowledge the real
and final nature of the death, countering denial; they also gar-
ner support for the bereaved, encouraging tribute to the dead,
uniting families, and facilitating community expressions of
sorrow. If cremation replaces burial, ceremonies associated
with dissemination of the ashes perform similar functions.
Visits, prayers, and other ceremonies allow for continuing
support, coming to terms with reality, remembering, emo-
tional expression, and concluding unfinished business with
the deceased. Several cultural and religious rituals provide
purpose and meaning, protect the survivors from isolation and
vulnerability, and set limits on grieving. Subsequent holidays,
birthdays, and anniversaries serve to remind the living of the
dead and may elicit grief as real and fresh as the original ex-
perience; over time, these anniversary grievings become attenu-
ated but often remain in some form.

Bereavement
Because bereavement often evokes depressive symptoms, it
may be necessary to demarcate normal grief reactions from
major depressive disorder (Table 34.1-2). In the fifth edition
of the Diagnostic and Statistical Manual of Mental Disorders
(DSM-5), a new condition has been proposed for further study
called persistent complex bereavement disorder to account for
bereavement that lasts for more than 1 year (Table 34.1-3). This
disorder may resemble symptoms of a major depressive epi-
sode, which is characterized by severe functional impairment
and includes morbid preoccupation with worthlessness, suicidal
ideation, psychotic symptoms, or psychomotor retardation. This
is discussed further below.

Complicated Bereavement
Complicated bereavement has a confusing array of terms to
describe it—abnormal, atypical, distorted, morbid, traumatic,
and unresolved, to name a few types. Three patterns of
complicated, dysfunctional grief syndromes have been iden-
tified—chronic, hypertrophic, and delayed grief. These are
not diagnostic categories within DSM-5 but are descriptive syn-
dromes that, if present, may be prodromata of a major depres-
sive disorder.

Chronic Grief. The most common type of complicated grief
is chronic grief, often highlighted by bitterness and idealization of

### Hypertrophic Grief.

Most often seen after a sudden and unexpected death, bereavement reactions are extraordinarily intense in hypertrophic grief. Customary coping strategies are ineffectual to mitigate anxiety, and withdrawal is frequent. When one family member is experiencing a hypertrophic grief reaction, disruption of family stability can occur. Hypertrophic grief frequently takes on a long-term course, albeit one attenuated over time.

### Delayed Grief.

Absent or inhibited grief when one normally expects to find overt signs and symptoms of acute mourning is referred.

**DSM-5 Diagnostic Criteria for Persistent Complex Bereavement Disorder**

<table>
<thead>
<tr>
<th>A. The individual experienced the death of someone with whom he or she had a close relationship.</th>
</tr>
</thead>
<tbody>
<tr>
<td>B. Since the death, at least one of the following symptoms is experienced on more days than not and to a clinically significant degree and has persisted for at least 12 months after the death in the case of bereaved adults and 6 months for bereaved children:</td>
</tr>
<tr>
<td>1. Persistent yearning/longing for the deceased. In young children, yearning may be expressed in play and behavior, including behaviors that reflect being separated from, and also reuniting with, a caregiver or other attachment figure.</td>
</tr>
<tr>
<td>2. Intense sorrow and emotional pain in response to the death.</td>
</tr>
<tr>
<td>3. Preoccupation with the deceased.</td>
</tr>
<tr>
<td>4. Preoccupation with the circumstances of the death. In children, this preoccupation with the deceased may be expressed through the themes of play and behavior and may extend to preoccupation with possible death of others close to them.</td>
</tr>
<tr>
<td>C. Since the death, at least six of the following symptoms are experienced on more days than not and to a clinically significant degree, and have persisted for at least 12 months after the death in the case of bereaved adults and more than 6 months for bereaved children:</td>
</tr>
<tr>
<td>Reactive distress to the death</td>
</tr>
<tr>
<td>1. Marked difficulty accepting the death. In children, this is dependent on the child’s capacity to comprehend the meaning and permanence of death.</td>
</tr>
<tr>
<td>2. Experiencing disbelief or emotional numbness over the loss.</td>
</tr>
<tr>
<td>3. Difficulty with positive reminiscing about the deceased.</td>
</tr>
<tr>
<td>4. Bitterness or anger related to the loss.</td>
</tr>
<tr>
<td>5. Maladaptive appraisals about oneself in relation to the deceased or the death (e.g., self-blame).</td>
</tr>
<tr>
<td>6. Excessive avoidance of reminders of the loss (e.g., avoidance of individuals, places, or situations associated with the deceased; in children, this may include avoidance of thoughts and feelings regarding the deceased).</td>
</tr>
<tr>
<td>Social/identity disruption</td>
</tr>
<tr>
<td>7. A desire to die in order to be with the deceased.</td>
</tr>
<tr>
<td>8. Difficulty trusting other individuals since the death.</td>
</tr>
<tr>
<td>9. Feeling alone or detached from other individuals since the death.</td>
</tr>
<tr>
<td>10. Feeling that life is meaningless or empty without the deceased, or the belief that one cannot function without the deceased.</td>
</tr>
<tr>
<td>11. Confusion about one’s role in life, or a diminished sense of one’s identity (e.g., feeling that a part of oneself died with the deceased).</td>
</tr>
<tr>
<td>12. Difficulty or reluctance to pursue interests since the loss or to plan for the future (e.g., friendships, activities).</td>
</tr>
<tr>
<td>D. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.</td>
</tr>
<tr>
<td>E. The bereavement reaction is out of proportion to or inconsistent with cultural, religious, or age-appropriate norms.</td>
</tr>
<tr>
<td>Specify if:</td>
</tr>
<tr>
<td>With traumatic bereavement: Bereavement due to homicide or suicide with persistent distressing preoccupations regarding the traumatic nature of the death (often in response to loss reminders), including the deceased’s last moments, degree of suffering and mutilating injury, or the malicious or intentional nature of the death.</td>
</tr>

to as delayed grief. This pattern is marked by prolonged denial; anger and guilt may complicate its course.

**Traumatic Bereavement.** Traumatic bereavement refers to grief that is both chronic and hypertrophic. This syndrome is characterized by recurrent, intense pangs of grief with persistent yearning, pining, and longing for the deceased; recurrent intrusive images of the death; and a distressing admixture of avoidance and preoccupation with reminders of the loss. Positive memories are often blocked or excessively sad, or they are experienced in prolonged states of reverie that interfere with daily activities. A history of psychiatric illness appears to be common in this condition, as is a very close, identity-defining relationship with the deceased person.

**Medical or Psychiatric Illnesses Associated with Bereavement.** Medical complications include exacerbations of existing diseases and vulnerability to new ones; fear for one’s health and more trips to the doctor; and an increased mortality rate, especially in men. The highest relative mortality risk is found immediately after bereavement, particularly from ischemic heart disease. The greatest effect of bereavement on mortality is for men younger than 65 years. Higher mortality rates in bereaved men than in bereaved women are due to increases in the relative risk of death by suicide, accident, cardiovascular disease, and some infectious diseases. In widows, the relative risk of death from cirrhosis and suicide may increase. In both sexes, bereavement appears to exacerbate health-compromising behaviors, such as increased alcohol consumption, smoking, and the use of over-the-counter medications.

Psychiatric complications of bereavement include an increased risk for major depressive disorder, prolonged anxiety, panic, and a posttraumatic stress–like syndrome; increased alcohol, drug, and cigarette consumption; and an increased risk of suicide. Because of their psychosocial, emotional, and cognitive immaturity, bereaved children may be especially vulnerable to psychopathology.

**Bereavement and Depression.** Although symptoms overlap, grief can be distinguished from a full depressive episode. Most bereaved individuals experience intense sadness, but only a few meet DSM-5 criteria for major depressive episode. Grief is a complex experience in which positive emotions take their place beside the negative ones. Grief is fluid and changing, an evolving state in which emotional intensity gradually lessens and positive, comforting aspects of the lost relationship come to the fore. Pangs of grief are stimulus bound, related to internal and external reminders of the deceased person. This differs from depression, which is more pervasive and characterized by much difficulty experiencing self-validating, positive feelings. Grief is a fluctuating state with individual variability, in which cognitive and behavioral adjustments are progressively made until the bereaved individual can hold the deceased person in a comfortable place in memory and a satisfying life can be resumed. By contrast, major depressive episode consists of a recognizable and stable cluster of debilitating symptoms accompanied by a protracted, enduring low mood. Major depressive episode tends to be persistent and associated with poor work and social functioning, pathological psychoneuroimmunological function, and other neurobiological changes, unless treated.

**Bereavement and Posttraumatic Stress Disorder.** Unnatural and violent deaths, such as homicide, suicide, or death in the context of terrorism, are much more likely to precipitate PTSD in surviving loved ones than are natural deaths. In such circumstances, themes of violence, victimization, and volition (i.e., the choice of death over life, as in the case of suicide) are intermixed with other aspects of grief, and traumatic distress marked by fear, horror, vulnerability, and disintegration of cognitive assumptions ensues. Disbelief, despair, anxiety symptoms, preoccupation with the deceased person and the circumstances of the death, withdrawal, hyperarousal, and dysphoria are more intense and more prolonged than they are under nontraumatic circumstances, and an increased risk may exist for other complications. Although treatment studies in survivors of sudden death are few and far between, most experts agree that initial attention should be focused on traumatic distress, that a role is seen for both pharmacotherapy and psychotherapy, and that self-help support groups can be enormously beneficial.

**Biological Perspectives**

Grief is both a physiological and an emotional response. During acute grief (as with other stressful events), persons may experience disruption of biological rhythms. Grief is also accompanied by impaired immune functioning, including decreased lymphocyte proliferation and impaired functioning of natural killer cells. Whether the immune changes are clinically significant has not been established, but the mortality rate for widows and widowers following the death of a spouse is higher than that in the general population. Widowers appear to be at risk longer than widows.

**Phenomenology of Grief.** Bereavement reactions include intense feeling states; invoke a variety of coping strategies; and lead to alterations in interpersonal relationships, biopsychosocial functioning, self-esteem, and world view that can last indefinitely. Manifestations of grief reflect the individual’s personality, previous life experiences, and past psychological history; the significance of the loss; the nature of the bereaved person’s relationship with the deceased person; the existing social network; intercurrent life events; health; and other resources. Despite individual variations in the bereavement process, investigators have proposed grieving process models, which include at least three partially overlapping phases or states: (1) initial shock, disbelief, and denial; (2) an intermediate period of acute discomfort and social withdrawal; and (3) a culminating period of restitution and reorganization. As with Kübler-Ross’ stages of dying, the grieving stages do not prescribe a correct course of grief; rather, they are general guidelines describing an overlapping and fluid process that varies with the survivors (Table 34.1–4).

**LIFE CYCLE PERSPECTIVES ABOUT BEREAVEMENT**

**Bereavement During Childhood and Adolescence**

Approximately 4 percent of North American children lose one or both parents by the age of 15 years; sibling death is the second most commonly experienced bereavement. Grief reactions
are colored by developmental levels and concepts of death and may not resemble adult reactions. Children may display minimal grief at time of death and experience the full effect of the loss later. Grieving children may not withdraw and dwell on the person who died, but instead, may throw themselves into activities. Indifference, anger, or misbehavior may be displayed rather than sadness; behaviors can be erratic and labile. Strong feelings of anger and fears of abandonment or death may show up in the behavior of grieving children. Children often play death games as a way of working out their feelings and anxieties. These games are familiar to the children and provide safe opportunities to express their feelings. Although they may seem to show grief only occasionally and briefly, in reality, a child's grief often lasts longer than that of an adult.

Mourning in children may need to be addressed again and again as the child gets older. Children will think about the loss repeatedly, especially during important times in their lives, such as going to camp, graduating from school, getting married, or giving birth to their own children. A child's grief can be influenced by his or her age, personality, developmental stage, earlier experiences with death, and relationship with the deceased person. The surroundings, cause of death, and family members' ability to communicate with one another and to continue as a family after the death can also affect grief. The child's ongoing need for care, his or her opportunity to share feelings and memories, the parent's ability to cope with stress, and the child's steady relationships with other adults are other factors that may influence grief. Even older children frequently feel abandoned or rejected when a parent dies and may show hostility toward the deceased or the surviving parent, now perceived as one who might also "abandon" them. They may feel responsible because of earlier misbehavior or because they said or wished that that person would die at some time.

Children younger than 2 years may show loss of speech or diffuse distress. Children younger than 5 years are apt to respond with eating, sleeping, and bowel and bladder dysfunc-

**Bereavement During Adulthood**

No consensus exists on which type of loss is associated with the most severe reactions. Although the death of a spouse is often ranked as the most stressful life event, some have argued that losing a child is even more profound. The death of a child is a special sorrow, a lifelong loss for surviving mothers, fathers, brothers, sisters, grandparents, and other family members. A child's death is a life-altering experience. The deaths of parents and siblings in adult life have not achieved much systematic study, but they are generally considered relatively mild compared with the loss of a spouse or child.

Grief appears most intense for the mother in late perinatal losses (stillbirths or neonatal deaths rather than miscarriages) and often is reexperienced during subsequent pregnancies. Sudden infant death syndrome is particularly problematic in that the death is sudden and unexpected. Parents may experience extra guilt or blame each other, often resulting in subsequent marital difficulties.

The surviving family members, friends, or lovers of individuals who have died from acquired immunodeficiency syndrome (AIDS) are uniquely challenged. The illness carries with it the stigmata of the illness itself and of the gay community in general; it carries with it caretakers' fears of contracting the illness; and it is most prevalent in people who are in the prime of life. Asymptomatic infection may permit the infected person and those close to him or her time to adapt to the diagnosis. When a person who is human immunodeficiency virus (HIV) positive begins to manifest symptoms of opportunistic infection or associated cancer, however, the illness again becomes a threat. Coping with the emotional reality is arduous and complex. Often caretakers, as well as HIV-positive patients, wish for death, which can evoke feelings of guilt. For bereaved lovers, their own HIV status, multiple losses, and other concurrent stressors can complicate recovery. Gay men who have lost lovers to AIDS may be more depressed, consider suicide more often, and be more vulnerable to illicit drug use than are other bereaved individuals.
Elderly adults face more losses than individuals at other phases of the life cycle, and intense loneliness may be a lasting memorial to those who have died. For highly impaired elders who lose a spouse they depended on for daily functions or who was their sole source of companionship, bereavement reactions are profound.

**Grief Therapy**

Persons in normal grief seldom seek psychiatric help because they accept their reactions and behavior as appropriate. Accordingly, a bereaved person should not routinely see a psychiatrist or psychologist unless a markedly divergent reaction to the loss is noted. For example, under usual circumstances, a bereaved person does not make a suicide attempt; if someone seriously contemplates suicide, psychiatric intervention is indicated.

When professional assistance is sought, it usually involves a request for sleeping medication from a family physician. A mild sedative to induce sleep may be useful in some situations, but antidepressant medication or anxiolytic agents are rarely indicated in normal grief. Bereaved persons may have to go through the mourning process, however painful it is, for successful resolution to occur. Narcotizing patients with drugs interferes with the normal process that ultimately can lead to a favorable outcome.

Because grief reactions can develop into a depressive disorder or pathological mourning, specific counseling sessions for bereaved individuals are often valuable. Grief therapy is an increasingly important skill. In regularly scheduled sessions, grieving persons are encouraged to talk about feelings of loss and about the person who has died. Many bereaved persons have difficulty recognizing and expressing angry or ambivalent feelings toward a deceased person, and they must be reassured that these feelings are normal.

Grief therapy need not be conducted only on a one-to-one basis; group counseling is also effective. Self-help groups also have great value in certain cases. About 30 percent of widows and widowers report that they become isolated from friends, withdraw from social life, and thus experience feelings of isolation and loneliness. Self-help groups offer companionship, social contacts, and emotional support; they eventually enable their members to reenter society in a meaningful way. Bereavement care and grief therapy have been most effective with widows and widowers. The necessity for this therapy stems, in part, from the contraction of the family unit; extended family members are no longer available to provide the needed emotional support and guidance during the mourning period.

**34.2 Palliative Care**

Psychological symptoms are nearly universal at the end of life. Psychiatric syndromes occur with an increased but definable frequency and have a different age and gender distribution. For example, anxiety and depression are as common in men as in women. Psychiatric classification remains an important framework on which to base clinical observations, but it was not designed with dying patients in mind. Hence, for such patients, it is pragmatically useful to think of a few syndromes for which this exists. The most common ones are anxiety states, depressive states, and confusional states. These frequently coexist and overlap. Rarely, specific phobias of needles, enclosures, and the like may interfere with comfort and should be addressed, adapting the usual treatments to the patient's medical status. Occasionally, an emotional crisis or exacerbation of symptoms can be identified as an adjustment disorder, but it is occurring against the backdrop of other serious symptoms, so technically it does not meet diagnostic criteria. However, this should not prevent the consultant from identifying the precipitating factor and defusing the response in the usual ways. Major psychotic disorders become submerged by the increasing symptomatology of the active dying process and only require specific attention when the patient is not actively dying and when the psychotic symptoms are clearly separate from and superimposed on the symptoms of the illness.

**PREVALENCE**

Much of the research on prevalence has been done in cancer and AIDS and shows a marked increase of psychiatric conditions near the end of life. Severe depressive symptoms rose from 25 to 77 percent in a sample of hospitalized cancer patients, although stricter criteria find 15 percent with major depression and another 15 percent having severe depressive symptoms. The prevalence of delirium rises from a range from 25 to 40 percent to as high as 85 percent with increasingly advanced disease. The association of psychiatric symptoms with pain was demonstrated in one of several consistent studies in which 39 percent of patients with a psychiatric diagnosis reported significant pain compared with 19 percent for those without a psychiatric diagnosis. In a sample of inpatients with AIDS, 65 percent had an organic mental disorder,
and 27 percent had major depression. The financial cost of psychiatric disorders can be inferred from a study in which patients with a psychiatric diagnosis remained in the hospital 60 days longer than those without a psychiatric diagnosis.

Most commonly, terminally ill patients demonstrate an intertwining of anxiety and depression. These are difficult to tease apart, and the term negative affect has been suggested to define them as a symptom complex. It is hard not to feel grief at what is being lost and fear about the ultimate unknown. Individuals whose deep faith in an afterlife animates their spirit are an exception, and, even among them, many describe coexisting regret at the loss of their temporal life and its furnishings.

GENERAL TREATMENT PRINCIPLES

Because improved quality of life is the primary goal, pharmacological treatment and any other measures that bring symptom relief should be instituted rapidly while an integrated plan for psychological and family interventions is being designed and set into motion. Psychiatric syndromes in this group are often secondary to medical conditions; hence, an etiological diagnosis often yields useful clues to prevention and improved management. It should be sought simultaneously as long as the search is in line with treatment goals.

ANXIETY IN PATIENTS WITH ADVANCED DISEASE

Anxiety can be the presenting symptom for almost all medical disorders and can occur as a side effect from many medications. However, in patients with advanced disease, it usually presents with somatic symptoms, such as restlessness, hyperactivity, tachycardia, gastrointestinal (GI) distress, nausea, insomnia, shortness of breath, numbness, or tremor. It lowers the threshold for pain, worsens functional impairment, and increases the distress experienced in all comorbid conditions. It often interferes with the patient’s ability to cooperate with other treatments or to relate optimally with loved ones. Patients refer to fear, worry, apprehension, or ruminations more often than to anxiety per se.

Mr. S, a 50-year-old physical therapist with newly diagnosed advanced lung cancer, was noted by his family to be anxious to the point of having panic symptoms when his wife would leave his bedside to attend to chores. He would start hyperventilating, would feel short of breath, would become restless and unable to concentrate on anything, and would be overwhelmed with morbid ruminations about his future. He was upset and felt guilty at having become overly dependent on his wife. He was taught relaxation and breathing exercises and was treated with clonazepam (Klonopin), which brought about a marked resolution of his anxiety. Mr. S felt more relaxed, less anxious, and more resilient and became able to withstand periods of solitude without difficulty. (Courtesy of Marguerite Lederberg, M.D.)

DEPRESSION IN PATIENTS WITH ADVANCED DISEASE

Depressive symptoms are also common in advanced disease and are associated with the same existential factors found with anxiety. Studies have found a prevalence ranging from 9 percent, using the strictest criteria, to 58 percent, with less demanding ones. Risk factors include a previous history or a family history. Having a way of differentiating somatic effects of disease from the neurovegetative criteria of major depression is especially daunting in terminally ill patients.

Table 34.2-1 describes the Endicott Substitution Criteria, which have been found to perform as well as the DSM criteria for depression and go further in that they also reflect the clinical observation that classically described depressive thoughts and feelings are not universal in terminally ill patients and, when present, reflect depression just as they do in physically healthy patients.

Although there are not many studies on the treatment of depression in terminally ill individuals, the available studies and a large body of clinical experience with medically ill patients show that the pharmacological treatment of depression can be useful even when definable medical causes exist and even in the last days of life.

A patient with diabetes and end-stage renal disease who had been on dialysis for 2 years was diagnosed with depression with marked insomnia and was started on 15 mg by mouth every day of mirtazapine, which helped her sleep immediately and showed an antidepressant effect within 3 weeks. Four weeks later, she was admitted to the hospital in congestive heart failure for what was to be her terminal admission. She did not wish to give up the antidepressant but now felt oversedated and wished that she could be more alert during the day to interact with her loved ones. She was started on methylphenidate 5 mg by mouth twice daily, after which she was more alert, engaged, and communicative with her family. On her death, her family was grateful to have been able to connect with her until the end.

CONFUSIONAL STATES IN PATIENTS WITH ADVANCED DISEASE

The prevalence of delirium rises to 85 percent in patients with advanced disease. If one includes the last hours of life, it nears 100 percent unless the patient lapses rapidly into coma or dies of an acute event, such as pulmonary embolus. Acute events are always unexpected and traumatize the survivors even though they knew full well that the patient was near the end of life. Some patients slip into an irreversible coma, leaving families in a bedside vigil, which may actually give them a period of adaptation before the final instant of death. However, for some
75 to 85 percent of patients, death is associated with a period of delirium.

Patients frequently experience some disorientation, impaired memory, concentration, and altered arousal as they become increasingly ill. These symptoms may remain mild or may be the harbingers of full delirium. Clinicians should be aware that mild and early signs of delirium are often mistaken for depression, anxiety, and poor coping.

A psychiatric consultation was sought to evaluate depression in a 56-year-old practicing attorney with pancreatic cancer. His moderately severe back pain was being treated with morphine. The patient was noted by the inpatient staff to be more withdrawn, disengaged, and quiet, making poor eye contact and sleeping most of the day.

On examination, the psychiatric consultant found Mr. K to have disturbed arousal and to be mildly confused and disoriented. His speech was slow and his thought process disorganized. Mr. K admitted to intermittently experiencing visual hallucinations that he had been too embarrassed to report earlier to the nursing staff.

Mr. K was diagnosed with a hypoactive delirium secondary to opioid medications. He was treated with a low dose of olanzapine, 2.5 mg at bedtime. Mr. K’s sensorium improved dramatically. He became alert, fully oriented, and better related, without any perceptual disturbances or thought disorder. This was accomplished without needing to decrease his much needed pain medications.

DISEASE-SPECIFIC CONSIDERATIONS

Different illnesses bring special issues. For example, a patient on dialysis can opt for death three times a week and is more vulnerable to acting on feelings of depression, anger, hopelessness, and reactions to family neglect or conflict. Patients with cancer must acknowledge possible death while hoping for a cure or remission. Treatment decisions in the face of disease that is less and less treatable become increasingly difficult and can cause acute anxiety. Stem cell transplant patients experience high levels of anxiety and depression because they are getting a last chance with high stakes and high risks. The availability of organ transplants has created a large population of patients who wait knowing that they may die while waiting for a cure that could be just around the corner. Neurodegenerative disorders are associated with increasing physical disability and dependence. When there is associated loss of cognitive faculties, the problems may be behavioral. Otherwise, depression is a frequent, although not inevitable, problem. Many patients state that they will not tolerate complete immobility and dependence, yet when the time comes, they go on life supports and stay on them. It has been shown in several settings that as patients become sicker, they accept an increasingly limited quality of life as worth living and opt for more onerous, less promising treatments if they offer even a small chance of help.

PATIENT–FAMILY UNIT

The intensity of family relationships becomes even greater during the terminal period. The response of family members can be a conspiracy of silence. Nothing is sadder than a bedside where family members are tense and silent because they want to protect the patient by not talking about dying and the patient is tense and silent because he or she is protecting the family by not talking about things that will upset them. Instead of closeness, expressions of gratitude, apologies, reminiscences, and farewells, there is distance, and the patient is dying alone even though he or she is physically surrounded by others.

The psychiatrist can use family sessions to open patient–family dialogues. He or she can identify discrepant views of the illness, can deal with conflicts regarding treatment, and can explore concerns regarding an absent member, all of which undermine patient support and medical management. A major crisis, such as the imminent loss of a member, destabilizes the family structure, creating an opportunity for the psychiatrist to promote adaptive change and reconstitution. Family-centered grief therapy, which initially includes the patient and continues after the patient’s death, provides a natural setting for such interventions.

When an older adolescent dropped out of college to take over her dying mother’s duties, the family subtly discouraged her return to school after her mother’s death. Psychiatric intervention allowed the patient to play a part in reorganizing family roles in a way that made it more possible for her daughter to continue her studies.

DECISION POINTS, ADVANCE DIRECTIVES, PROXIES, AND SURrogATES

This section reviews transitions and decisions that characterize the end of life.

Transition to Palliative Care

The transition to palliative care is not always clear. As soon as a diagnosis of an incurable disease is made, cure is no longer the goal of care. However, if death is distant or even if some life extension can still be obtained, the patient and family focus on this positive goal. The physician is under no illusion about the future but has the delicate task of promoting short-term gains without obliterating the awareness of what lies ahead. Only when the nearness of death is acknowledged can thoughtful decisions be made about palliative care.

Where to Die?

Unattended Deaths. Many traumatic or unexpected deaths become known from a catastrophic phone call. The patient is gone, but the traumatized family needs help to absorb the loss, to cope with the circumstances, and to come to some kind of closure. It is not realized how much the experience of living through the illness, the death, and the funeral rites is crucial to the normal resolution of the mourning process.

A totally unexpected death, even an understandable one, such as a heart attack, leaves an aching sense of unfinished business over and above the expected grief. If the person was the victim of a crime, obsessive thoughts may be difficult to repress, and grief may turn to unquenchable anger with profound psychological disruption. It is also difficult, if not impossible, for survivors to make peace with suicide.
Emergency departments, police departments, and religious and community institutions should be equipped with a list of referral resources to help survivors of traumatic deaths. Psychiatric input can include program development and consultation to a wide range of professionals and individuals. Families must be helped to construct their own rituals whereby they acknowledge to themselves and others the finality of their loss and perhaps create a place, if not a grave, around which to center their memorializing.

**Attended Deaths.** Patients can die in an acute hospital, in nursing homes, in hospices, and at home, with or without hospice support. Many patients still die in acute care hospitals, having received active care until shortly before they die. This may occur because death is sudden or because the family or patient needed to be in a place where “everything is being done.” Fortunately, a growing number of hospitals have palliative care teams that provide appropriate care in the acute hospital setting.

Many patients die in nursing homes without the benefit of special care. This unfortunate situation could be remedied by bringing formal hospice care into nursing homes, but funding sources and turf issues need to be settled before it can become routine practice.

Inpatient hospice care was the first model of care to be developed and is warmly remembered by grateful families whose multiple human needs and those of their loved one had been met in ways that they had not been trained to expect. As hospice gained acceptance, the insufficiency of inpatient beds encouraged the development of home hospice. Its existence has, in turn, encouraged more families to elect to keep dying patients at home.

In a home hospice program, the patient is evaluated and accepted in the usual manner but stays at home. The patient and family receive extensive instruction about what to expect. They are helped to obtain necessary materials, taught how to use them, and helped to obtain as much home help as they need. All the while, they receive medical supervision, nursing care, and emotional support with 24-hour phone availability and routine daily contacts.

Without this kind of help, a good death at home can be difficult to achieve. With it, patients feel safe from the abandonment that is so commonly feared, and families feel safe from the terror of an unmanageable event. The families of these patients work hard, but they are more likely to feel competent and in control. They experience more of a sense of achievement and less of the gnawing sense of inadequacy that is otherwise common.

**CARING FOR THE DYING PATIENT**

Marguerite S. Lederberg, M.D., at Memorial Sloan-Kettering Cancer Center in New York makes the following observation:

A dying human being whose physical, social, emotional, and spiritual needs are being effectively attended to seldom demands to be helped to commit suicide, and the family members—given proper help and support—derive a deep sense of peace from having helped their loved one to die feeling loved and secure.

One of the most important tasks for a physician caring for a dying patient is to determine when the time for curative care has ceased. It is only then that palliative care can begin. Some physicians are so upset by death that they are reluctant to use palliative methods; rather, they continue to treat the patient knowing that efforts are futile. Or they resort to using so-called heroic methods that do not prevent death and that may produce needless suffering. Ideally, physicians should strive to extend life and decrease suffering; at the same time, they must accept death as a defining characteristic of life. Some physicians, however, have developed dysfunctional attitudes about death, which have been reinforced throughout their lives by their experiences and training. It has been postulated that doctors are more frightened of death than members of other professional groups and that many enter the study of medicine so they may gain control of their own mortality using the defense mechanism of intellectualization. Risk factors that can interfere with a physician’s ability to care optimally for dying patients are listed in Table 34.2-2. These factors range from overidentifying with the patient to being fearful of death as mentioned.

Physicians able to deal with death and dying are able to communicate effectively in several areas: diagnosis and prognosis, the nature of terminal illness, advance directives about life-sustaining treatment, hospice care, legal and ethical issues, grief and bereavement, and psychiatric care. In addition, palliative care physicians must be skilled in pain management, especially in the use of powerful opioids—the gold standard of drugs used for pain relief. In 1991, the American Board of Pain Medicine was established to ensure that physicians treating patients in pain were both qualified to do so and were kept up to date on the latest advances in the field.

**COMMUNICATION**

After a diagnosis and prognosis have been made, physicians need to talk to the patient and the patient’s family. Formerly, doctors subscribed to a conspiracy of silence, believing that their patient’s chances for recovery would improve if they knew less because news of impending death might bring despair. The current practice is now one of honesty and openness toward patients; in fact, the question is not whether to tell the patient but when and how. In 1972, the American Hospital Association drafted the Patient’s Bill of Rights, declaring that patients have the “right to obtain complete, current information regarding diagnosis, treatment and prognosis in terms the patient can be reasonably expected to understand.”

Breaking Bad News

When breaking news of impending death to the patient, as when relating any bad news, diplomacy and compassion should be the guiding principles. Often, bad news is not completely related during one meeting but rather is absorbed gradually over a series of separate conversations. Advance preparations, including scheduling sufficient time for the visit; researching pertinent information, such as test results and facts about the case; and even arranging furniture appropriately can only make the patient feel more comfortable.

If possible, these conversations should take place in a private, suitable space with the patient on equal terms with the physician (i.e., the patient dressed and the physician seated). If it is possible and desired by the patient, the patient’s spouse or partner should be present. The treating physician should explain the current situation to the patient in clear, simple language even when speaking to highly educated patients. Information may need to be repeated or additional meetings may be necessary to communicate all of the information. A gentle, sensible approach will help modulate the patient’s own denial and acceptance. At no time should physicians take their patient’s angry comments personally, and they should never criticize the patient’s response to the bad news.

Physicians can signal their availability for honest communication by encouraging and answering questions from patients. Estimates on how long a patient has to live are usually inaccurate and thus should not be given, or given with that caveat. Also, physicians should make it clear to their patients that they are willing to see them through until death occurs. Ultimately, physicians must choose how much information to give and when on the basis of each patient’s needs and capacities.

The same general approaches apply as physicians seek to comfort members of the patient’s family. Helping family members deal with feelings about the patient’s illness can be just as important as comforting the patient because family members are often the main source of emotional support for patients.

Telling the Truth

Tactful honesty is the doctor’s most important aid. Honesty, however, need not preclude hope or guarded optimism. It is important to be aware that if 85 percent of patients with a particular disease die in 5 years, 15 percent are still alive after that time. The principles of doing good and not doing harm inform the decision of whether to tell the patient the truth. In general, most patients want to know the truth about their condition. Various studies of patients with malignancies show that 80 to 90 percent want to know their diagnosis.

Doctors, however, should ask patients how much they want to know because some persons do not want to know all the facts about their illness. Such patients, if told the truth, deny that they ever were told, and they cannot participate in end-of-life decisions, such as the use of life-sustaining equipment. The patients who openly request that they not be given “bad news” are often those who most fear death. Physicians should deal with these fears directly, but if the patient still cannot bear to hear the truth, someone closely related to the patient must be informed.

Informed Consent

In the United States, informed consent is legally required for both conventional and experimental treatment. Patients must be given sufficient information about their diagnosis, prognosis, and treatment options to make knowledgeable decisions. This includes discussion of potential risks and benefits, available alternative treatments, and the results of not receiving treatment. This approach may come at some psychological cost; severe anxiety and occasional psychiatric decompensation can occur when patients feel overburdened by demands to make decisions. Nevertheless, patients respond best to doctors who explain the various options in detail. Physicians must be prepared to deal with difficult questions posed by patients. Some of them are listed in Table 34.2-3.

When dealing with patients’ end-of-life decisions, the physician must be aware of the patient’s previous wishes and the patient’s current ability to make decisions. It is important to be aware that a patient who is not aware of the full extent of their condition may be able to make decisions about their care. It is also important to be aware that a patient who is aware of the full extent of their condition may be able to make decisions about their care. It is important to be aware that a patient who is not aware of the full extent of their condition may be able to make decisions about their care. It is important to be aware that a patient who is not aware of the full extent of their condition may be able to make decisions about their care.

TERMINAL CARE DECISIONS

Modern society is poorly equipped to cope with the life-and-death decisions spawned by technology. When it first emerged, cardiopulmonary resuscitation was enthusiastically supported by the medical profession. It was endowed with magical power and eventually became a ritualized rite rather than an optional medical treatment. That practice played into the therapeutic activism characteristic of many physicians. By the end of the 20th century, however, a countermovement began. First, the right to refuse treatment was established, largely because of synergy between the consumer movement and the bioethics movement, with its emphasis on patient autonomy. Next, the legality of DNR orders and the moral equivalence of stopping and not starting treatment were established. The medical profession was less enthusiastic than the public about these changes, perhaps because practitioners know too well the emotional ambiguities that surround death and must repeatedly experience them.

Brain Death and Persistent Vegetative State

In an attempt to deal with these ambiguities, the concept of brain death emerged. Brain death is associated with the loss of higher brain functions (e.g., cognition) and all brain stem function (e.g., pupillary and reflex eye movement), respiration, and gag and corneal reflexes. Determination of brain death is generally accepted criterion for death. Some clinicians advocate an absence of brain waves on electroencephalography (EEG) to confirm the diagnosis.

Persistent vegetative state was defined by the American Academy of Neurology as a condition in which no awareness exists of self or environment associated with severe neurological
petent gives specific instructions that doctors must follow when the patient cannot communicate them because of illness. These orders may include rejection of feeding tubes, artificial airways, and any other measures to prolong life.

In 1976, the case of Karen Quinlan made international headlines when her parents sought the assistance of a judge to discontinue the use of a ventilator in their daughter, who was in a persistent vegetative state. Ms. Quinlan’s physician had refused her parents’ request to remove the ventilator because, they said, they feared that they might be held civilly or even criminally liable for her death. The New Jersey Supreme Court ruled that competent persons have a right to refuse life-sustaining treatment and that this right should not be lost when a person becomes incompetent. Because the Court believed that the physicians were unwilling to withdraw the ventilator because of the fear of legal liability, not precepts of medical ethics, it devised a mechanism to grant the physicians prospective legal immunity for taking this action. Specifically, the New Jersey Supreme Court ruled that after a prognosis, confirmed by a hospital ethics committee, that “no reasonable possibility of a patient returning to a cognitive, sapient state,” exists, life-sustaining treatment can be removed, and no one involved, including the physicians, can be held civilly or criminally responsible for the death.

The publicity surrounding the Quinlan case motivated two independent developments: It encouraged states to enact “living will” legislation that provided legal immunity to physicians who honored patients’ written “advance directives” specifying how they would want to be treated if they ever became incompetent, and it encouraged hospitals to establish ethics committees that could attempt to resolve similar treatment disputes without going to court. (Annas GJ. “Culture of life” politics at the bedside. N Engl J Med. 2005;352:16.)

**Advance Directives**

Advance directives are wishes and choices about medical intervention when the patient’s condition is considered terminal. Advance directives, which are legally binding in all 50 states, include three types: living will, health care proxy, and DNR and DNI orders.

**Living Will.** In a living will, a patient who is mentally competent gives specific instructions that doctors must follow when the patient cannot communicate them because of illness. These instructions may include rejection of feeding tubes, artificial airways, and any other measures to prolong life.

**Health Care Proxy.** Also known as durable power of attorney, the health care proxy gives another person the power to make medical decisions if the patient cannot do so. That person, also known as the surrogate, is empowered to make all decisions about terminal care on the basis of what he or she thinks the patient would want.

**Do Not Resuscitate and Do Not Intubate Orders.** These orders prohibit doctors from attempting to resuscitate (DNR) or intubate (DNI) the patient who is in extremis. DNR and DNI orders are made by the patient who is competent to do so. They can be made part of the living will or expressed by the health care proxy. A sample advance directive that incorporates both a living will and a health care proxy is given in Table 34.2-5.

The Uniform Rights of the Terminally Ill Act, drafted by the National Conference on Uniform State Laws, was approved and recommended for enactment in all states. This act authorizes an adult to control the decisions regarding the administration of life-sustaining treatment by executing a declaration instructing a physician to withhold or to withdraw life-sustaining treatment if the person is in a terminal condition and cannot participate in medical treatment decisions. In 1991, the Federal Patient Self-Determination Act became law in the United States and required that all health care facilities (1) provide each patient admitted to a hospital with written information about the right to refuse treatment, (2) ask about advance directives, and (3) keep written records of whether the patient has an advance directive or has designated a health care proxy.

Today, patients who have left no advance directives or who are legally incompetent to do so have access to hospital ethics committees that hold active legal and ethical debates about these issues. These ethics committees are also of help to doctors, who can gain both legal and moral support when recommending that no further treatment occur. It is much easier for all parties, however, if the patient has advance directives or a proxy. Ideally, physicians should initiate discussions with patients about advance directives and proxies early even while the patient is healthy. The patient should be reminded that these early formulations can be modified but that even having preliminary advance directives will ensure that treating physicians observe the patient’s wishes in the event of an emergency.

**CARING FOR THE FAMILY**

Family members play an important role as caregivers to terminally ill patients and have needs of their own that often go unrecognized. Their responsibilities can be overwhelming, especially if only one family member is available or if family members themselves are infirm or elderly. Table 34.2-6 lists some family caregiving tasks. Many of these tasks require long hours of work or supervision that can lead to physical and emotional fatigue. One study of caregivers reports that 25 to 30 percent lost their jobs and more than half moved to lower paying jobs to accommodate the need for flexibility. The highest stress level was found in families who cared for a terminally ill patient at home, especially when death occurs in the home, and realized in retrospect that they would have preferred an environment in which death occurs in the presence of skilled caretakers.
Table 34.2-5
Advance Directive Living Will and Health Care Proxy

Death is a part of life. It is a reality like birth, growth, and aging. I am using this advance directive to convey my wishes about medical care to my doctors and other people looking after me at the end of my life. It is called an advance directive because it gives instructions in advance about what I want to happen to me in the future. It expresses my wishes about medical treatment that might keep me alive. I want this to be legally binding.

If I cannot make or communicate decisions about my medical care, those around me should rely on this document for instructions about measures that could keep me alive.

I do not want medical treatment (including feeding and water by tube) that will keep me alive if:

- I am unconscious and there is no reasonable prospect that I will ever be conscious again (even if I am not going to die soon in my medical condition), or
- I am near death from an illness or injury with no reasonable prospect of recovery.

I do want medicine and other care to make me more comfortable and to take care of pain and suffering. I want this even if the pain medicine makes me die sooner.

I want to give some extra instructions: ([Here list any special instructions, e.g., some people fear being kept alive after a debilitating stroke. If you have wishes about this, or any other condition, please write them here.]

The legal language in the box that follows is a health care proxy. It gives another person the power to make medical decisions for me.

I _________________________________ name

who _______________________________ lives at

phone number ________________________, to make medical decisions for me if I cannot make them myself. This person is called a health care “surrogate,” “agent,” “proxy,” or “attorney in fact.” This power of attorney shall become effective when I become incapable of making or communicating decisions about my medical care. This means that this document stays legal when and if I lose the power to speak for myself, for instance, if I am in a coma or have Alzheimer’s disease.

My health care proxy has power to tell others what my advance directive means. This person also has power to make decisions for me based either on what I would have wanted, or, if this is not known, on what he or she thinks is best for me.

If my first choice health care proxy cannot or decides not to act for me, I name _________________________________, address ____________________, phone number ____________________, as my second choice.

I have discussed my wishes with my health care proxy and with my second choice if I have chosen to appoint a second person. My proxy(ies) has(have) agreed to act for me.

I have thought about this advance directive carefully. I know what it means and want to sign it. I have chosen two witnesses, neither of whom is a member of my family, nor will inherit from me when I die. My witnesses are not the same people as those I named as my health care proxies. I understand that this form should be notarized if I use the box to name a health care proxy(ies).

*The reader should be advised that this sample is one of many directives available. (From Choice in Dying, Inc.—the National Council for the Right to Die.)

Dying at Home

Depending on the patient’s wishes and the nature of his or her disease, the choice to die at home is one that should be explored. Although it is more burdensome on a family than dying in a hospital or hospice, death at home can be a welcome alternative for the patient and family seeking to spend quality time together. A home care team can assess a home for its suitability and suggest ways to facilitate activities of daily living, including modifications to furniture; hospital bed leasing; and installation of assistive devices, such as handrails and commodes. The family’s care can be supplemented with house calls by physicians, nurses, therapists, and chaplains. In any case, the family must know what their responsibilities are and must be well prepared to care for the patient. Recently, hospice home care was approved by Medicare and is being more widely used.
Table 34.2-6
Tasks of Family Members of Dying Individuals

1. Administering medications
2. Dealing with adverse effects of medications
3. Providing help with, or actually performing, activities of daily living
4. Changing wound dressing
5. Managing ambulatory infusion pumps or other equipment
6. Providing symptom management (e.g., for pain, nausea and vomiting, shortness of breath, seizures, and terminal agitation)
7. Notifying the nurse or doctor when they are needed
8. Shopping for needed items and picking up prescriptions
9. Providing a presence and companionship
10. Attending to spiritual and religious needs
11. Carrying out advance directives
12. Managing financial matters

Family therapy sessions allow family members to explore feelings about death and dying. They serve as a forum in which anticipatory grief and mourning can take place. The ability to share feelings can be cathartic, especially if guilt is involved. Family members often have to deal with feelings of guilt about past interactions with the dying patient. Family sessions also help to achieve consensus about the patient's advance directives. If family members disagree about the patient's wishes, the medical staff may be unable to act. In such cases, legal action may be needed to resolve family disputes about what course of action to pursue.

PALLIATIVE CARE

Palliative care is the most important part of end-of-life care. It refers to providing relief from the suffering caused by pain or other symptoms of terminal disease. Although this is most commonly associated with analgesic drug administration, many other medical interventions and surgical procedures fall under the umbrella of palliative care because they can make the patient more comfortable. Monitors and their alarms, peripheral and central lines, phlebotomy, measurement of signs, and even supplemental oxygen are usually discontinued to allow the patient to die peacefully. Relocating the patient to a quiet, private room (as opposed to an intensive care unit) and allowing family members to be present is another very important palliative care modality.

The shift from active, curative treatment to palliative care is often the first tangible sign that the patient will die, a transition that is emotionally difficult for everyone concerned about the patient to accept. The discontinuation of machines and measurements, which up until this point have been an integral part of the hospital experience, can be extremely disconcerting to the patient, family members, and even other physicians. Indeed, if these parties are not active in planning this transition, it can easily seem that persons have given up on the patient.

Because of this difficulty, palliative care is sometimes avoided altogether (i.e., curative treatment is continued until the patient dies). This approach is likely to cause problems if it is adopted merely to avoid the reality of impending death. A well-negotiated transition to palliative care often decreases anxiety after the patient and family go through an appropriate anticipatory grief reaction. Furthermore, a positive emotional outcome is much more likely if the physician and staff project a conviction that palliative care will be an active, involved process, without hint of withdrawal or abandonment. When this does not occur or when the family cannot tolerate the transition, the ensuing stress frequently results in a need for psychiatric consultation.

Psychiatric consultation is indicated for patients who become severely anxious, suicidal, depressed, or overtly psychotic. In each instance, appropriate psychiatric medication can be prescribed to provide relief. Patients who are suicidal do not always have to be transferred to a psychiatric service. An attendant or nurse can be assigned to the patient on a 24-hour basis (one-on-one coverage). In such instances, the relationship that develops between the observer and the patient may have therapeutic overtones, especially with patients whose depression is related to a sense of abandonment. Patients who are terminal and who are at high risk for suicide are usually in pain. When pain is relieved, suicidal ideation is likely to diminish. A careful evaluation of suicide potential is required for all patients. A premorbid history of past suicide attempts is a high risk factor for suicide in terminally ill patients. In patients who become psychotic, impaired cognitive function secondary to metastatic lesions to the brain must always be considered. Such patients respond to antipsychotic medications, and psychotherapy may also be of use.

PAIN MANAGEMENT

Types of Pain

Dying patients are subject to several different kinds of pain, summarized in Table 34.2-7. The distinctions are important because they call for different treatment strategies; whereas somatic and visceral pain are responsive to opiates, neuropathic and sympathetically maintained pain may require adjuvant medications in addition to opiates. Most patients with advanced cancer, for example, have more than one kind of pain and require complex treatment regimens.

Treatment of Pain

It cannot be overemphasized that pain management should be aggressive, and treatment should be multimodal. In fact, a good pain regimen may require several drugs or the same drug used in different ways and administered via different routes. For example, intravenous morphine can be supplemented by self-administered...
oral "rescue" doses, or a continuous epidural drip can be supplemented by bolus intravenous doses. Transdermal patches may provide baseline concentrations in patients for whom intravenous or oral intake is difficult. Patient-controlled analgesia systems for intravenous opiate administration result in better pain relief with lower amounts dispensed than in staff-administered dosing.

Opioids commonly cause delirium and hallucinations. A frequent mechanism of psychototoxicity is the accumulation of drugs or metabolites whose durations of analgesia are shorter than their plasma half-lives (morphine, levorphanol [Levo-Dromoran], and methadone [Dolophine]). Use of drugs such as hydromorphone (Dilaudid), which have half-lives closer to their analgesic duration, can relieve the problem without loss of pain control. Cross-tolerance is incomplete between opiates; hence, several should be tried in any patient with the dosage lowered when switching drugs. Table 34.2-8 lists opioid analgesics.

The benefits of maintenance analgesia administration in terminally ill patients compared with as-needed administration cannot be overemphasized. Maintenance dosing improves pain control, increases drug efficiency, and relieves patient anxiety, but as-needed orders allow pain to increase while waiting for the drug to be given. Moreover, as-needed analgesia administration perversely sets up the patient for staff complaints about drug-seeking behavior. Even when maintenance treatment is used, extra doses of medication should be available for breakthrough pain, and repeated use of these medications should signal the need to raise the maintenance dose. Depending on their previous experiences with opioid analgesics and their weight, it is not unusual for some patients to require 2 g or more of morphine per day for relief of symptoms.

Knowing doses of different drugs and different routes of administration is important to avoid accidental undermedication. For example, when
changing a patient from intramuscular to oral morphine use, the intramuscular dose must be multiplied by 6 to avoid causing the patient pain and provoking drug-seeking behavior. Many adjuvant drugs used for pain are psychotropics with which psychiatrists are familiar, but in some cases, their analgesic effect is separate from their primary psychotropic effect. Commonly used adjuvants include antidepressants, mood stabilizers (e.g., gabapentin) phenothiazines, butyrophenones, antihistamines, amphetamines, and steroids. They are particularly important in neuropathic and sympathetically maintained pain, for which they can be the mainstay of treatment.

Other developments in pain management include more intrusive procedures, such as nerve blocks or the use of continuous epidural infusions. Additionally, radiation therapy, chemotherapy, and even surgical resection can be considered as pain management modalities in palliative care. Short courses of radiotherapy or chemotheraphy can be used to shrink tumors or manage metastatic lesions that cause pain or impairment. In patients with end-stage Hodgkin's disease, for example, systemic chemotheraphy can improve the patient's quality of life by decreasing tumor burden. Surgical resection of invasive tumors, most notably breast carcinomas, can be useful for the same reason.

PALLIATION OF OTHER SYMPTOMS

Symptom management is a high priority in palliative care. Patients are often more concerned about the day-to-day distress of their symptoms than they are about their impending death, which may not be as real to them. Table 34.2-9 lists common end-of-life symptoms. A comprehensive approach to palliation involves attending to these end-of-life symptoms as well as pain. Sources of distress include psychiatric symptoms, such as anxiety, and physical symptoms. Foremost among physical symptoms are those involving the GI system, including diarrhea, constipation, anorexia, nausea, vomiting, and bowel obstruction. Other important symptoms include insomnia, confusion, mouth sores, dyspnea, cough, pruritus, decubitus ulcers, and urinary frequency or incontinence. Caretakers should follow these symptoms closely and establish appropriate early and aggressive care for these symptoms before they become burdensome.

An effective treatment for nausea and vomiting associated with chemotheraphy is the use of Δ-tetrahydrocannabinol (THC), the active ingredient of marijuana. Oral synthetic cannabinoid, dronabinol (Marinol) is used in 1- to 2-mg doses every 8 hours. The use of marijuana cigarettes to deliver THC is believed to be more effective than pills. Proponents say that its absorption is faster and antiemetic properties are more potent via the pulmonary system. Repeated attempts to legalize marijuana cigarettes for medical use have met with only limited success in this country.

A 47-year-old man with incurable lung cancer who had been treated unsuccessfully with chemotheraphy and radiotherapy had been suffering from intractable dyspnea for 1 week. His family, nursing, and other staff were increasingly upset by his difficulty breathing and his pleas for relief. The attending physician refused to prescribe anything stronger than codeine. The palliative care team at the hospital intervened at the family's request. Relief was obtained with the use of 5 to 10 mg of an intravenous bolus of morphine every 15 minutes. When the patient became comfortable, a continuous drip of intravenous morphine was instituted, complemented by subcutaneous morphine as needed.

The American Medical Association supports the position that patients with a terminal condition require substantial doses of opioids on a regular basis and should not be denied drugs for fear of producing physical dependence. A similar

Data from National Coalition on Health Care (NCHC) and the Institute for Health Care Improvement (IHI). Promises to Keep: Changing the Way We Provide Care at the End of Life, release, October 12, 2000.
view is endorsed in *Goodman and Gilman's the Pharmacological Basis of Therapeutics* as follows:

The physician should not wait until the pain becomes agonizing; no patient should ever wish for death because of a physician's reluctance to use adequate amounts of effective opioids. Accordingly, physicians who treat the terminally ill should not be intimidated by legal oversight.

This is especially important because the Drug Enforcement Administration (DEA) is considering examining the prescribing practices of physicians who care for terminally ill patients. In a strongly worded editorial (*New England Journal of Medicine*, January 5, 2006), the DEA was criticized for its involvement in what constitutes acceptable medical practice for dying patients because the DEA's federal mandate is limited to combating criminal substance abuse, not monitoring the care of dying patients. Physicians must be vigilant and forceful in protecting their rights to administer opioids to treat patients for intractable pain.

**HOSPICE CARE**

In 1967, the founding of St. Christopher's Hospice in England by Cicely Saunders launched the modern hospice movement. Several factors in the 1960s propelled the development of hospices, including concerns about inadequately trained physicians, inept terminal care, gross inequities in health care, and neglect of elderly adults. Life expectancy had increased, and heart disease and cancer were becoming more common. Saunders emphasized an interdisciplinary approach to symptom control, care of the patient and family as a unit, the use of volunteers, continuity of care (including home care), and follow-up with family members after a patient's death. The first hospice in the United States, Connecticut Hospice, opened in 1974. By 2000, more than 3,000 hospices were open in the United States. Round-the-clock pain control with opioids is an essential component of hospice management. In 1983, Medicare began reimbursing hospice care. Medicare hospice guidelines emphasize home care, with benefits provided for a broad spectrum of physician, nursing, psychosocial, and spiritual services at home or, if necessary, in a hospital or nursing home. To be eligible, the patient must be physician certified as having 6 months or less to live. By electing hospice care, patients agree to receive palliative rather than curative treatment. Many hospice programs are hospital-based, sometimes in separate units and sometimes in the form of hospice beds interspersed throughout the facility. Other program models include free-standing hospices and programs, hospital-affiliated hospices, nursing home hospice care, and home care programs. Nursing homes are the site of death for many elderly patients with incurable chronic illness, yet dying nursing home residents have limited access to palliative and hospice care. Families generally express satisfaction with their personal involvement in hospice care. Savings with hospice care vary, but home care programs generally cost less than conventional institutional care, particularly in the final months of life. Hospice patients are less likely to receive diagnostic studies or such intensive therapy as surgery or chemotherapy; however, a new trend is to allow treatment programs to continue while the patient remains in the hospice. Hospice care is a proven, viable alternative for patients who elect a palliative approach to terminal care. In addition, hospice goals of dignified, comfortable death for terminally ill patients and care for patients and families together have been increasingly adopted in mainstream medicine.

**NEONATAL AND INFANT END-OF-LIFE CARE**

Advances in reproductive medicine have increased the number of infants born prematurely as well as the number of multiple births. These advances have increased the need for life-sustaining methods of care and have made decisions about when to use palliative care more complex. Some bioethicists believe that withholding life-sustaining interventions is appropriate under certain circumstances; others maintain that life-sustaining methods should not be used at all. An extensive study of attitudes among neonatologists about end-of-life decisions found no consensus about if and when to terminate life.

Most decisions to forego life-sustaining procedures for newborns concern those whose death is imminent. Even if their future quality of life is determined to be bleak, most physicians believe that some life is better than no life at all. Physicians who support withholding intensive care consider the following quality-of-life issues: (1) extent of bodily damage (e.g., severe neurological impairment), (2) the burden that a disabled child will place on the family, and (3) the ability of the child to derive some pleasure from existence (e.g., having an awareness of being alive and being able to form relationships).

The American Academy of Pediatrics permits nontreatment decisions for newborns when the infant is irreversibly comatose or when treatment would be futile and only prolong the process of dying. These standards do not permit the parents to have any input in the decision-making process. In a well-publicized case in England in 2000, it was decided to surgically separate conjoined twins knowing that one would die as a result of the procedure and despite the objections of the parents, who believed that nature should take its course even if that led to the death of both infants. Neonatal end-of-life decisions remain in a state of limbo. No clear-cut criteria exist about which patients should receive intensive care and which should receive palliative care.

**CHILD END-OF-LIFE CARE**

After accidents, cancer is the second most common cause of death in children. Although many childhood cancers are treatable, palliative care is necessary for children with cancers that are not. Children require more support than adults in coping with death. On average, a child does not view death as permanent until the age of about 10 years; before that, death is viewed as a sleep or separation. Therefore, children should be told only what they can understand; if they are capable, they should be involved in the decision-making process about treatment plans. Assurances that patients are pain free and physically comfortable are just as important for children as they are for adults.

A unique aspect of end-of-life care in children involves addressing their fear of being separated from their parents. It is helpful to have parents participate in end-of-life care tasks within their capacities. Family sessions with the child in attendance allow feelings to emerge and questions to be answered.

**SPIRITUAL ISSUES**

There is increasing awareness of the importance of this area to patients, families, and many staff members as well. Several studies have shown that religious beliefs are often associated with mature and active coping methods, and the field of psychological and spiritual interfaces in terminally ill patients is spawning a whole new area of psychological research within the traditional medical establishment. The psychiatric consultant should inquire about faith, its meaning, associated
religious practices, and impact on the coping response. It can be a source of strength or guilt at all stages of the disease, ranging from the earliest “What did I do to cause this?” through “Will God give me only what I can carry?” to the poignant life review of the late stage. It is often a primary factor in the reactions to suicidality and in attitudes toward terminal care decisions. Mental health professionals should deal with these areas in an unself-conscious and noncondescending manner and work to help patients fully integrate this aspect of their personality into their current crisis. The professional should also work in harmony with the patient’s spiritual guide if one is available. Sometimes an experienced, effective chaplain working with the appropriate patient can achieve positive results more directly than any psychotherapy. The following case exemplifies how creative pastoral care can relieve suffering.

A young woman was admitted to a hospice in a terminal state. She was experiencing a severe depression, which she attributed to not being able to see her oldest daughter receive her first communion. Arrangements were made for a ceremonial communion for her daughter to take place at the hospice. After the ceremony, the patient’s mood improved markedly as one of her fears was alleviated and a religious need was satisfied. As her mood improved, she was able to address other unresolved issues and have quality visits with her children in her remaining days. (From O’Neil MT. Pastoral care. In: Cimino JE, Brescia MJ, eds. Calvary Hospital Model for Palliative Care in Advanced Cancer. Bronx, NY: Palliative Care Institute; 1998, with permission.)

ALTERNATIVE AND COMPLEMENTARY MEDICINE

Many patients, when they are told they are terminally ill, seek alternative treatments, ranging from innocuous programs aimed at enhancing general health to more aggressive, harmful, or fraudulent regimens. Although most patients combine the alternative and the traditional, a substantial number favor complementary medicine as the only treatment for their disease.

Complementary methods to cure terminal illness, especially cancer, emphasize a holistic approach, involving purification of the body, detoxification through internal cleansing, and attention to nutritional and emotional well-being. Despite their widespread appeal, not one of these methods has been demonstrated to cure cancer or prolong life, yet all have strong followings bolstered by anecdotal accounts of their efficacy. The popular metabolic therapy attributes cancer and other potentially fatal illnesses to toxins and waste materials accumulating in the body; treatment is based on reversing this process by diet, vitamins, minerals, enzymes, and colonic irrigations. Another approach includes microbiotic diets or megavitamins to enhance the body’s capacity to destroy malignancy. In 1987, the National Research Council recommended minimizing carcinogenic substances and fat in the diet and increasing whole-grain, fruit, and vegetable consumption as preventive guidelines. Psychological approaches cite maladaptive personality and coping styles as contributors to fatal diseases; treatment consists of shaping a positive attitude. Spiritual approaches aim at achieving harmony between the patient and nature. Some groups use spirituality as a way to ward off illness, which is sometimes seen as an external evil to be exorcised. Immuno-therapies have gained popularity in recent years; cancer is attributed to a defective immune system, and restoration of immunocompetency is seen as the cure. Many patients find increased strength to endure the suffering of terminal illness with the help of alternative medicine even though the course of the disease may not be affected. (For a further discussion of alternative medicine, see Chapter 24.)

▲ 34.3 Euthanasia and Physician-Assisted Suicide

EUTHANASIA

From the Greek term for good death, euthanasia means compassionately allowing, hastening, or causing the death of another. Generally, someone resorts to euthanasia to relieve suffering, maintain dignity, and shorten the course of dying when death is inevitable. Euthanasia can be voluntary if the patient has requested it or involuntary if the decision is made against the patient’s wishes or without the patient’s consent. Euthanasia can be passive—simply withholding heroic lifesaving measures—or active—deliberately taking a person’s life. Euthanasia assumes that the intent of the physician is to aid and abet the patient’s wish to die.

Arguments for euthanasia revolve around patient autonomy and dignified dying. One of the most dramatic ways patients can exercise their right to self-determination is by asking that life-sustaining treatment to be withdrawn. If the patient is mentally competent, physicians must respect such wishes. Proponents of
active, voluntary euthanasia argue that the same rights should be extended to patients who are not on life-sustaining treatment but also choose to have their physicians help them die. Opponents of euthanasia also provide strong ethical and medical justification for their position. First, active euthanasia, even if the patient voluntarily requests it, is a form of killing and should never be sanctioned. Second, many patients who request aid in dying may be suffering from depression, which, when treated, will change the patient’s mind about wanting to die.

Most medical, religious, and legal groups in the United States are against euthanasia. Both the American Psychiatric Association (APA) and the American Medical Association (AMA) condemn active euthanasia as illegal and contrary to medical ethics; however, few individuals have been convicted of euthanasia. Most physicians and medical groups in other parts of the world also oppose legalizing euthanasia. In the United Kingdom, for example, the British Medical Association believes that euthanasia is “alien to the traditional ethos and moral focus of medicine” and, if legalized, “would irrevocably change the context of health care for everyone, but especially for the most vulnerable.”

The World Medical Association issued the following declaration on euthanasia in October 1987:

Euthanasia, that is, the act of deliberately ending the life of a patient, even at his own request or at the request of his close relatives, is unethical. This does not prevent the physician from respecting the will of a patient to allow the natural process of death to follow its course in the terminal phase of sickness.

Again, in 2002, the World Medical Association reissued a resolution condemning euthanasia as “unethical” and urging all doctors and medical associations to refrain from the practice.

Similarly, the New York State Committee on Bioethical Issues issued a statement declaring its opposition to euthanasia. The committee stated that the physician’s obligation to relieve pain and suffering and to promote the dignity and autonomy of dying patients in their care, including providing effective palliative treatment, even though it may occasionally hasten death. Physicians, however, should not perform active euthanasia or participate in assisted suicide. The Committee believed that support, comfort, respect for patient autonomy, good communication, and adequate pain control would dramatically decrease the demand for euthanasia and assisted suicide. They argued that the societal risks of involving physicians in medical interventions to cause a patient’s death were too great to condone active euthanasia or physician-assisted suicide. In response to shifting public opinion and lobbying groups with different views, state laws that banned physician-assisted death in Washington State and New York were sent to the United States Supreme Court, challenging the constitutionality of these prohibitions. In June 1997, the Court unanimously held that terminally ill patients do not have the right to physician aid in dying. The ruling, however, left room for continuing debate and future policy initiatives at the state level.

**PHYSICIAN-ASSISTED SUICIDE**

In the United States, most of the debate centers on physician-assisted suicide rather than on euthanasia. Some have argued that physician-assisted suicide is a humane alternative to active euthanasia in that the patient maintains more autonomy, remains the actual agent of death, and may be less likely to be coerced. Others believe that the distinctions are capricious in that the intent in both cases is to bring about a patient’s death. Indeed, it may be difficult to justify providing a lethal dose of medication to a terminally ill patient (physician-assisted suicide) while ignoring the desperate pleas of another patient who may be even more ill and distressed but who cannot complete the act because of problems with swallowing, dexterity, or strength.

Several degrees are seen to which a physician may assist the suicidal patient to end his or her life. Physician-assisted suicide can involve providing information on ways of committing suicide, supplying a prescription for a lethal dose of medication or a means of inhaling a lethal amount of carbon monoxide, or perhaps even providing a suicide device that the patient can operate.

The controversy over physician-suicide came to national attention surrounding the activities of retired pathologist Jack Kevorkian, who, in 1989, provided his suicide machine to a 54-year-old woman with probable Alzheimer’s disease. After the woman killed herself with his device, Kevorkian was charged with first-degree murder. The charges were later dismissed because Michigan had no law against physician-assisted suicide. Since that first case, Kevorkian assisted in several more suicides, often for persons he met on only a few occasions and frequently for persons who did not have a terminal illness. Claiming to have helped more than 130 people take their lives, Kevorkian was sent to prison in 1999, was released in 2006, and died in 2011. His attorneys and followers applauded his courage in easing pain and suffering; his detractors countered that he was a serial mercy killer. Opponents of Kevorkian’s methods charged that, without safeguards, consultations, and thorough psychiatric evaluations, patients may search out suicide not because of terminal illness or intractable pain but because of untreated depressive disorders. They argued that suicide rarely occurs in the absence of psychiatric illness. Finding more effective treatments for pain and depression, rather than inventing more sophisticated devices to help desperate patients kill themselves, defines compassionate and effective physician care.

In 1994, Oregon passed a ballot initiative legalizing physician-assisted suicide (Death with Dignity Act), making Oregon the first state in the United States to permit assisted suicides (Table 34.3-1). An assessment of the first 4 years revealed the following: Patients dying from physician-assisted suicide represented approximately eight of 10,000 deaths. The most common underlying illnesses were cancer, amyotrophic lateral sclerosis, and chronic lower respiratory disease. The three most common end-of-life concerns were loss of autonomy (85 percent), a decreasing ability to participate in activities that made life enjoyable (77 percent), and losing control of bodily functions (63 percent). Eighty percent of the patients were enrolled in hospice programs, and 91 percent died at home. The prescribing physician was present in 52 percent of the cases.

In 2001, Attorney General John Ashcroft attempted to prosecute Oregon doctors who helped terminally ill patients die, claiming that doctor-assisted suicide is not a legitimate medical purpose. The case was brought to the Supreme Court, which in 2006 supported the Oregon law and said the “authority claimed by the attorney general is both beyond his expertise and incongruous with the statutory purposes and design.” Since
The patient must be terminally ill and expected to die within 6 mo; mentally competent; fully informed about his or her diagnosis, prognosis, risks, and alternatives, such as comfort care; and be making a voluntary choice. A second doctor must agree that the patient is terminally ill, acting on his or her own free will, fully informed, and capable of making health care decisions. If either doctor thinks that the patient is suffering from any form of mental illness that could affect his or her judgment, they must refer the patient for counseling. The patient must make one written request and two spoken requests. The doctor must ask the patient to tell the next of kin, but the patient may decide not to do so. The patient is free to change his or her mind at any time. There is a 15-day waiting period between the patient making the request and the doctor writing the prescription. All information must be written down in the medical records. Only people who normally live in Oregon may use the Act. Mercy killing, lethal injection, and active euthanasia are not permitted. Pharmacists must be told of the prescribed medication’s ultimate use. Physicians, pharmacists, and health care systems are under no obligation to participate in the Death with Dignity Act.

Despite the abhorrence that many physicians and medical ethicists express regarding physician-assisted suicide, poll after poll shows that as many as two thirds of Americans favor the legalization of physician-assisted suicide in certain circumstances, and evidence even indicates that the formerly uniform opposition to physician-assisted suicide within the medical community has eroded. Consistent with their positions on active euthanasia, the AMA, APA, and American Bar Association, however, continue to oppose physician-assisted suicide. Recently, the American College of Physicians—American Society of Internal Medicine (ACP-ASIM) expressed its commitment to improving care for patients at the end of life while recommending against legalization of physician-assisted suicide. The ACP-ASIM believes physician-assisted suicide raises serious ethical concerns, undermines the physician–patient relationship and the trust necessary to sustain it, alters the medical profession’s role in society, and endangers the values American society places on life, especially on the lives of disabled, incompetant, and vulnerable individuals.

The American Association of Suicidology in its 1996 Report of the Committee on Physician-Assisted Suicide and Euthanasia concluded that involuntary euthanasia can never be condoned; the report also stated, however, that “intolerable, prolonged suffering of persons in extremis should never be insisted upon, against their wishes, in single-minded efforts to preserve life at all cost.” This position acknowledges that patients can die as a result of treatment given to them for the explicit purpose of relieving suffering, but death associated with palliative care differs greatly from physician-assisted suicide in that death is not the goal of treatment and is not intentional.

How to Deal with Requests for Suicide

To help guide clinicians facing requests for physician-assisted suicide, the AMA’s Institute for Ethics has proposed the following eight-step clinical protocol:

1. Evaluation of the patient for depression or other psychiatric conditions that could cause disordered thought
2. Evaluation of the patient’s “decision-making competence”
3. Discussion with the patient about his or her goals for care
4. Evaluation and response to the patient’s “physical, mental, social, and spiritual suffering”
5. Discussion with the patient about the full range of treatment and care options
6. Consultation by the attending physician with other professional colleagues
7. Assurance that care plans chosen by the patient are being followed, including removal of unwanted treatment and the provision of adequate pain and symptom relief
8. Discussion with the patient explaining why physician-assisted suicide is to be avoided and why it is not compatible with the principled nature of the care protocol

Psychiatrists view suicide as an irrational act that is the product of mental illness, usually depression. In almost every case in which a patient asks to be put to death, a triad exists of depression associated with an incurable medical condition that causes the patient intolerable pain. In these instances, every effort should be made to provide antidepressants or psychostimulants for depression and opioids for pain. Psychotherapy, spiritual counseling, or both may also be needed. In addition, family therapy to help with the stress of dealing with a dying patient may be necessary. Family therapy is also useful because some patients may ask to be put to death because they do not wish to be a burden to their families; others may feel coerced by their families into believing that they are, or will be, a burden and may choose death as a result. Currently, no professional codes countenance euthanasia or assisted suicide in the United States. Therefore, psychiatrists must stand on the side of responsible rescue and treatment.

A distinction also is needed between major depression and suffering. The nature of suffering has not been sufficiently studied by psychiatrists. It remains the province of theologians and philosophers. Suffering is a complex mix of spiritual, emotional, and physical factors that transcends pain and other symptoms of terminal illness. Physicians are more skilled at dealing with depression than with suffering. Anatole Broyard, who chronicled his own death in his book Intoxicated by My Illness, wrote the following:

I see no reason or need for my doctor to love me nor would I expect him to suffer with me. I wouldn't demand a lot of my doctor's time; I just wish he would brood on my situation for perhaps five minutes, that he would give me his whole mind just once, be bonded with me for a brief space, survey my soul as well as my flesh, to get at my illness, for each man is ill in his own way.
FUTURE DIRECTIONS

Advances in technology bring more complex medical, legal, moral, and ethical controversies regarding life, death, euthanasia, and physician-assisted suicide. Some forms of euthanasia have found a place in modern medicine, and expansion of the boundaries of patients’ rights and their ability to choose the way they live and die are inevitable. Both patients and physicians need to be better educated about depression, pain management, palliative care, and quality of life. Medical schools and residency training programs need to give the topics of death, dying, and palliative care the attention they deserve. Society must ensure that economic, ageism, and racism do not get in the way of adequate and humane management of patients with chronic terminal illnesses. Finally, national health care policy must provide adequate insurance coverage, home care, and hospice services to all appropriate patients. If these mandates are followed, the argument for physician assistance in dying will lose much of its impact.

REFERENCES

The subject area of public psychiatry embodies a fundamental core of experience and tradition. In the context of the reexamination of American health care initiated by the effect of managed care and the health care reform, the experience of public psychiatry is poised to serve as the foundation for a transformation of behavioral health care.

The term public can refer to psychiatric programs, treatment, or institutions paid for by public funds or as objects of public policy, whether paid for or not. The traditional concept of public psychiatry has been expanded to include medical and psychosocial initiatives directed for the public good, whether funded by public or private funds, and directed in particular to those who are economically disadvantaged.

The care and treatment offered under public psychiatry are delivered in a variegated mosaic of inpatient and community-based services that are more or less integrated into a coherent network sponsored by public agencies. Funding for public psychiatric services tends to be provided by federally legislated appropriations that are passed through state, county, and municipal government agencies (such as departments of mental health; substance use treatment services; children, youth, and family services; and public health, social services, education, adult corrections, and juvenile justice agencies). Ultimately, most public psychiatry and community services are provided by not-for-profit community mental health, substance use treatment, child guidance, or health care organizations that either are funded by or subcontracted to government agencies. Thus, the very existence of public and community psychiatric services and the policies and resources determining how they are delivered are extremely dependent on legislative mandates and fiscal appropriations from all levels of public government.

CONTEMPORARY PUBLIC AND COMMUNITY PSYCHIATRY

There are five themes around which the discussion of contemporary public and community psychiatry is structured: public health, public agencies, evidence-based psychiatry, roles for psychiatrists, and delivery systems.

Public Health

Public health is not simply publicly funded health care but is rather a specific discipline and tradition. It is a complicated field that historically has been defined negatively by the dominance of personal health, that is, the health care delivery systems that take care of individual patients. Until the advent of managed care in the 1990s, U.S. health care was an industry organized largely in terms of individual doctor-entrepreneurs. Each jurisdiction uniquely defined and organized its public health programs, and the particular pattern of personal health practices had substantial influence—hence the wide variation in public health programs. Nonetheless, as a discipline and tradition, public health’s mission is to assure the conditions in which people can be healthy. Public health consists of organized community efforts aimed at the prevention of disease and the promotion of health. It involves many disciplines but rests on the scientific core of epidemiology. It provides an essential template for contemporary public and community psychiatry.

The Surgeon General’s report on mental health underscored the necessity of a public health approach to care and rehabilitation for people experiencing mental illness that is “broader in focus than medical models that concentrate on diagnosis and treatment.” Although diagnosis and treatment are core areas of expertise for all psychiatrists, the Surgeon General recommended that even when psychiatric diagnosis or treatment is the primary focus for practitioners, researchers, or educators, they should ground their professional activities in a vision and knowledge base that is “population-based... encompass[ing] a focus on epidemiologic surveillance, health promotion, disease prevention, and access to services.” These fundamental public health functions define the public health perspective in public and community psychiatry. In the discussion that follows, these four public health components are framed in current terms of health care reform to define a coherent “public health” strategy for public and community psychiatry.

Health Promotion

Psychiatric professionals can contribute substantially to the promotion of public health by working with primary health care professionals and educators to identify and provide front-line treatment and referrals to adults and children who have undetected psychiatric symptoms, subthreshold syndromes, and psychiatric disorders. Collaborative care models bring psychiatric professionals into primary care and school settings as consultants for medical, nursing, and education professionals who work in those settings, as well as for educators and direct treatment providers to at-risk or psychiatrically impaired individuals.

Furthermore, people with identified mental illness or addictive disorders can benefit from enhanced physical and mental health care, as well as from the alleviation or management of psychiatric symptoms. Achieving or regaining physical or mental health (i.e., recovery) depends not only on genetic and biological factors but also on a person’s or family’s access to social and psychological resources and integration into supportive...
social networks. Illness management (also known as disease management or chronic illness care management) is a framework that has been adapted from medicine to guide mental health professionals in delivering services that go beyond traditional diagnostic treatment to promote the health and recovery of people with mental illness or addiction. Illness management has been defined as “professional-based interventions designed to help people collaborate with professionals in the treatment of their mental illness, reduce their susceptibility to relapses, and cope more effectively with their symptoms...[to] improve self-efficacy and self-esteem and to foster skills that help people pursue their personal goals.” A number of approaches to illness management have been scientifically and clinically evaluated and have been found to enhance standard psychiatric treatment.

Prevention. Psychiatric disorders most often follow a course over time that begins with an often lengthy period in which prodromal or subthreshold symptoms or functional problems precede the full onset of a disorder with marked impairment. Intervention with adults, adolescents, or children who are not clinically impaired but who are at high risk (e.g., owing to a family history of psychiatric or addictive disorders or exposure to extreme stressors, such as violence, neglect, or the modeling of antisocial behavior) or who are manifesting preclinical symptoms or functional problems (e.g., periodic or pervasive dysphoria, problems with separation from caregivers, or involvement with deviant peers) is an approach to prevention that has been found to be cost effective because it targets a relatively small group of individuals in a timely manner.

Application of the traditional public health concepts of primary, secondary, and tertiary psychiatry has been confusing in psychiatry. Primary prevention involves addressing the root causes of illness with healthy individuals, with a goal of preventing illness before it occurs. Secondary prevention involves the early identification and early treatment of individuals with acute or subclinical disorders or high-risk persons to reduce morbidity. Tertiary prevention attempts to reduce the effects of a disorder on an individual through rehabilitation and chronic illness care management. The Institute of Medicine, in an effort to clarify different aspects of prevention, developed a classification system with three different categories. Universal interventions are those intended for the general public, such as immunizations or media campaigns providing information about illnesses, early warning signs, and resources for health promotion and timely treatment. Selective interventions focus on individuals at higher-than-average risk (e.g., persons with prodromal symptoms or a family history of psychiatric disorders) to reduce morbidity by enhancing resilience and preventing the onset of illness. Indicated interventions target individuals who are experiencing impairment as a result of illness as early as possible in the course of the illness, to reduce the burden of the illness on the individual, family, community, and treatment system. Psychiatric services most often take the form of indicated interventions, but the smaller number of psychiatric practitioners and researchers who conduct and evaluate selective or universal interventions in public and community settings is making a substantial contribution to the larger health of society.

Prevention interventions have been found to be effective with adults with a variety of risk factors or preclinical problems. For example, women who have been raped are less likely to develop posttraumatic stress disorder (PTSD) if they receive a five-session cognitive-behavioral treatment than if their recovery is left to chance. Men and women identified with subthreshold symptoms of depression by primary care medical providers are more likely to remain free from the full syndrome of depression or to be able to recover rapidly with treatment if they do become clinically depressed if their standard medical treatment is enhanced by education about depression and learning skills for coping actively with depressive symptoms or stressors. Prevention with adults must be judiciously designed to address the specific factors that place a person at risk for illness or that enhance the person’s ability to cope effectively. For example, brief supportive meetings with people who have experienced a traumatic stressor (e.g., a mass disaster or life-threatening accident) tend to have little benefit and may inadvertently intensify posttraumatic stress, whereas a focused cognitive-behavioral approach to teaching skills for coping with traumatic memories and stress symptoms has been shown to be effective in preventing posttraumatic stress and depressive disorders with adult and child disaster or accident survivors.

A number of prevention programs have been developed and evaluated to address physical and mental health risks in childhood and adolescence, incorporating several elements that influence intervention effectiveness. Their broad and systematic implementation, however, has been halting. A number of states have made an effort to implement school-based interventions involving teachers and the peer group. These tend to be more effective than programs exclusively relying on intervening with parents or children alone. Such interventions in middle childhood have been successful in influencing peer group norms regarding alcohol and substance use, violence and bullying, and depression, thus achieving the dual outcome of reducing immediate initiation of alcohol and substance use and increasing the long-term support within the peer group for sustained abstinence into adolescence. Thus, systems-based multimodal interventions simultaneously targeting and developing enhanced relationships among the child, peer group, school personnel, parents, and the wider community tend to be most effective as universal or selected approaches to early prevention of what otherwise may become lifelong behavioral, legal, academic, and addictive problems.

Access to Effective Mental Health Care. Access is a serious problem for most people with severe mental illness or addictions. In the United States, the National Comorbidity Study (NCS) and the National Comorbidity Study-Replication (NCS-R) found that fewer than 40 percent of people with severe psychiatric disorders had received any mental health treatment in the previous year, and fewer than one in six (15 percent) had received minimally adequate mental health services. Young adults, African Americans, people residing in certain geographical areas, people with psychotic disorders, and patients treated by medical but not mental health providers were at highest risk for inadequate psychiatric treatment. Although income was not a predictor of inadequate treatment, it is likely that many of the people who did not receive adequate mental health services were uninsured or had insufficient insurance coverage for mental health conditions and had no viable source of mental health care other than through a medical provider or clinic or in the public mental health system.

Even when mental illness is identified, people with socioeconomic adversities often do not, or cannot, get adequate mental health services in their communities. For example, although it is estimated that more than 200,000 incarcerated adults in the United States have psychiatric
disorders, few were detected or received treatment until they reached jail or prison. Federal and state correctional systems have instituted mental health screening and treatment programs to address psychiatric disorders as a health problem for incarcerated adults and to manage the problematic behavior that can occur in controlled settings as a result of mental illness. On returning to the community, the vast majority of prisoners with psychiatric disorders cease to receive more than minimal mental health services: A recent study found that fewer than one in six (16 percent—similarly striking to the NCS finding) received steady mental health services, and only one in 20 with addictions received steady substance abuse recovery services. Thus, access to mental health and addiction treatment services is far better in prison than in the community! This has caused great concern because of the possibility that correctional facilities may be a de facto system of care for low-income people (often of minority backgrounds) with serious mental illness.

Evidence of serious and pervasive barriers to accessing mental health care can be found in several social crises. Poor children and adults increasingly are deferring physical and mental health care until illnesses become chronic and severe and then often do not know or cannot gain entry into any setting for services except public hospital emergency departments. Children with severe psychiatric or behavioral disorders are being held in emergency department facilities for days and even weeks because the staff cannot locate any treatment facilities with an appropriate level of care that have an opening or are willing to take the child as a patient (or accept the child or family's insurance coverage or lack thereof). People who cannot afford private services thus face daunting obstacles when seeking appropriate mental health care as a result of a serious underfunding of practitioners and programs. The economic forces and public policy dilemmas driven by the ever-increasing cost of health care bear directly on the field of public psychiatry, as well as the lives of tens or hundreds of thousands of people who do not receive adequate care.

Psychiatry and Public Agencies

Psychiatry's relationship to public sector agencies has, with some specific exceptions, been one of detachment because of the dominance of the private practice models before the advent of managed care and also largely because of the nature and structure of U.S. social welfare programs. This is a divide that often begins during academic preparation, in that many psychiatry training programs eschew meaningful rotations in public sector settings. In contrast to most industrial nations in which comprehensive social welfare reforms have been initiated, U.S. social welfare programs grew incrementally and categorically, that is, one category of service at a time. Large-scale initiatives, such as President Johnson's War on Poverty, have been implemented in piecemeal fashion by fragmented federal, state, and local government bureaucracies and have been vastly reduced through subsequent initiatives, such as the recent changes in federal regulations to "end welfare as we know it." Various social service agencies have been created through a process and set of alliances that has been called the iron triangle. Advocates form an organization to champion a particular cause, such as blindness, developmental disabilities, primary care, or mental health, among others. They find key legislative sponsors who advance the cause through legislation and appropriation. This creates a bureaucracy and bureaucrats that join the alliance. Through successive legislative sessions, the alliance of advocates, lawmakers, and bureaucrats builds a stronger and stronger categorical agency, for example, adults and families with dependent children or people with biologically based, severe mental illness.

From the 1930s through the end of the twentieth century, U.S. social welfare agencies were created on this pattern: The system has resulted in generous funding and hopeless fragmentation of services at local service delivery levels in which each agency depends on separate funding silos that also deliver conflicting rules and regulations.

It has been said that "mental health is not a place." Psychiatrists have a role at the receiving end of every categorical silo because the clients of each categorical agency experience mental illness or various addictions. Services for children with severe emotional, mental, or behavioral disturbances are a dramatic case. Five categorical agencies—child welfare, education, primary health, substance abuse, and juvenile justice—all have a responsibility to care for these children (and, indirectly, for their caregivers, including parents and families). Especially for the children with the most severe disabilities, the protective service worker taking a child into court, the special education teacher working day to day with the child, the juvenile probation officer, the substance abuse counselor, and the child's pediatrician all need the consultation and support of a skilled psychiatrist. The situation is similar for adults with severe mental illness, for whom case managers, vocational rehabilitation counselors, basic needs benefits specialists, social workers, psychotherapists, substance abuse counselors, parole or probation officers, legal conservators, visiting nurses, peer specialists, and physicians all may be mandated to deliver services.

Workforce Influences on Contemporary Practice

Shortages in the ranks of psychiatry have been well documented historically, and some project this to continue. However, as the field of psychiatry connects with its science and evidence base (e.g., neuroscience, genetics, pharmacology, outcomes science) while retaining its strength in the meaningful connection with patients and their families, some would argue that the reversal of the shortage trend has begun. The Decade of the Brain in the 1990s and the Decade of the Mind begun in the 2000s sponsored by the National Institutes of Health (NIH) contributed to this change. Medical students are increasingly stimulated to enter the field by recognizing the importance of psychiatry to health care in general, realizing that this is still a field in which the practitioner (and by extension the interdisciplinary team) is an instrument of change through integration of contemporary knowledge, skillful learned interactions with patients, and a willingness to commit to providing value. The national aggregate numbers, however, cannot adequately capture the extreme variations that exist geographically: Rural and frontier sites are dramatically more likely to experience shortages than more urban environments.

Because subsets of the public sector populations have special needs, responses to their needs have to be correspondingly tailored:

- Children and family needs are expressed differently than those for adults and require different responses.
- Mental illnesses have culturally driven ways of presenting, and interventions must be culturally competent.
- Issues of language (including American Sign Language with hearing-impaired individuals) can complicate diagnosis and treatment.
- The rapidly expanding elderly population will pose significant new challenges for effective treatment.
Just these few examples suggest the sophistication with which education and training must be engineered to meet the existing and changing demands of people in need of services.

**Contemporary Evidence Base for Effective Public and Community Psychiatry**

Since the 1980s, several structured interventions have been developed to address the gap between what historically has been taught in most psychiatry training programs—typically, an office-, clinic-, or hospital-based approach focusing on diagnoses and pharmacotherapy supplemented by psychotherapy—and the competencies required to deliver or to support the delivery of the full array of psychiatric rehabilitation services. Public and community approaches to psychiatric rehabilitation involve not only pharmacotherapy but also an array of complementary services that must be coordinated to assist people with severe mental illness or behavioral disorders and their families and support systems to manage symptoms, to access and use resources effectively, and to gain the greatest degree of autonomy in the least restrictive setting possible. The competences required to effect these interventions go beyond the scope of psychiatry, thus requiring that psychiatrists effectively collaborate with other rehabilitation and mental health specialists. Although psychiatrists rarely implement the educational, resource linkage, and psychotherapy interventions involved in these protocols, it is essential that the psychiatrist become aware of and be able to reinforce these interventions. Hence, familiarity with the manuals that describe how to implement these interventions with fidelity is strongly advised—and increasingly incorporated into psychiatry training.

**Evidence-Based Manualized Interventions for Child Psychiatric Rehabilitation.** Children with severe emotional disturbance and adolescents with severe behavioral disorders traditionally have been removed from their families and placed in restrictive psychiatric or juvenile justice settings (e.g., psychiatric inpatient wards, residential group homes, and juvenile detention centers). These placements separate the child from the natural family, school, peer group, and community environments, which may provide some benefit by reducing the child's exposure to addiction, conflict, violence, or deviant behavior. However, the placements also deprive the child and family of the opportunity to build better relationships with one another and with other children, families, teachers, and community groups. The second key ingredient to effective public and community child psychiatry comprises interventions that complement pharmacotherapy. Since the 1970s, several rehabilitative approaches for children with severe disorders (and their families) have been developed, tested, and disseminated in replicable manuals and training programs.

Implementation of evidence-based practices is not always easy and rarely occurs even in clinics and practice groups that are well trained and motivated to use evidence-based treatment models, given that most current systems of payment and service delivery were not designed to accommodate or support the use of science-based interventions such as those highlighted here. In addition, evidence-based dissemination and implementation strategies must be deliberately designed to support the initial adoption and sustained use of evidence-based mental health treatment models. For example, a recent study of the implementation of one of the most widely disseminated evidence-based mental health interventions for children and families, multisystemic therapy (MST), demonstrated that initial training yielded a very positive early rate of adoption of the program with good fidelity to the model, but only teams that were provided with regular ongoing supervision and support (for supervisors as well as therapists) from expert consultants were able to sustain the initial successes.

**Roles of Psychiatrists in Public and Community Psychiatry Multidisciplinary Teams**

Psychiatrists in the public sector rarely work in isolation. Most often, psychiatrists work within a team that includes professionals from several disciplines (e.g., psychology, social work, nursing, occupational therapy, rehabilitation or addiction counseling, social services, housing, and employment specialists) and nondegree direct care workers (e.g., bachelor's degree-level counselors or case managers, high school graduate indigenous outreach workers, peer-support specialists, and family advocates), each of whom brings unique skills and experience to address the varied needs of people with severe and persistent mental illnesses. The team, rather than any single provider, assumes responsibility for the ongoing care of each patient across the many levels of services and often for many years. Its success is based on effective communication. Every communication should be explicitly focused on the client's (i.e., patient and family) stated goals, as well as on the team's technical and logistical issues, to maximize the client's motivation to participate actively and productively in all services by ensuring that the services truly are patient centered and collaborative.

Psychiatrists play three primary roles on multidisciplinary psychiatric rehabilitation teams: Conducting psychiatric evaluations, providing pharmacotherapy, and serving as the team's medical director (and, at times, as the administrative supervisor or team leader).

**Psychiatric Evaluation and Diagnosis.** In public and community settings and populations no less than in any other practice setting or patient population, the sine qua non is a thorough evaluation of all relevant history and systems and an accurate diagnosis. The goal of evaluation and diagnosis is to develop the most clinically effective individualized approach to treatment and rehabilitation for each patient. Psychiatric evaluations in public and community settings must include a careful review of the individual's psychosocial strengths and resources. The focus on strengths and resources often is lost or obscured when systemic factors (e.g., eligibility regulations for governmentally funded services or benefits) emphasize disability or limit the individual's or family's access to services or benefits (e.g., welfare-to-work regulations that place time or other eligibility restrictions on types of temporary aid, such as food stamps or vouchers for household supplies or housing).

**Pharmacotherapy.** The psychiatrist's most visible role usually is providing pharmacotherapy. The most difficult challenge in public sector mental health settings often is not the technical formulation of an effective medication regimen but instead the arranging of a plan of care so that the patient reliably
follows the prescribed regimen (i.e., adherence or compliance). A recent review of interventions designed to enhance adherence to psychotropic medication regimens by patients with schizophrenia found that education alone often was the only strategy used even though it was less effective than approaches that focus on “concrete problem solving,” “motivational techniques,” and “reminders, self-monitoring tools, cues, and reinforcements” or that provide “an array of supportive and rehabilitative community-based services.” Thus, although the psychiatrist must address technical medical issues accurately to formulate diagnoses and to establish an effective psychotropic regimen, effective pharmacotherapy depends heavily on providing—directly, in encounters with patients, or indirectly, by working closely with nonpsychiatric mental health professionals and nondegree care workers—practical assistance to patients to enable them to anticipate and to manage the psychosocial stressors or problems that can render even the most technically sound medication regimen completely ineffective as a result of nonadherence by the patient.

Team Leadership. The psychiatrist also often plays a leadership role as the project or program medical director—with the attendant responsibilities of monitoring the medical safety and well-being of all patients and establishing or supporting management and clinical procedures that support quality of care and a cohesive treatment team. As the team leader or simple as a team member, the psychiatrist serves as a role model for compassionate and professional behavior in relation not only to patients but also to all other team members. Formal or informal leadership is especially important when psychiatry residents and medical students work on a team as a training experience. The team psychiatrist serves not only as a mentor and a role model for the core aspects of psychiatric practice but also to demonstrate the values and skills necessary to integrate psychiatry within the framework of multimodal community-based longitudinal psychosocial interventions.

Psychiatrists who work with persons with severe mental illness and who wish to contribute as key members or leaders of their teams must go beyond their prescription pads to acquire knowledge, attitudes, and skills congruent with contemporary practice guidelines for psychiatric rehabilitation; give respect and support to multidisciplinary team members and gain their respect and support in return; cope with large caseloads; collaborate with agencies and programs to ensure continuity, consistency, and coordination of care; and value the roles and expertise of staff who provide case management, supported employment, skills training, and family and housing supports. If psychiatrists can incorporate these attitudes and skills, they can expect reciprocity and cohesion from other team members, and clients will benefit. Surveys of psychiatrists in the public sector indicate that those who embrace the rehabilitation perspective by expanding their roles to be consultants and teachers for patients, families, trainees, and colleagues from other mental health disciplines are more satisfied professionally than those who focus on diagnosis and treatment alone.

New Paradigms. Virtually all health care should be integrated and coordinated to deliver effective, rational, and cost-efficient care. The broader, contemporary definition of care must include public health. In fact, linking public health models with acute care management, which, in turn, is coupled with chronic illness care management, rehabilitation, or recovery models, represents the continuum for an integrated system.

However, this continuum is insufficient without four other components: (1) the application of new research to improve care and the application of bench-to-bedside models to translational research, (2) meaningful involvement of patients and families in a shared decision-making paradigm, (3) integration with primary and specialty care systems, and (4) the development of the clinical system as a system of advocacy. Training preprofessionals in such a model is one approach to introduce meaningful and sustained change to health care and its delivery and is already operational in some systems.

New Models for Service Delivery and Treatment

Organized Systems of Care. The focus of reform has moved increasingly to coherent, efficient, and accountable delivery systems. The basic idea of the system of care for children with serious emotional disturbances can be described in two ways—in terms of interagency structures and in terms of clinical processes. Five categorical agencies in a given community form a strong consortium that targets a specific population of children (and their families) to whose needs none of the agencies can adequately respond on their own. The consortium agencies commit themselves to treat the child and family with a common plan of care and to find ways to pool their resources to do so appropriately. This often requires that in the central bureaucracies at the state level, a parallel interagency commitment be in place that supports the local system of care initiative, resolves any regulatory conflicts that may arise, and gives permission to innovative aspects of the delivery system. The collaborative interagency structure provides the resources and the flexibility for effective clinical work.

From the viewpoint of clinical processes, the system of care provides a full enactment of the traditional clinical practice that meets the requirements of medical quality assurance. What is different is that it is carried out in home and community settings, and it involves participants from different disciplines—child welfare, special education, and juvenile justice—in one standardized treatment methodology. The center of the system of care is the child and family team that is made up the child and family, clinicians and agency representatives involved in the case, and significant supportive individuals identified by the child and family. Current issues are reviewed—strengths, problems, and needs—diagnostic issues are considered, clinical goals are articulated, and appropriate treatment strategies are identified. The expected outcome of each intervention is specified, and progress toward it is systematically charted. The system of care requires a full array of flexible services. The essential starters include clinical diagnostic services, care coordination or case management, crisis intervention services, and a flexible essential supportive service—child care specialists who can be assigned to support the child and family in any situation. Systems of care that have been particularly effective have relied on substantial community organization and collaboration or innovative funding models, or both, that blend or braid funding streams to focus on clear assignment of responsibility for a particular child and family, as well as adequate resources.

The basic model for community support for adults was called assertive community treatment (ACT). ACT was implemented with multidisciplinary teams with psychiatrists, nurses, psychologists, social workers, psychiatric aides, and paraprofessionals. The ACT team would assume the care of a designated number of adult patients with serious and persistent mental illness and would be available around the clock, 7 days a week.
The team would help find housing, manage money, organize household routines, find social contacts, find work, and support the individual's adjustment to workplace settings. Concurrently, medications would be managed and help provided to facilitate an individual adjusting to community living. At the heart of the program was the basic clinical process that developed and maintained an individualized treatment plan, which was constantly adjusted to the changing needs of each client. The ACT model has been modified in various ways as it has been implemented in different states. Innovative funding models have been developed in several states by using bundled rates and case rates, which make it easier to implement and to sustain than traditional fee-for-service payment systems.

In contemporary managed care terms, ACT teams are disease and disability management models that assign accountability to provider systems that may not assume risk in managing community support of persons with disabling conditions. The National Alliance on Mental Illness (NAMI) has developed program models and protocols for the Program for Assertive Community Treatment (PACT) to encourage public agencies to contract for ACT services.

Effective Treatment Models. The previous discussions have outlined the various treatment models that have been introduced since the 1980s in the effort to establish an evidence base for the effectiveness of specific interventions and approaches to care. The attention to evidence-based treatment models has been a response to the call for quality and accountability for service outcomes demanded from health care services in general by purchasers and policy makers and part of an effort to cope with the difficulties of evaluating service delivery models or systems of care.

The movement to evidence-based services is necessary to break down components of the service delivery system to determine the relative effectiveness of specific service interventions using the evaluative tools and methods that are available. Eventually, the case will be made to address the larger policy questions concerning the value of coherent and rationally organized service delivery in mitigating the effects of mental disability on the development of the child and enabling the recovery process for adults with serious and persistent mental illness.

Chronic Illness Care Model: Psychiatry in the Context of Primary Care. Finally, the care of persons with long-term mental health problems is included in innovative developments in the provision of primary health care for persons with chronic illnesses (http://www.improvingchroniccare.org). The Health Resources Services Administration (HRSA), the federal agency responsible for the community health centers or Federally Qualified Health Centers (FQHCs), has adopted the chronic illness care model in its training and technical assistance efforts for community health centers. The model grows out of the current concern for quality of care and accountability for health care delivery systems for effective outcomes. Depression management is one of the four chronic health conditions that the HRSA has selected for its training collaboratives.

The model begins with the assumption that the health care delivery system is part of a community context and must be responsive in its interactions with the community. Four areas of focus are essential in implementing the model in the health care delivery system: self-management support, delivery system design, decision support, and clinical tracking system. Self-management support gives patients a central role in determining their care, fostering a sense of responsibility for their health. Patients collaborate with the primary care team to establish goals, create treatment plans, and solve problems along the way. Delivery system design requires a reorganization of the way in which the health system operates, so that up-to-date information about a given patient is centralized, follow-up responsibility is assigned as a standard procedure, and so on. Decision support requires that treatment decisions are based on explicit, proven practice guidelines supported by at least one defining study. Guidelines are discussed with patients and providers, and treatment team members are constantly trained in the latest proven methods. Finally, clinical tracking systems track individual patients and populations of patients with similar problems. These systems must be practical and operational—able to check an individual's treatment at any point to confirm that the treatment conforms to recommended guidelines. The real integration of psychiatric care into primary care is an important innovation to consider that would improve physical health care for individuals with psychiatric disorders and eliminate the separation imposed by placing individuals with psychiatric problems into community mental health centers.

THE ROLE OF PUBLIC AND COMMUNITY PSYCHIATRY IN TWENTY-FIRST CENTURY HEALTH CARE

Public psychiatry emerged historically as an attempt to provide humane care for people with severe mental disabilities who did not have the resources to be protected from the stigma and approbation that shielded so-called "eccentrics" and "black sheep" fortunate enough to have been born into the wealthier social strata. Community psychiatry evolved as an answer to concerns that public psychiatric treatment was a de facto form of marginalization and oppression, if not inhumane exile and imprisonment, of economically disadvantaged persons with mental illness. The great ideas of public psychiatry (e.g., providing compassionate respite and meaningful social and vocational rehabilitation) and community psychiatry (e.g., preserving social ties while providing evidence-based treatment) often are lost in the competition for scarce economic and political resources that faces every mental health, medical, and human service profession and organization in the early twenty-first century. The spirit and skills of advocacy that sparked the development and continue to characterize the best practices of public and community psychiatry, as well as the dedication to bring demonstrably effective services to the people who are most in need but are least served, have never been more needed by the entire mental health field.

References

36.1 Forensic Psychiatry

The word *forensic* means belonging to the courts of law, and at various times, psychiatry and the law converge. Forensic psychiatry covers a broad range of topics that involve psychiatrists' professional, ethical, and legal duties to provide competent care to patients; the patients' rights of self-determination to receive or refuse treatment; court decisions, legislative directives, governmental regulatory agencies, and licensure boards; and the evaluation of those charged with crimes to determine their culpability and ability to stand trial. Finally, the ethical codes and practice guidelines of professional organizations and their adherence also fall within the realm of forensic psychiatry.

**MEDICAL MALPRACTICE**

Medical malpractice is a tort, or civil wrong. It is a wrong resulting from a physician's negligence. Simply put, negligence means doing something that a physician with a duty to care for the patient should not have done or failing to do something that should have been done as defined by current medical practice. Usually, the standard of care in malpractice cases is established by expert witnesses. The standard of care is also determined by reference to journal articles; professional textbooks, such as the *Comprehensive Textbook of Psychiatry*; professional practice guidelines; and ethical practices promulgated by professional organizations.

To prove malpractice, the plaintiff (e.g., patient, family, or estate) must establish by a preponderance of evidence that (1) a doctor–patient relationship existed that created a duty of care, (2) a deviation from the standard of care occurred, (3) the patient was damaged, and (4) the deviation directly caused the damage.

These elements of a malpractice claim are sometimes referred to as the 4 *Ds* (duty, deviation, damage, direct causation).

Each of the four elements of a malpractice claim must be present or there can be no finding of liability. For example, a psychiatrist whose negligence is the direct cause of harm to an individual (physical, psychological, or both) is not liable for malpractice if no doctor–patient relationship existed to create a duty of care. Psychiatrists are not likely to be sued successfully if they give advice on a radio program that is harmful to a caller, particularly if a caveat was given to the caller that no doctor–patient relationship was being created. No malpractice claim will be sustained against a psychiatrist if a patient's worsening condition is unrelated to negligent care. Not every bad outcome is the result of negligence. Psychiatrists cannot guarantee correct diagnoses and treatments. When the psychiatrist provides care, mistakes may be made without necessarily incurring liability. Most psychiatric cases are complicated. Psychiatrists make judgment calls when selecting a particular treatment course among the many options that may exist. In hindsight, the decision may prove wrong but not be a deviation in the standard of care.

In addition to negligence suits, psychiatrists can be sued for the intentional torts of assault, battery, false imprisonment, defamation, fraud or misrepresentation, invasion of privacy, and intentional infliction of emotional distress. In an intentional tort, wrongdoers are motivated by the intent to harm another person or realize, or should have realized, that such harm is likely to result from their actions. For example, telling a patient that sex with the therapist is therapeutic perpetuates a fraud. Most malpractice policies do not provide coverage for intentional torts.

**Negligent Prescription Practices**

Negligent prescription practices usually include exceeding recommended dosages and then failing to adjust the medication level to therapeutic levels, unreasonable mixing of drugs, prescribing medication that is not indicated, prescribing too many drugs at one time, and failing to disclose medication effects. Elderly patients frequently take a variety of drugs prescribed by different physicians. Multiple psychotropic medications must be prescribed with special care because of possible harmful interactions and adverse effects.

Psychiatrists who prescribe medications must explain the diagnosis, risks, and benefits of the drug within reason and as circumstances permit (Table 36.1-1). Obtaining competent informed consent can be problematic if a psychiatric patient has diminished cognitive capacity because of mental illness or chronic brain impairment; a substitute health care decision maker may need to provide consent. Informed consent should be obtained each time a medication is changed and a new drug is introduced. If patients are injured because they were not properly informed of the risks and consequences of taking a medication, sufficient grounds may exist for a malpractice action.
Although there exists no consistently accepted standard for information disclosure for any given medical or psychiatric situation, as a rule of thumb, five areas of information are generally provided:

1. Diagnosis—description of the condition or problem
2. Treatment—nature and purpose of proposed treatment
3. Consequences—risks and benefits of the proposed treatment
4. Alternatives—viable alternatives to the proposed treatment, including risks and benefits
5. Prognosis—projected outcome with and without treatment

The question is often asked: How frequently should patients be seen for medication follow-up? The answer is that patients should be seen according to their clinical needs. No stock answer about the frequency of visits can be given. The longer the time interval between visits, however, the greater the likelihood of adverse drug reactions and clinical developments. Patients taking medications should probably not go beyond 6 months for follow-up visits. Managed care policies that do not reimburse for frequent follow-up appointments can result in a psychiatrist prescribing large amounts of medications. The psychiatrist is duty bound to provide appropriate treatment to the patient, quite apart from managed care or other payment policies.

Other areas of negligence involving medication that have resulted in malpractice actions include failure to treat adverse effects that have, or should have, been recognized; failure to monitor a patient's compliance with prescription limits; failure to prescribe medication or appropriate levels of medication according to the treatment needs of the patient; prescribing addictive drugs to vulnerable patients; failure to refer a patient for consultation or treatment by a specialist; and negligent withdrawal of medication treatment.

Split Treatment

In split treatment, the psychiatrist provides medication, and a nonmedical therapist conducts the psychotherapy. The following vignette illustrates a possible complication.

A psychiatrist provided medications for a depressed 43-year-old woman. A master's level counselor saw the patient for outpatient psychotherapy. The psychiatrist saw the patient for 20 minutes during the initial evaluation and prescribed a tricyclic drug, and the patient was prescribed sufficient drugs for follow-up in 3 months. The psychiatrist's initial diagnosis was recurrent major depression. The patient denied suicidal ideation. Appetite and sleep were markedly diminished. The patient had a long history of recurrent depression with suicide attempts. No further discussions were held between the psychiatrist and the counselor, who saw the patient once a week for 30 minutes in psychotherapy. Within 3 weeks, after a failed romantic relationship, the patient stopped taking her antidepressant medication, started to drink heavily, and committed suicide with an overdose of alcohol and antidepressant drugs. The counselor and psychiatrist were sued for negligent diagnosis and treatment.

Psychiatrists must do an adequate evaluation, obtain prior medical records, and understand that no such thing as a partial patient exists. Split treatments are potential malpractice traps because patients can “fall between the cracks” of fragmented care. The psychiatrist retains full responsibility for the patient's care in a split treatment situation. This does not preempt the responsibility of the other mental health professionals involved in the patient's treatment. Section V, annotation 3 of the Principles of Medical Ethics with Annotations Especially Applicable to Psychiatry, states: “When the psychiatrist assumes a collaborative or supervisory role with another mental health worker, he/she must expend sufficient time to assure that proper care is given.”

In managed care or other settings, a marginalized role of merely prescribing medication apart from a working doctor–patient relationship does not meet generally accepted standards of good clinical care. The psychiatrist must be more than just a medication technician. Fragmented care in which the psychiatrist only dispenses medication while remaining uninformed about the patient's overall clinical status constitutes substandard treatment that may lead to a malpractice action. At a minimum, such a practice diminishes the efficacy of the drug treatment itself or may even lead to the patient's failure to take the prescribed medication.

Split-treatment situations require that the psychiatrist remain fully informed of the patient's clinical status as well as the nature and quality of treatment the patient is receiving from the nonmedical therapist. In a collaborative relationship, the responsibility for the patient's care is shared according to the qualifications and limitations of each discipline. The responsibilities of each discipline do not diminish those of the other disciplines. Patients should be informed of the separate responsibilities of each discipline. The psychiatrist and the nonmedical therapist must periodically evaluate the patient's clinical condition and requirements to determine whether the collaboration should continue. On termination of the collaborative relationship, both parties treating the patient should inform the patient either separately or jointly. In split treatments, if the nonmedical therapist is sued, the collaborating psychiatrist will likely be sued also and vice versa.

Psychiatrists who prescribe medications in a split-treatment arrangement should be able to hospitalize a patient if it becomes necessary. If the psychiatrist does not have admitting privileges, prearrangements should be made with other psychiatrists who can hospitalize patients if emergencies arise. Split treatment is increasingly used by managed care companies and is a potential malpractice minefield.

PRIVILEGE AND CONFIDENTIALITY

Privilege

Privilege is the right to maintain secrecy or confidentiality in the face of a subpoena. Privileged communications are statements made by certain persons within a relationship—such as husband–wife, priest–penitent, or doctor–patient—that the law protects from forced disclosure on the witness stand. The right of privilege belongs to the patient, not to the physician, so the patient can waive the right.
Psychiatrists, who are licensed to practice medicine, may claim medical privilege, but privilege has some qualifications. For example, privilege does not exist at all in military courts, regardless of whether the physician is military or civilian and whether the privilege is recognized in the state in which the court martial takes place.

In 1996, the United States Supreme Court recognized a psychotherapist–patient privilege in Jaffee v. Redmon. Emphasizing the important public and private interests served by the psychotherapist–patient privilege, the Court wrote: Because we agree with the judgment of the state legislatures and the Advisory Committee that a psychotherapist-patient privilege will serve a “public good transcending the normal predominant principle utilizing all rational means for ascertaining truth”… we hold that confidential communications between a licensed psychotherapist and her patients in the course of diagnosis or treatment are protected from compelled disclosure under Rule 501 of the Federal Rules of Evidence.

Confidentiality

A long-held premise of medical ethics binds physicians to hold secret all information given by patients. This professional obligation is called confidentiality. Confidentiality applies to certain populations and not to others; a group that is within the circle of confidentiality shares information without receiving specific permission from a patient. Such groups include, in addition to the physician, other staff members treating the patient, clinical supervisors, and consultants.

A subpoena can force a psychiatrist to breach confidentiality, and courts must be able to compel witnesses to testify for the law to function adequately. A subpoena (“under penalty”) is an order to appear as a witness in court or at a deposition. Physicians usually are served with a subpoena duces tecum, which requires that they also produce their relevant records and documents. Although the power to issue subpoenas belongs to a judge, they are routinely issued at the request of an attorney representing a party to an action.

In bona fide emergencies, information may be released in as limited a way as feasible to carry out necessary interventions. Sound clinical practice holds that a psychiatrist should make the effort, time allowing, to obtain the patient's permission anyway and should debrief the patient after the emergency.

As a rule, clinical information may be shared with the patient's permission—preferably written permission, although oral permission suffices with proper documentation. Each release is good for only one piece of information, and permission should be reobtained for each subsequent release, even to the same party. Permission overrides only the legal barrier, not the clinical one; the release is permission, not obligation. If a clinician believes that the information may be destructive, the matter should be discussed, and the release may be refused, with some exceptions.

Third-Party Payers and Supervision. Increased insurance coverage for health care is precipitating a concern about confidentiality and the conceptual model of psychiatric practice. Today, insurance covers about 70 percent of all health care bills; to provide coverage, an insurance carrier must be able to obtain information with which it can assess the administration and costs of various programs.

Quality control of care necessitates that confidentiality not be absolute; it also requires a review of individual patients and therapists. The therapist in training must breach a patient's confidence by discussing the case with a supervisor. Institutionalized patients who have been ordered by a court to get treatment must have their individualized treatment programs submitted to a mental health board.

Discussions About Patients. In general, psychiatrists have multiple loyalties: to patients, to society, and to the profession. Through their writings, teaching, and seminars, they can share their acquired knowledge and experience and provide information that may be valuable to other professionals and to the public. It is not easy to write or talk about a psychiatric patient, however, without breaching the confidentiality of the relationship. Unlike physical ailments, which can be discussed without anyone's recognizing the patient, a psychiatric history usually entails a discussion of distinguishing characteristics. Psychiatrists have an obligation not to disclose identifiable patient information (and, perhaps, any descriptive patient information) without appropriate informed consent. Failure to obtain informed consent could result in a claim based on breach of privacy, defamation, or both.

Internet and Social Media. It is imperative that psychiatrists and other mental health professionals be aware of the legal implications of discussing patients over the Internet. Internet communications about patients are not confidential, are subject to hacking, and are open to legal subpoenas. Some psychiatrists have blogged about patients thinking they were sufficiently disguised only to find that they were recognized by others, including the involved patient. Some professional organizations have electronic mailing lists in which they ask advice about patients from their colleagues or make referrals and in so doing provide detailed information about the patient that can easily be traced. Similarly, using social media to communicate about patients is equally risky.

Child Abuse. In many states, all physicians are legally required to take a course on child abuse for medical licensure. All states now legally require that psychiatrists, among others, who have reason to believe that a child has been the victim of physical or sexual abuse make an immediate report to an appropriate agency. In this situation, confidentiality is decisively limited by legal statute on the grounds that potential or actual harm to vulnerable children outweighs the value of confidentiality in a psychiatric setting. Although many complex psychodynamic nuances accompany the required reporting of suspected child abuse, such reports generally are considered ethically justified.

HIGH-RISK CLINICAL SITUATIONS

Tardive Dyskinesia

It is estimated that at least 10 to 20 percent of patients and perhaps as high as 50 percent of patients treated with neuroleptic drugs for more than 1 year exhibit some tardive dyskinesia. These figures are even higher for elderly patients. Despite the possibility for many tardive dyskinesia-related suits, relatively
few psychiatrists have been sued. In addition, patients who develop tardive dyskinesia may not have the physical energy and psychological motivation to pursue litigation. Allegations of negligence involving tardive dyskinesia are based on a failure to evaluate a patient properly, a failure to obtain informed consent, a negligent diagnosis of a patient’s condition, and a failure to monitor.

**Suicidal Patients**

Psychiatrists may be sued when their patients commit suicide, particularly when psychiatric inpatients kill themselves. Psychiatrists are assumed to have more control over inpatients, making the suicide preventable.

The evaluation of suicide risk is one of the most complex, dauntingly difficult clinical tasks in psychiatry. Suicide is a rare event. In our current state of knowledge, clinicians cannot accurately predict when or if a patient will commit suicide. No professional standards exist for predicting who will or will not commit suicide. Professional standards do exist for assessing suicide risk, but at best, only the degree of suicide risk can be judged clinically after a comprehensive psychiatric assessment.

A review of the case law on suicide reveals that certain affirmative precautions should be taken with a suspected or confirmed suicidal patient. For example, failing to perform a reasonable assessment of a suicidal patient's risk for suicide or implement an appropriate precautionary plan will likely render a practitioner liable. The law tends to assume that suicide is preventable if it is foreseeable. Courts closely scrutinize suicide cases to determine if a patient's suicide was foreseeable. *Foreseeability* is a deliberately vague legal term that has no comparable clinical counterpart, a common-sense rather than a scientific construct. It does not (and should not) imply that clinicians can predict suicide. Foreseeability should not be confused with preventability, however. In hindsight, many suicides seem preventable that were clearly not foreseeable.

**Violent Patients**

Psychiatrists who treat violent or potentially violent patients may be sued for failure to control aggressive outpatients and for the discharge of violent inpatients. Psychiatrists can be sued for failing to protect society from the violent acts of their patients if it was reasonable for the psychiatrist to have known about the patient's violent tendencies and if the psychiatrist could have done something that could have safeguarded the public. In the landmark case *Tarasoff v. Regents of the University of California*, the California Supreme Court ruled that mental health professionals have a duty to protect identifiable, endangered third parties from imminent threats of serious harm made by their outpatients. Since then, courts and state legislatures have increasingly held psychiatrists to a fictional standard of having to predict the future behavior (dangerousness) of their potentially violent patients. Research has consistently demonstrated that psychiatrists cannot predict future violence with any dependable accuracy.

The duty to protect patients and endangered third parties should be considered primarily a professional and moral obligation and, only secondarily, a legal duty. Most psychiatrists acted to protect both their patients and others threatened by violence long before *Tarasoff*.

If a patient threatens harm to another person, most states require that the psychiatrist perform some intervention that might prevent the harm from occurring. In states with duty-to-warn statutes, the options available to psychiatrists and psychotherapists are defined by law. In states offering no such guidance, health care providers are required to use their clinical judgment and act to protect endangered third persons. Typically, a variety of options to warn and protect are clinically and legally available, including voluntary hospitalization, involuntary hospitalization (if civil commitment requirements are met), warning the intended victim of the threat, notifying the police, adjusting medication, and seeing the patient more frequently. Warning others of danger, by itself, is usually insufficient. Psychiatrists should consider the *Tarasoff* duty to be a national standard of care, even if they practice in states that do not have a duty to warn and protect.

**Tarasoff I.** This issue was raised in 1976 in the case of *Tarasoff v. Regents of University of California* (now known as *Tarasoff I*). In this case, Prosenjit Poddar, a student and a voluntary outpatient at the mental health clinic of the University of California, told his therapist that he intended to kill a student readily identified as Tatiana Tarasoff. Realizing the seriousness of the intention, the therapist, with the concurrence of a colleague, concluded that Poddar should be committed for observation under a 72-hour emergency psychiatric detention provision of the California commitment law. The therapist notified the campus police, both orally and in writing, that Poddar was dangerous and should be committed.

Concerned about the breach of confidentiality, the therapist's supervisor vetoed the recommendation and ordered all records relating to Poddar's treatment destroyed. At the same time, the campus police temporarily detained Poddar but released him on his assurance that he would “stay away from that girl.” Poddar stopped going to the clinic when he learned from the police about his therapist's recommendation to commit him. Two months later, he carried out his previously announced threat to kill Tatiana. The young woman's parents thereupon sued the university for negligence.

As a consequence, the California Supreme Court, which deliberated the case for the unprecedented time of about 14 months, ruled that a physician or a psychotherapist who has reason to believe that a patient may injure or kill someone warn the potential victim.

The discharge of the duty imposed on the therapist to warn intended victims against danger may take one or more forms, depending on the case. Therefore, stated the court, it may call for the therapist to notify the intended victim or others likely to notify the victim of the danger, to notify the police, or to take whatever other steps are reasonably necessary under the circumstances.

The *Tarasoff I* ruling does not require therapists to report a patient's fantasies; instead, it requires them to report an intended homicide, and it is the therapist's duty to exercise good judgment.

**Tarasoff II.** In 1982, the California Supreme Court issued a second ruling in the case of *Tarasoff v. Regents of University of California* (now known as *Tarasoff II*), which broadened its earlier ruling extending the duty to warn to include the duty to protect.

The *Tarasoff II* ruling has stimulated intense debates in the medicolegal field. Lawyers, judges, and expert witnesses...
argue the definition of protection, the nature of the relationship between the therapist and the patient, and the balance between public safety and individual privacy.

Clinicians argue that the duty to protect hinders treatment because a patient may not trust a doctor if confidentiality is not maintained. Furthermore, because it is not easy to determine whether a patient is sufficiently dangerous to justify long-term incarceration, unnecessary involuntary hospitalization may occur because of a therapist's defensive practices.

As a result of such debates in the medicolegal field, since 1976, the state courts have not made a uniform interpretation of the Tarasoff II ruling (the duty to protect). Generally, clinicians should note whether a specific identifiable victim seems to be in imminent and probable danger from the threat of an action contemplated by a mentally ill patient; the harm, in addition to being imminent, should be potentially serious or severe. Usually, the patient must be a danger to another person and not to property; the therapist should take clinically reasonable action.

**HOSPITALIZATION**

All states provide for some form of involuntary hospitalization. Such action usually is taken when psychiatric patients present a danger to themselves or others in their environment to the extent that their urgent need for treatment in a closed institution is evident. Certain states allow involuntary hospitalization when patients are unable to care for themselves adequately.

The doctrine of *parens patriae* allows the state to intervene and to act as a surrogate parent for those who are unable to care for themselves or who may harm themselves. In English common law, *parens patriae* ("father of his country") dates to the time of King Edward I and originally referred to a monarch's duty to protect the people. In US common law, the doctrine has been transformed into a paternalism in which the state acts for persons who are mentally ill and for minors.

The statutes governing hospitalization of persons who are mentally ill generally have been designated commitment laws, but psychiatrists have long considered the term to be undesirable. *Commitment* legally means a warrant for imprisonment. The American Bar Association and the American Psychiatric Association have recommended that the term *commitment* be replaced by the less offensive and more accurate term *hospitalization*, which most states have adopted. Although this change in terminology does not correct the punitive attitudes of the past, the emphasis on hospitalization is in keeping with psychiatrists' views of treatment rather than punishment.

**Procedures of Admission**

Four procedures of admission to psychiatric facilities have been endorsed by the American Bar Association to safeguard civil liberties and to make sure that no person is railroaded into a mental hospital. Although each of the 50 states has the power to enact its own laws on psychiatric hospitalization, the procedures outlined here are gaining much acceptance.

**Informal Admission.** Informal admission operates on the general hospital model, in which a patient is admitted to a psychiatric unit of a general hospital in the same way that a medical or surgical patient is admitted. Under such circumstances, the ordinary doctor–patient relationship applies, with the patient free to enter and to leave, even against medical advice.

**Voluntary Admission.** In cases of voluntary admission, patients apply in writing for admission to a psychiatric hospital. They may come to the hospital on the advice of a personal physician, or they may seek help on their own. In either case, patients are admitted if an examination reveals the need for hospital treatment. The patient is free to leave, even against medical advice.

**Temporary Admission.** Temporary admission is used for patients who are so senile or so confused that they require hospitalization and are not able to make decisions on their own and for patients who are so acutely disturbed that they must be admitted immediately to a psychiatric hospital on an emergency basis. Under the procedure, a person is admitted to the hospital on the written recommendation of one physician. After the patient has been admitted, the need for hospitalization must be confirmed by a psychiatrist on the hospital staff. The procedure is temporary because patients cannot be hospitalized against their will for more than 15 days.

**Involuntary Admission.** Involuntary admission involves the question of whether patients are suicidal and thus a danger to themselves or homicidal and thus a danger to others. Because these persons do not recognize their need for hospital care, the application for admission to a hospital may be made by a relative or a friend. After the application is made, the patient must be examined by two physicians, and if both physicians confirm the need for hospitalization, the patient can then be admitted.

Involuntary hospitalization involves an established procedure for written notification of the next of kin. Furthermore, the patients have access at any time to legal counsel, who can bring the case before a judge. If the judge does not think that hospitalization is indicated, the patient's release can be ordered.

Involuntary admission allows a patient to be hospitalized for 60 days. After this time, if the patient is to remain hospitalized, the case must be reviewed periodically by a board consisting of psychiatrists, nonpsychiatric physicians, lawyers, and other citizens not connected with the institution. In New York State, the board is called the Mental Health Information Service.

Persons who have been hospitalized involuntarily and who believe that they should be released have the right to file a petition for a writ of habeas corpus. Under law, a writ of habeas corpus can be proclaimed by those who believe that they have been illegally deprived of liberty. The legal procedure asks a court to decide whether a patient has been hospitalized without due process of law. The case must be heard by a court at once, regardless of the manner or the form in which the motion is filed. Hospitals are obligated to submit the petitions to the court immediately.

**RIGHT TO TREATMENT**

Among the rights of patients, the right to the standard quality of care is fundamental. This right has been litigated in highly publicized cases in recent years under the slogan of "right to treatment."

In 1966, Judge David Bazelon, speaking for the District of Columbia Court of Appeals in *Rouse v. Cameron*, noted that
the purpose of involuntary hospitalization is treatment and concluded that the absence of treatment draws into question the constitutionality of the confinement. Treatment in exchange for liberty is the logic of the ruling. In this case, the patient was discharged on a writ of habeas corpus, the basic legal remedy to ensure liberty. Judge Bazelon further held that if alternative treatments that infringe less on personal liberty are available, involuntary hospitalization cannot take place.

Alabama Federal Court Judge Frank Johnson was more venturesome in the decree he rendered in 1971 in Wyatt v. Stickney. The Wyatt case was a class-action proceeding brought under newly developed rules that sought not release but treatment. Judge Johnson ruled that persons civilly committed to a mental institution have a constitutional right to receive such individual treatment as will give them a reasonable opportunity to be cured or to have their mental condition improved. Judge Johnson set out minimal requirements for staffing, specified physical facilities, and nutritional standards and required individualized treatment plans.

The new codes, more detailed than the old ones, include the right to be free from excessive or unnecessary medication; the right to privacy and dignity; the right to the least restrictive environment; the unrestricted right to be visited by attorneys, clergy, and private physicians; and the right not to be subjected to lobotomies, electroconvulsive treatments, and other procedures without fully informed consent. Patients can be required to perform therapeutic tasks but not hospital chores unless they volunteer for them and are paid the federal minimum wage. This requirement is an attempt to eliminate the practice of peonage, in which psychiatric patients were forced to work at menial tasks, without payment, for the benefit of the state.

In a number of states today, medication or electroconvulsive therapy cannot be forcibly administered to a patient without first obtaining court approval, which may take as long as 10 days.

**RIGHT TO REFUSE TREATMENT**

The right to refuse treatment is a legal doctrine that holds that, except in emergencies, persons cannot be forced to accept treatment against their will. An emergency is defined as a condition in clinical practice that requires immediate intervention to prevent death or serious harm to the patient or another person or to prevent deterioration of the patient's clinical state.

In the 1976 case of O'Connor v. Donaldson, the Supreme Court of the United States ruled that harmless mentally ill patients cannot be confined against their will without treatment if they can survive outside. According to the Court, a finding of mental illness alone cannot justify a state's confining persons in a hospital against their will. Instead, involuntarily confined patients must be considered dangerous to themselves or others or possibly so unable to care for themselves that they cannot survive outside. As a result of the 1979 case of Rennie v. Klein, patients have the right to refuse treatment and to use an appeal process. As a result of the 1981 case of Roger v. Oken, patients have an absolute right to refuse treatment, but a guardian may authorize treatment.

Questions have been raised about psychiatrists' ability to accurately predict dangerousness to self or others and about the risk to psychiatrists, who may be sued for monetary damages if persons who are involuntarily hospitalized are thereby deprived of their civil rights.

**CIVIL RIGHTS OF PATIENTS**

Because of several clinical, public, and legal movements, criteria for the civil rights of persons who are mentally ill, apart from their rights as patients, have been both established and affirmed.

**Least Restrictive Alternative**

The principle holds that patients have the right to receive the least restrictive means of treatment for the requisite clinical effect. Therefore, if a patient can be treated as an outpatient, commitment should not be used; if a patient can be treated on an open ward, seclusion should not be used.

Although apparently fairly straightforward on first reading, difficulty arises when clinicians attempt to apply the concept to choose among involuntary medication, seclusion, and restraint as the intervention of choice. Distinguishing among these interventions on the basis of restrictiveness proves to be a purely subjective exercise fraught with personal bias. Moreover, each of these three interventions is both more and less restrictive than each of the other two. Nevertheless, the effort should be made to think in terms of restrictiveness when deciding how to treat patients.

**Visitation Rights**

Patients have the right to receive visitors and to do so at reasonable hours (customary hospital visiting hours). Allowance must be made for the possibility that, at certain times, a patient's clinical condition may not permit visits. This fact should be clearly documented, however, because such rights must not be suspended without good reason.

Certain categories of visitors are not limited to the regular visiting hours; these include a patient's attorney, private physician, and members of the clergy—all of whom, broadly speaking, have unrestricted access to the patient, including the right to privacy in their discussions. Even here, a bona fide emergency may delay such visits. Again, the patient's needs come first. Under similar reasoning, certain noxious visits may be curtailed (e.g., a patient's relative bringing drugs into the ward).

**Communication Rights**

Patients should generally have free and open communication with the outside world by telephone or mail, but this right varies regionally to some degree. Some jurisdictions charge the hospital administration with a responsibility for monitoring the communications of patients. In some areas, hospitals are expected to make available reasonable supplies of paper, envelopes, and stamps for patient's use.

Specific circumstances affect communication rights. A patient who is hospitalized in relation to a criminal charge of making harassing or threatening phone calls should not be given unrestricted access to the telephone, and similar considerations apply to mail. As a rule, however, patients should be allowed private telephone calls, and their incoming and outgoing mail should not be opened by hospital staff members.

**Private Rights**

Patients have several rights to privacy. In addition to confidentiality, they are allowed private bathroom and shower space,
secure storage space for clothing and other belongings, and adequate floor space per person. They also have the right to wear their own clothes and to carry their own money.

**Economic Rights**

Apart from special considerations related to incompetence, psychiatric patients generally are permitted to manage their own financial affairs. One feature of this fiscal right is the requirement that patients be paid if they work in the institution (e.g., gardening or preparing food). This right often creates tension between the valid therapeutic need for activity, including jobs, and exploitative labor. A consequence of this tension is that valuable occupational, vocational, and rehabilitative therapeutic programs may have to be eliminated because of the failure of legislatures to supply the funding to pay wages to patients who participate in these programs.

**SECLUSION AND RESTRAINT**

Seclusion and restraint raise complex psychiatric legal issues. Seclusion and restraint have both indications and contraindications (Table 36.1-2). Seclusion and restraint have become increasingly regulated over the past decade.

Legal challenges to the use of restraints and seclusion have been brought on behalf of institutionalized persons with psychiatric illnesses or cognitive disabilities. Typically, these lawsuits do not stand alone but are part of a challenge to a wide range of alleged abuses.

Generally, courts hold, or consent decrees provide, that restraints and seclusion be implemented only when a patient creates a risk of harm to self or others and no less restrictive alternative is available. Table 36.1-3 lists additional restrictions.

**INFORMED CONSENT**

Lawyers representing an injured claimant now invariably add to a claim of negligent performance of procedures (malpractice) an informed consent claim as another possible area of liability. Ironically, this is one claim under which the requirement of expert testimony may be avoided. The usual claim of medical malpractice requires the litigant to produce an expert to establish that the defendant physician departed from accepted medical practice. But in a case in which the physician did not obtain informed consent, the fact that the treatment was technically well performed, was in accord with the generally accepted standard of care, and effected a complete cure is immaterial. As a practical matter, however, unless the treatment had adverse consequences, a complainant will not get far with a jury in an action based solely on an allegation that the treatment was performed without consent.

In the case of minors, the parent or guardian is legally empowered to give consent to medical treatment. By statute, most states, however, list specific diseases and conditions that a minor can consent to have treated—including venereal disease, pregnancy, substance dependence, alcohol abuse, and contagious diseases. In an emergency, a physician can treat a minor without parental consent. The trend is to adopt the so-called mature minor rule, which allows minors to consent to treatment under ordinary circumstances. As a result of the Supreme Court’s 1967 *Gault* decision, all juveniles must now be represented by counsel, must be able to confront witnesses, and must be given proper notice of any charges. Emancipated minors have the rights of an adult when it can be shown that they are living as adults with control over their own lives.

### Table 36.1-3
**Restrictions for Seclusion and Restraint**

<table>
<thead>
<tr>
<th>Restriction</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Seclusion only.</td>
<td>Restraints and seclusion can be implemented only when a patient creates a risk of harm to self or others and no less restrictive alternative is available.</td>
</tr>
<tr>
<td>Restrained and seclusion can only be implemented by a written order from an appropriate medical official.</td>
<td>Orders are to be confined to specific, time-limited periods.</td>
</tr>
<tr>
<td>A patient’s condition must be regularly reviewed and documented.</td>
<td>Any extension of an original order must be reviewed and reauthorized.</td>
</tr>
</tbody>
</table>

**Consent Form**

The basic elements of a consent form should include a fair explanation of the procedures to be followed and their purposes, including identification of any procedures that are experimental, a description of any attendant discomforts and risks reasonably to be expected, a description of any benefits reasonably to be expected, a disclosure of any appropriate alternative procedures that may be advantageous to the patient, an offer to answer any inquiries concerning the procedures, and an instruction that the patient is free to withdraw patient consent and to discontinue participation in the project or activity at any time without prejudice.

Some theorists have suggested that the form can be replaced by a standardized discussion that covers the issues noted above and a progress note that documents that the issues were discussed.
CHILD CUSTODY

The action of a court in a child custody dispute is now predicated on the child's best interests. The maxim reflects the idea that a natural parent does not have an inherent right to be named a custodial parent, but the presumption, although a bit eroded, remains in favor of the mother in the case of young children. As a rule, the courts assume that the welfare of a child of tender years generally is best served by maternal custody when the mother is a good and fit parent. The best interest of the mother may be served by naming her as the custodial parent because a mother may never resolve the effects of the loss of a child, but her best interest is not to be equated ipso facto with the best interest of the child. Care and protection proceedings are the court's interventions in the welfare of a child when the parents are unable to care for the child.

More fathers are asserting custodial claims. In about 5 percent of all cases, fathers are named custodians. The movement supporting women's rights also is enhancing the chances of paternal custody. With more women going to work outside the home, the traditional rationale for maternal custody has less force today than it did in the past.

Currently, every state has a statute allowing a court, usually a juvenile court, to assume jurisdiction over a neglected or abused child and to remove the child from parental custody. It usually orders that the care and custody of the child be supervised by the welfare or probation department.

TESTAMENTARY AND CONTRACTUAL CAPACITY AND COMPETENCE

Psychiatrists may be asked to evaluate patients' testamentary capacities or their competence to make a will. Three psychological abilities are necessary to prove this competence. Patients must know the nature and the extent of their bounty (property), the fact that they are making a bequest, and the identities of their natural beneficiaries (spouse, children, and other relatives).

When a will is being probated, one of the heirs or another person may challenge its validity. A judgment in such cases must be based on a reconstruction, using data from documents and from expert psychiatric testimony, of the testator's mental state at the time the will was written. When a person is unable to, or does not exercise the right to, make a will, the law in all states provides for the distribution of property to the heirs. If there are no heirs, the estate goes to the public treasury.

Witnesses at the signing of a will, who might include a psychiatrist, may attest that the testator was rational at the time the will was executed. In unusual cases, a lawyer may videotape the signing to safeguard the will from attack. Ideally, persons who are thinking of making a will and believe that questions might be raised about their testamentary competence hire a forensic psychiatrist to perform a dispassionate examination antemortem to validate and record their capacity.

An incompetence proceeding and the appointment of a guardian may be considered necessary when a family member is spending the family's assets and the property is in danger of dissipation, as in the case of patients who are elderly, have cognitive disabilities, are dependent on alcohol, or have psychosis. At issue is whether such persons are capable of managing their own affairs. A guardian appointed to take control of the property of one deemed incompetent, however, cannot make a will for the ward (the incompetent person).

Competence is determined on the basis of a person's ability to make a sound judgment—to weigh, to reason, and to make reasonable decisions. Competence is task specific, not general; the capacity to weigh decision-making factors (competence) often is best demonstrated by a person's ability to ask pertinent and knowledgeable questions after the risks and the benefits have been explained. Although physicians (especially psychiatrists) often give opinions on competence, only a judge's ruling converts the opinion into a finding; a patient is not competent or incompetent until the court so rules. The diagnosis of a mental disorder is not, in itself, sufficient to warrant a finding of incompetence. Instead, the mental disorder must cause an impairment in judgment for the specific issues involved. After they have been declared incompetent, persons are deprived of certain rights: they cannot make contracts, marry, start a divorce action, drive a vehicle, handle their own property, or practice their professions. Incompetence is decided at a formal courtroom proceeding, and the court usually appoints a guardian who will best serve a patient's interests. Another hearing is necessary to declare a patient competent. Admission to a mental hospital does not automatically mean that a person is incompetent.

Competence also is essential in contracts because a contract is an agreement between parties to do a specific act. A contract is declared invalid if, when it was signed, one of the parties was unable to comprehend the nature and effect of his or her act. The marriage contract is subject to the same standard and thus can be voided if either party did not understand the nature, duties, obligations, and other characteristics entailed at the time of the marriage. In general, however, the courts are unwilling to declare a marriage void on the basis of incompetence.

Whether competence is related to wills, contracts, or the making or breaking of marriages, the fundamental concern is a person's state of awareness and capacity to comprehend the significance of the particular commitment made.

Durable Power of Attorney

A modern development that permits persons to make provisions for their own anticipated loss of decision-making capacity is called a durable power of attorney. The document permits the advance selection of a substitute decision maker who can act without the necessity of court proceedings when the signatory becomes incompetent through illness or progressive dementia.

CRIMINAL LAW

Competence to Stand Trial

The Supreme Court of the United States stated that the prohibition against trying someone who is mentally incompetent is fundamental to the US system of justice. Accordingly, the Court, in Dusky v. United States, approved a test of competence that seeks to ascertain whether a criminal defendant "has sufficient present ability to consult with his lawyer with a reasonable degree of rational understanding—and whether he has a rational as well as factual understanding of the proceedings against him."
Competence to Be Executed

One of the new areas of competence to emerge in the interface between psychiatry and the law is the question of a person's competence to be executed. The requirement for competence in this area is believed to rest on three general principles. First, a person's awareness of what is happening is supposed to heighten the retributive element of the punishment. Punishment is meaningless unless the person is aware of it and knows the punishment's purpose. Second, a competent person who is about to be executed is believed to be in the best position to make whatever peace is appropriate with his or her religious beliefs, including confession and absolution. Third, a competent person who is about to be executed preserves, until the end, the possibility (admittedly slight) of recalling a forgotten detail of the events or the crime that may prove exonerating.

The need to preserve competence was supported recently in the Supreme Court case of Ford v. Wainwright. But no matter the outcome of legal struggles with this question, most medical bodies have gravitated toward the position that it is unethical for any clinician to participate, no matter how remotely, in state-mandated executions; a physician's duty to preserve life transcends all other competing requirements. Major medical societies, such as the American Medical Association (AMA), believe that doctors should not participate in the death penalty. A psychiatrist who agrees to examine a patient slated for execution may find the person incompetent on the basis of a mental disorder and may recommend a treatment plan, which, if implemented, would ensure the person's fitness to be executed. Although room exists for a difference of opinion regarding whether or not a psychiatrist should become involved, the authors of this text believe such involvement to be wrong.

Criminal Responsibility

According to criminal law, committing an act that is socially harmful is not the sole criterion of whether a crime has been committed. Instead, the objectionable act must have two components: voluntary conduct (actus reus) and evil intent (mens rea). An evil intent cannot exist when an offender's mental status is so deficient, so abnormal, or so diseased to have deprived the offender of the capacity for rational intent. The law can be invoked only when an illegal intent is implemented. Neither behavior, however harmful, nor the intent to do harm is, in itself, a ground for criminal action.

M'Naghten Rule. The precedent for determining legal responsibility was established in 1843 in the British courts. The so-called M'Naghten rule, which, until recently, has determined criminal responsibility in most of the United States, holds that persons are not guilty by reason of insanity if they labored under a mental disease such that they were unaware of the nature, the quality, and the consequences of their acts or if they were incapable of realizing that their acts were wrong. Moreover, to absolve persons from punishment, a delusion used as evidence must be one that, if true, would be an adequate defense. If the delusional idea does not justify the crime, such persons are presumably held responsible, guilty, and punishable. The M'Naghten rule is known commonly as the right–wrong test.

The M'Naghten rule derives from the famous M'Naghten case of 1843. When Daniel M'Naghten murdered Edward Drummond, the private secretary of Robert Peel, M'Naghten had been suffering from delusions of persecution for several years, had complained to many persons about his "persecutors," and finally had decided to correct the situation by murdering Robert Peel. When Drummond came out of Peel's home, M'Naghten shot Drummond, mistaking him for Peel. The jury, as instructed under the prevailing law, found M'Naghten not guilty by reason of insanity. In response to questions about what guidelines could be used to determine whether a person could plead insanity as a defense against criminal responsibility, the English chief judge wrote:

1. To establish a defense on the ground of insanity, it must be clearly proved that, at the time of committing the act, the party accused was laboring under such a defect of reason, from disease of the mind, as not to know the nature and quality of the act he was doing, or if he did know it, he did not know he was doing what was wrong.

2. Where a person labors under partial delusions only and is not in other respects insane and as a result commits an offense, he must be considered in the same situation regarding responsibility as if the facts with respect to which the delusion exists were real.

According to the M'Naghten rule, the question is not whether the accused knows the difference between right and wrong in general; rather, it is whether the defendant understood the nature and the quality of the act and whether the defendant knew the difference between right and wrong with respect to the act—that is, specifically whether the defendant knew the act was wrong or perhaps thought the act was correct, a delusion causing the defendant to act in legitimate self-defense.

Jeffery Dahmer (Fig. 36.1-1) killed 17 young men and boys between June 1978 and July 1991. Most of his victims were either homosexual or bisexual. He would meet and select his prey at gay bars or bathhouses and then lure them by offering them money for posing for photographs or simply to enjoy some beer and videos. Then he would drug them, strangle them, masturbate on the body or have sex with the corpse, dismember the body, and dispose of it. Sometimes he would keep the skull or other body parts as souvenirs. On July 13, 1992, Dahmer changed his plea to guilty by means of insanity. That Dahmer could plan his murders and systematically dispose of the bodies convinced the jury, however, that he was able to control his behavior. All of the testimony bolstered the notion that, as with most serial killers, Dahmer knew what he was doing and knew right from wrong. Finally, the jury did not accept the defense that Dahmer experienced a mental illness to the degree that it had disabled his thinking or behavioral controls. Dahmer was sentenced to 15 consecutive life terms or a total of 957 years in prison. He was killed by an inmate on November 28, 1994.

Irresistible Impulse. In 1922, a committee of jurists in England reexamined the M'Naghten rule. The committee suggested broadening the concept of insanity in criminal cases to include the irresistible impulse test, which rules that a person charged with a criminal offense is not responsible for an act if the act was committed under an impulse that the person was unable to resist because of mental disease. The courts have chosen to interpret this concept in such a way that it has been called the policeman-at-the-elbow law. In other words, the court grants
an impulse to be irresistible only when it can be determined that the accused would have committed the act even if a policeman had been at the accused person's elbow. To most psychiatrists, this interpretation is unsatisfactory because it covers only a small, special group of those who are mentally ill.

**Durham Rule.** In the case of *Durham v. United States*, Judge Bazelon handed down a decision in 1954 in the District of Columbia Court of Appeals. The decision resulted in the product rule of criminal responsibility, namely that an accused person is not criminally responsible if his or her unlawful act was the product of mental disease or mental defect. In the Durham case, Judge Bazelon expressly stated that the purpose of the rule was to get good and complete psychiatric testimony. He sought to release the criminal law from the theoretical straitjacket of the M'Naghten rule, but judges and juries in cases using the Durham rule became mired in confusion over the terms product, disease, and defect. In 1972, some 18 years after the rule's adoption, the Court of Appeals for the District of Columbia, in *United States v. Brawner*, discarded the rule. The court—all nine members, including Judge Bazelon—decided in a 143-page opinion to throw out its Durham rule and to adopt in its place the test recommended in 1962 by the American Law Institute in its model penal code, which is the law in the federal courts today.

**Model Penal Code.** In its model penal code, the American Law Institute recommended the following test of criminal responsibility: Persons are not responsible for criminal conduct if, at the time of such conduct, as a result of mental disease or defect, they lacked substantial capacity either to appreciate the criminality (wrongfulness) of their conduct or to conform their conduct to the requirements of the law. The term mental disease or defect does not include an abnormality manifest only by repeated criminal or otherwise antisocial conduct.

Subsection 1 of the American Law Institute rule contains five operative concepts: mental disease or defect, lack of substantial capacity, appreciation, wrongfulness, and conformity of conduct to the requirements of law. The rule's second subsection, stating that repeated criminal or antisocial conduct is not, of itself, to be taken as mental disease or defect, aims to keep the sociopath or psychopath within the scope of criminal responsibility.

**Guilty but Mentally Ill.** Some states have established an alternative verdict of guilty but mentally ill. Under guilty but mentally ill statutes, this alternative verdict is available to the jury if the defendant pleads not guilty by reason of insanity. Under an insanity plea, four outcomes are possible: not guilty, not guilty by reason of insanity, guilty but mentally ill, and guilty.

The problem with guilty but mentally ill is that it is an alternative verdict without a difference. It is basically the same as finding the defendant just plain guilty. The court must still impose a sentence on the convicted person. Although the convicted person supposedly receives psychiatric treatment, if necessary, this treatment provision is available to all prisoners.

Some famous cases of persons declared not guilty by reason of insanity are illustrated in Figure 36.1-1.

### OTHER AREAS OF FORENSIC PSYCHIATRY

#### Emotional Damage and Distress

A rapidly rising trend in recent years is to sue for psychological and emotional damage, both secondary to physical injury or as a consequence of witnessing a stressful act and from the suffering endured under the stress of such circumstances as concentration camp experiences. The German government heard many of these claims from persons detained in Nazi camps during World War II. In the United States, the courts have moved from a conservative to a liberal position in awarding damages for such claims. Psychiatric examinations and testimony are sought in these cases, often by both the plaintiffs and the defendants.

#### Recovered Memories

Patients alleging recovered memories of abuse have sued parents and other alleged perpetrators. In a number of instances, the alleged victimizers have sued therapists who, they claim, negligently induced false memories of sexual abuse. In an about-face, some patients have recanted and joined forces with others (usually their parents) to sue therapists.

Courts have handed down multimillion dollar judgments against mental health practitioners. A fundamental allegation in these cases is that the therapist abandoned a position of neutrality to suggest, persuade, coerce, and implant false memories of childhood sexual abuse. The guiding principle of clinical risk management in recovered memory cases is maintenance of therapist neutrality and establishment of sound treatment boundaries. Table 36.1-4 lists the risk management principles that should be considered when evaluating or treating a patient who recovers memories of abuse in psychotherapy.

<table>
<thead>
<tr>
<th>Table 36.1-4 Risk Management Principles for Cases of Recovered Memories of Abuse in Psychotherapy</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Maintain therapist neutrality: Do not suggest abuse.</td>
</tr>
<tr>
<td>2. Stay clinically focused: Provide adequate evaluation and treatment for patients presenting problems and symptoms.</td>
</tr>
<tr>
<td>3. Carefully document the memory recovery process.</td>
</tr>
<tr>
<td>4. Manage personal bias and countertransference.</td>
</tr>
<tr>
<td>5. Avoid mixingreater and expert witness roles.</td>
</tr>
<tr>
<td>6. Closely monitor supervisory and collaborative therapy relationships.</td>
</tr>
<tr>
<td>7. Clarify nontreatment roles with family members.</td>
</tr>
<tr>
<td>8. Avoid special techniques (e.g., hypnosis or sodium amobarbital [Amytal]) unless clearly indicated; obtain consultation first.</td>
</tr>
<tr>
<td>9. Stay within professional competence: Do not take cases that you cannot handle.</td>
</tr>
<tr>
<td>10. Distinguish between narrative truth and historical truth.</td>
</tr>
<tr>
<td>11. Obtain consultation in problematic cases.</td>
</tr>
<tr>
<td>12. Foster patient autonomy and self-determination: Do not suggest lawsuits.</td>
</tr>

<td>15. Stop and refer, if uncomfortable with a patient who is recovering memories of childhood abuse.</td>
</tr>
<tr>
<td>16. Do not be afraid to ask about abuse as part of a competent psychiatric evaluation.</td>
</tr>
</tbody>
</table>
Worker’s Compensation

The stresses of employment can cause or accentuate mental illness. Patients are entitled to be compensated for their job-related disabilities or to receive disability retirement benefits. A psychiatrist is often called on to evaluate such situations.

Civil Liability

Psychiatrists who sexually exploit their patients are subject to civil and criminal actions in addition to ethical and professional licensure revocation proceedings. Malpractice is the most common legal action (Table 36.1-5).
Ethical guidelines and a knowledge of ethical principles help psychiatrists avoid ethical conflicts (which can be defined as tension between what one wants to do and what is ethically right to do) and think through ethical dilemmas (conflicts between ethical perspectives or values).

Ethics deal with the relations between people in different groups and often entail balancing rights. Professional ethics refer to the appropriate way to act when in a professional role. Professional ethics derive from a combination of morality, social norms, and the parameters of the relationship people have agreed to have.

### References

### Professional Codes

Most professional organizations and many business groups have codes of ethics that reflect a consensus about the general standards of appropriate professional conduct. The American Medical Association’s (AMA’s) Principles of Medical Ethics and the American Psychiatric Association’s (APA’s) Principles of Medical Ethics with Annotations Especially Applicable to Psychiatry articulate ideal standards of practice and professional virtues of practitioners. These codes include exhortations to use skillful and scientific techniques; to self-regulate misconduct within the profession; and to respect the rights and needs of patients, families, colleagues, and society.

### Basic Ethical Principles

Four ethical principles that psychiatrists ought to weigh in their work are respect for autonomy, beneficence, nonmaleficence, and justice. At times, they are in conflict, and decisions must be made concerning how to balance them.

#### Respect for Autonomy

Autonomy requires that a person act intentionally after being given sufficient information and time to understand the benefits, risks, and costs of all reasonable options. It may mean honoring an individual’s right not to hear every detail and even choosing someone else (e.g., family or doctor) to decide the best course of treatment.

Psychiatrists need to provide patients with a rational understanding of their disorder and options for treatment. Patients need conceptual understanding; the psychiatrist should not simply state isolated facts. Patients also need time to think and to talk with friends and family about their decision. Finally, if a patient is not in a state of mind to make decisions for himself or herself, the psychiatrist should consider mechanisms for alternative decision making, such as guardianship, conservators, and health care proxy.

A young adult experienced a schizophrenic episode in which his religious fervor turned into psychotic delusions. After being involuntarily hospitalized because he became suicidal, he insistently refused medication, claiming that his physicians were trying to poison him. His psychiatrist decided to respect his refusal of medication as long as his suicidal tendencies could be controlled. As his mental suffering became more intense, in 1 week the patient changed his mind about medication and agreed to try it. The therapeutic relationship with his psychiatrist deepened, and the patient left the hospital willing to continue with both antipsychotic medication and psychotherapy. Although not all cases work out so well, this one illustrates the benefits of negotiation about treatment even when hospitalization is involuntary.

### Beneficence

The requirement for psychiatrists to act with beneficence derives from their fiduciary relationship with patients and the profession’s belief that they also have an obligation to society. As a result of the role obligation of trust, psychiatrists must heed their patients’ interests, even to the neglect of their own.
The expression of the principle is paternalism, the use of the psychiatrist’s judgment about the best course of action for the patient or research subject. Weak paternalism is acting beneficently when the patient’s impaired faculties prevent an autonomous choice. Strong paternalism is acting beneficently despite the patient’s intact autonomy.

Guidelines have been proposed for permitting beneficence to overrule patient autonomy; when the patient faces substantial harm or risk of harm, the paternalistic act is chosen that ensures the optimal combination of maximal harm reduction, low added risk, and minimal necessary infringement on patient autonomy.

Nonmaleficence
To adhere to the principle of nonmaleficence (primum non nocere or first, do no harm), psychiatrists must be careful in their decisions and actions and must ensure that they have had adequate training for what they do. They also need to be open to seeking second opinions and consultations. They need to avoid creating risks for patients by an action or inaction.

Justice
The concept of justice concerns the issues of reward and punishment and the equitable distribution of social benefits. Relevant issues include whether resources should be distributed equally to those in greatest need, whether they should go to where they can have the greatest impact on the well-being of each individual served, or to where they will ultimately have the greatest impact on society.

SPECIFIC ISSUES
From a practical point of view, several specific issues most frequently involve psychiatrists. These include (1) sexual boundary violations, (2) nonsexual boundary violations, (3) violations of confidentiality, (4) mistreatment of the patient (incompetence, double agentry), and (5) illegal activities (insurance, billing, insider stock trading).

Sexual Boundary Violations
For a psychiatrist to engage a patient in a sexual relationship is clearly unethical. Furthermore, legal sanctions against such behavior make the ethical question moot. Various criminal law statutes have been used against psychiatrists who violate this ethical principle. Rape charges may be, and have been, brought against such psychiatrists; sexual assault and battery charges also have been used to convict psychiatrists.

In addition, patients who have been victimized sexually by psychiatrists and other physicians have won damages in malpractice suits. Insurance carriers for the APA and the AMA no longer insure against patient–therapist sexual relations, and the carriers exclude liability for any such sexual activity.

The issue of whether sexual relations between an ex-patient and a therapist violate an ethical principle, however, remains controversial. Proponents of the view “Once a patient, always a patient” insist that any involvement with an ex-patient—even one that leads to marriage—should be prohibited. They maintain that a transferential reaction that always exists between the patient and the therapist prevents a rational decision about their emotional or sexual union. Others insist that, if a transferential reaction still exists, the therapy is incomplete and that as autonomous human beings, ex-patients should not be subjected to paternalistic moralizing by physicians. Accordingly, they believe that no sanctions should prohibit emotional or sexual involvement by ex-patients and their psychiatrists. Some psychiatrists maintain that a reasonable time should elapse before such a liaison. The length of the “reasonable” period remains controversial: Some have suggested 2 years. Other psychiatrists maintain that any period of prohibited involvement with an ex-patient is an unnecessary restriction. The Principles, however, states: “Sexual activity with a current or former patient is unethical.”

Although not spelled out in The Principles, sexual activity with a patient’s family member is also unethical. This is most important when the psychiatrist is treating a child or adolescent. Most training programs in child and adolescent psychiatry emphasize that the parents are patients too and that the ethical and legal proscriptions apply to parents (or parent surrogates) as well as to the child. Nevertheless, some psychiatrists misunderstand this concept. Sexual activity between a doctor and a patient’s family member is also unethical.

An egregious example of a sexual boundary violation was reported in the Medical Board of California Action Report (July 2006) of a psychiatrist who had a 7-year affair with a patient who had schizophrenia. The doctor not only had sex with the patient but also had her procure prostitutes with whom he and the patient had group sex. He paid for their services by providing them with prescriptions for controlled substances and went so far as to bill Medi-Cal for these encounters as group therapy. The physician’s license was revoked, and he was also criminally convicted of fraud.

Nonsexual Boundary Violations
The relationship between a doctor and a patient for the purposes of providing and obtaining treatment is what is usually called the doctor–patient relationship. That relationship has both boundaries around it and boundaries within it. Either person may cross the boundary.

Not all boundary crossings are boundary violations. For example, a patient may say to a doctor at the end of an hour, “I have left my money at home, and I need a dollar to get my car out of the garage. Will you lend me a dollar until next time?” The patient has invited the doctor to cross the doctor–patient boundary and set up a lender–borrower relationship as well. Depending on the doctor’s theoretical orientation, the clinical situation with the patient, and other factors, the doctor may elect to cross the boundary. Whether the boundary crossing is also a boundary violation is debatable. A boundary violation is a boundary crossing that is exploitative. It gratifies the doctor’s needs at the expense of the patient. The doctor is responsible for preserving the boundary and for ensuring that boundary crossings are held to a minimum and that exploitation does not occur.

A resident in psychiatry was admonished by her psychotherapy supervisor to never, under any circumstances, accept a gift from a patient. In the course of treating a young girl with schizophrenia, she was offered a Christmas gift (a cotton scarf), which she refused.
be avoided during treatment. Similarly, psychiatrists should not treat their social friends for the same set of reasons. Obviously, in an emergency, a person does what a person must.

Financial. For psychiatrists who practice in the private sector, dealing with the patient about money is a part of treatment. Issues surrounding setting the fee, collecting the fee, and other financial matters are grist for the mill. Even so, ethical concerns must be observed. The Principles advises the doctor on such matters as charging for missed appointments and other contractual problems. Ethics complaints against doctors are frequently precipitated by financial issues; thus, the doctor must recognize the power that these issues have in the therapeutic relationship. Because the psychotherapeutic relationship is so much like a social relationship—the office looks like a living room; the doctor wears regular clothes; some patients might, without recognizing it, assume that a friendship exists that forgives payment of a fee. When the bill is presented, feelings, even though they are unconscious, are ruffled. The idea that psychiatric services are dispensed in a contractual context cannot be sufficiently emphasized. Early in their careers, psychiatrists are often reluctant to discuss fees openly out of a sense of embarrassment over discussing money or a sense of protecting the patient.

How an ethical psychiatrist handles the situation when a patient temporarily or permanently runs out of money is important. Many options are available—some more problematic than others. The psychiatrist can certainly lower the fee, but caution is needed because a fee lowered to the point where the treatment is not somehow being compensated may evoke countertransference resentment. The number of patients being seen at a reduced fee is a similar consideration. Running up a bill can also be a problem. Is there an expectation of eventually being paid? Is the hypertrophic bill a sham? The frequency of sessions may have to be altered. Any psychiatrist who sees private patients will definitely face these problems.

Confidentiality

Confidentiality refers to the therapist's responsibility not to release information learned in the course of treatment to third parties. Privilege refers to the patient's right to prevent disclosure of information from treatment in judicial hearings. Psychiatrists must maintain confidentiality because it is an essential ingredient of psychiatric care; it is a prerequisite for patients to be willing to speak freely to therapists. Violating confidentiality by gossiping embarrasses people and violates nonmaleficence. Violation of confidentiality also breaks the promise that a psychiatrist has explicitly or implicitly made to keep material confidential.

Confidentiality must also give way to the responsibility to protect others when a patient makes a credible threat to harm someone. The situation becomes complicated when the risk is not to a particular individual, such as when a doctor is impaired or someone's mental state adversely affects his or her performance of a dangerous job, such as police work, firefighting, or use of dangerous machinery. Erosion has also arisen from the demands of an insurance company for detailed information. Patients must be told that information may be released to insurance companies, but they do not need to be warned that
information concerning abuse of a child or threat to themselves or others needs to be reported.

Various settings exist in which patient data can be used to some degree. The general rule for doing so is to disclose only that information that is truly necessary. In teaching, research, and supervision, patients' names or information that might allow others to identify them should not be unnecessarily released. In ward rounds and case conferences, in which patient material is presented, attendees should be reminded that what they hear should not be repeated.

Confidentiality endures after death, with the ethical obligation to withhold information unless the next of kin provides consent. A subpoena is not automatic license to release the entire record. A psychiatrist can petition the judge for an in-camera (private) review to define what precise information must be disclosed.

Ethics in Managed Care

Psychiatrists have certain responsibilities toward patients treated in managed care settings, including the responsibilities to disclose all treatment options, exercise appeal rights, continue emergency treatment, and cooperate reasonably with utilization reviewers.

Responsibility to Disclose. Psychiatrists have a continuing responsibility to the patient to obtain informed consent for treatments or procedures. All treatment options should be fully disclosed, even those not covered under the terms of a managed care plan. Most states have enacted legislation making gag rules illegal that limit information about treatment provided to patients under managed care.

Responsibility to Appeal. The AMA Council on Ethical and Judicial Affairs states that physicians have an ethical obligation to advocate for any care that they believe will materially benefit their patients, regardless of any allocation guidelines or gatekeeper directives.

Responsibility to Treat. Physicians are liable for failure to treat their patients within the defined standard of care. The treating physician has sole responsibility to determine what is medically necessary. Psychiatrists must be careful not to discharge suicidal or violent patients prematurely merely because continued coverage of benefits is not approved by a managed care company.

Responsibility to Cooperate with Utilization Review. The psychiatrist should cooperate with utilization reviewers' requests for information on proper authorization from the patient. When benefits are denied, it is important to understand and follow grievance procedures carefully; return telephone calls from review agencies; and provide documented, solid justification for continued treatment.

With the advent of managed care and the need to send periodic progress reports and documentation of signs and symptoms to third-party reviewers to pay for treatment, some psychiatrists may diminish or exaggerate symptomatology. The following case report and discussion illustrates the ethical difficulties psychiatrists face in dealing with managed care.

Mrs. P admitted herself to the hospital because she was afraid she might kill herself. She was experiencing a major depressive episode, but she improved markedly during the first weeks on Dr. A's ward. Although Dr. A believed that Mrs. P was no longer suicidal, he thought she would benefit greatly from continued hospitalization. Because he knew that Mrs. P could not afford to pay for hospitalization and that the insurance company would pay only if the patient was suicidally depressed, he decided not to document Mrs. P's improvement. He noted in the chart that "the patient continues to have a risk of suicide."

Does Dr. A engage in a form of deception? Yes, he intentionally misleads by what he writes and what he omits writing in the chart. Although what he writes is true in some literal sense, his statement is misleading in the context of treatment. Mrs. P is not suicidally depressed in the way that she was.

What does Dr. A omit from the chart is also deceptive. Whether a particular omission is deceptive depends, in part, on the roles and expectations of the people involved. Not telling a colleague that one dislikes his tie is not a deception. It is simply tact unless the role or relationship involves the expectation that one offers a candid opinion. Dr. A's case is different. His professional role is to document the patient's course and the expectation is that he will note any significant improvement. Thus, his failure to document Mrs. P's progress accurately is a kind of deception.

The second and more difficult question is whether deception is justified in this instance. The answer to that question depends on the reasons for the deception, the reasons against it, and the alternatives available. The reasons for this deception are obvious. Dr. A's aim and primary obligation is to help the patient. He believes that Mrs. P would benefit greatly from continued hospitalization that she cannot afford. He may also believe that it is unfair for the insurance company to refuse to pay for inpatient treatment of nonsuicidal depression and that his deception rectifies that unfair practice.

Important reasons also exist against this deception. The first concerns honesty and social trust. It is a good thing if people can rely on what others say and write. Without some honesty and trust, many social exchanges and practices would be impossible. Deception, even for beneficial purposes, has real potential to damage social trust. A risk exists that deception may damage people's trust in the profession of psychiatry and even patients' trust in their psychiatrists. Damage to trust may, in turn, compromise treatment.

The second reason concerns future medical treatment. If Mrs. P seeks medical treatment in the future, the physicians who attend her will read the misleading notes. If they believe that the notes are an accurate account of the previous treatment, they may suggest an inappropriate treatment for the present problem. Even if they have doubts about the accuracy of the notes in her chart, they are deprived of an accurate history and report. In either case, the prior deception can hinder treatment.

The third reason concerns obligations and coverage policies. Dr. A seems to ignore the obligation that he has to the population that is covered by the insurance policy. He shifts a burden onto this population by forcing the insurance company to pay for treatment that it did not agree to cover. Perhaps the insurance company should pay for inpatient treatment in cases such as Mrs. P's; perhaps its policies are unreasonable and unfair. However, Dr. A's deception does not challenge the insurance company and pressure it to change its policy, nor does his deception encourage patients and their families to contest the company's policies. The use of deception simply circumvents, in an ad hoc way, a policy that should be challenged and discussed.

Dr. A also seems to ignore his obligation to future patients. By introducing an inaccuracy into the chart, he compromises the value of medical records research. His deception works, in a small way,
Impaired Physicians

A physician may become impaired as the result of psychiatric or medical disorders or the use of mind-altering and habit-forming substances (e.g., alcohol and drugs). Many organic illnesses can interfere with the cognitive and motor skills required to provide competent medical care. Although the legal responsibility to report an impaired physician varies, depending on the state, the ethical responsibility remains universal. An incapacitated physician should be reported to an appropriate authority, and the reporting physician is required to follow specific hospital, state, and legal procedures. A physician who treats an impaired physician should not be required to monitor the impaired physician's progress or fitness to return to work. This monitoring should be performed by an independent physician or group of physicians who have no conflicts of interest.

The Office of Professional Medical Conduct (OPMC) in New York State regulates the practice of medicine by investigating illegal or unethical practice by physicians and other health professionals, such as physician assistants. Similar regulatory agencies exist in other states. Professional misconduct in New York State is defined as one of the following:

1. Practicing fraudulently and with gross negligence or incompetence
2. Practicing while the ability to practice is impaired
3. Being habitually drunk or being dependent on, or a habitual user of, narcotics or a habitual user of other drugs having similar effects
4. Immoral conduct in the practice of the profession
5. Permitting, aiding, or abetting an unlicensed person to perform activities requiring a license
6. Refusing a client or patient service because of creed, color, or national origin
7. Practicing beyond the scope of practice permitted by law
8. Being convicted of a crime or being the subject of disciplinary action in another jurisdiction

Professional misconduct complaints derive mainly from the public in addition to insurance companies, law enforcement agencies, and doctors, among others.

New York State has established a program called Committee for Physician Health (CPH) in which impaired physicians receive appropriate treatment for their condition without losing their medical license as long as they comply with a treatment program. For example, a physician addicted to opioids or alcohol might be hospitalized to safely withdraw from the drugs and then move to a sober house for further rehabilitation that would involve intensive individual and group psychotherapy, mandatory supervised drug testing and careful oversight by CPH. The physician must be compliant for 5 years during which time he or she may gradually return to practice under supervision. The program has rehabilitated many physicians successfully.

Physicians in Training

It is unethical to delegate authority for patient care to anyone who is not appropriately qualified and experienced, such as a medical student or a resident, without adequate supervision from an attending physician. Residents are physicians in training and, as such, must provide a good deal of patient care. Within a healthy, ethical teaching environment, residents and medical students may be involved with, and responsible for, the day-to-day care of many ill patients, but they are supervised, supported, and directed by highly trained and experienced physicians. Patients have the right to know the level of training of their care providers and should be informed about the resident's or medical student's level of training. Residents and medical students should know and acknowledge their limitations and should ask for supervision from experienced colleagues as necessary.

Physician Charter of Professionalism

In 2001, a movement to clarify the concept of “professionalism” was begun by the American Board of Internal Medicine. A set of principles called the Physician Charter of Professionalism was developed, which describes what it means for physicians to perform at their highest and most ethical level. Table 36.2-1 lists the principles and commitments of professional behaviors in the Physician Charter of Professionalism to which all physicians (including psychiatrists) are expected to adhere.

A summary of ethical issues discussed in this section is presented in a question-and-answer format in Table 36.2-2.

Military Psychiatry

Psychiatrists in the military face unique ethical problems because confidentiality does not exist under the military code of conduct.

A 19-year-old white single man, new to military service, presented with a history of periodic episodes of anxiety when taking showers in groups with other men. He identified himself as gay and recognized that his anxiety was related to his fear of acting out his sexual impulses, thus risking court martial and dishonorable discharge, if he is ever discovered. The psychiatrist was faced with a dilemma: whether to report the soldier to his commanding officer (as he was obliged to do under the military code) or to protect the soldier from acting on his impulses that would place him in danger (in keeping with the medical ethic to do no harm). After discussing various options, he and the patient agreed on the latter option. A diagnosis of anxiety disorder was made, which allowed the patient to receive an honorable discharge on medical grounds based on a recognized psychiatric disorder. No record of his homosexual orientation was made.
Table 36.2-1
Physician Charter of Professionalism

Fundamental Principles
- **Primer of patient welfare.** Altruism contributes to the trust central to doctor-patient relationships. Market forces, societal pressures, and administrative exigencies must not compromise this principle.
- **Patient autonomy.** Physicians must be honest with patients and empower them to make informed decisions about treatment.
- **Social justice.** Physicians should work actively to eliminate discrimination in health care, whether based on race, gender, socioeconomic status, ethnicity, religion, or any other social category.

A Set of Commitments
- **Professional competence.** Physicians must be committed to lifelong learning. The profession as a whole must strive to see that all of its members are competent.
- **Honesty with patients.** Physicians must ensure that patients are completely and honestly informed before consenting to a treatment; they must be empowered to decide about the course of therapy. Physicians should also acknowledge that medical errors that injure patients sometimes occur. If a patient is injured through error, he or she should be informed promptly because failure to do so seriously compromises patient and societal trust.
- **Patient confidentiality.** Fulfilling the commitment to confidentiality is more pressing now than ever before given the widespread use of electronic information systems for compiling patient data.
- **Improving appropriate relations with patients.** Physicians should never exploit patients for any sexual advantage, personal financial gain, or other private purpose.
- **Improving quality of care.** This commitment entails both maintaining clinical competence and working collaboratively with other professionals to reduce medical error, increase patient safety, minimize overuse of health care resources, and optimize the outcomes of care.
- **Improving access to care.** Physicians must individually and collectively strive to reduce barriers to equitable health care.
- **Just distribution of finite resources.** Physicians should be committed to working with other physicians, hospitals, and payers to develop guidelines for cost-effective care. The physician’s professional responsibility for appropriate allocation of resources requires scrupulous avoidance of superfluous tests and procedures.
- **Scientific knowledge.** Physicians have a duty to uphold scientific standards, to promote research, and to create new knowledge and ensure its appropriate use.
- **Maintaining trust by managing conflicts of interest.** Physicians have an obligation to recognize, disclose to the general public, and address conflicts of interest. Relationships between industry and opinion leaders should be disclosed.
- **Professional responsibilities.** Physicians are expected to participate in the process of self-regulation, including remediation and discipline of members who have failed to meet professional standards.

Ethical Questions and Answers

<table>
<thead>
<tr>
<th>Topic</th>
<th>Question</th>
<th>Answer</th>
</tr>
</thead>
<tbody>
<tr>
<td>Abandonment</td>
<td>How can psychiatrists avoid being charged with patient abandonment on retirement?</td>
<td>Retiring psychiatrists are not abandoning patients if they provide their patients with sufficient notice and make every reasonable effort to find follow-up care for the patients. This could constitute abandonment unless the outpatient practitioner or agency arranges for their patients to receive inpatient care from another provider.</td>
</tr>
<tr>
<td></td>
<td>Is it ethical to provide only outpatient care to a seriously ill patient who may require hospitalization?</td>
<td>No. Accepting the bequest seems improper and exploitative of the therapeutic relationship. However, it may be ethical to accept a token bequest from a deceased patient who named his or her psychiatrist in the will without that psychiatrist’s knowledge.</td>
</tr>
<tr>
<td>Bequests</td>
<td>A dying patient bequeaths his or her estate to his or her treating psychiatrist. Is this ethical?</td>
<td>Psychiatrists may provide nonpsychiatric medical procedures if they are competent to do so and if the procedures do not preclude effective psychiatric treatment by distorting the transference. Pelvic examinations carry a high risk of distorting the transference and would be better performed by another clinician.</td>
</tr>
<tr>
<td>Competency</td>
<td>Is it ethical for psychiatrists to perform vaginal examinations? Hospital physical examinations?</td>
<td>Yes. Incompetency is an ethical issue.</td>
</tr>
<tr>
<td></td>
<td>Can ethics committees review issues of physician competency?</td>
<td>Yes. Ethically, confidences survive a patient’s death. Exceptions include protecting others from imminent harm or proper legal compulsions.</td>
</tr>
<tr>
<td>Confidentiality</td>
<td>Must confidentiality be maintained after the death of a patient?</td>
<td>Yes, if the information provided is limited to that which is needed to process the insurance claim.</td>
</tr>
<tr>
<td></td>
<td>Is it ethical to release information about a patient to an insurance company?</td>
<td>Yes, if informed, uncoerced consent has been obtained, anonymity is maintained, the audience is advised that editing makes this an incomplete session, and the patient knows the purpose of the videotape.</td>
</tr>
<tr>
<td></td>
<td>Can a videotaped segment of a therapy session be used at a workshop for professionals?</td>
<td></td>

Ethical Questions and Answers (Continued)

<table>
<thead>
<tr>
<th>Topic</th>
<th>Question</th>
<th>Answer</th>
</tr>
</thead>
<tbody>
<tr>
<td>Taping and recording</td>
<td>Should a physician report mere suspicion of child abuse in a state requiring reporting of child abuse?</td>
<td>No. A physician must make several assessments before deciding whether to report suspected abuse. One must consider whether abuse is ongoing, whether abuse is responsive to treatment, and whether reporting will cause potential harm. Check specific statutes. Make safety for potential victims the top priority.</td>
</tr>
<tr>
<td>Supervision</td>
<td>Is there a potential ethical conflict if a psychiatrist has both psychotherapeutic and administrative duties in dealing with students or trainees?</td>
<td>Yes. You must define your role in advance to the trainees or students. Administrative opinions should be obtained from a psychiatrist who is not involved in a treatment relationship with the trainee or student.</td>
</tr>
<tr>
<td>The Health Insurance Portability and Accountability Act (HIPAA) was passed in 1996 to address the medical delivery system’s mounting complexity and its rising dependence on electronic communication. The act orders that the federal Department of Health and Human Services (HHS) develop rules protecting the transmission and confidentiality of patient information, and all units under HIPAA must comply with such rules. The Privacy Rule, administered by the Office of Civil Rights (OCR) at HHS, protects the confidentiality of patient information (Table 36.2-3).</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Conflict of interest</td>
<td>Is it ethical for a supervising psychiatrist to sign a diagnosis on an insurance form for services provided by a supervisee when the psychiatrist has not examined the patient?</td>
<td>Yes, if the psychiatrist ensures that proper care is given and the insurance form clearly indicates the role of supervisor and supervisee.</td>
</tr>
<tr>
<td>Exploitation</td>
<td>Is it ethical to offer a diagnosis based only on review of records to determine, for insurance purposes, if suicide was the result of illness?</td>
<td>Exploitation occurs when the psychiatrist uses the therapeutic relationship for personal gain. This includes adopting or hiring a patient as well as sexual or financial relationships.</td>
</tr>
<tr>
<td>Exploitation (also see Bequests)</td>
<td>Is it ethical for a supervising psychiatrist to sign a diagnosis on an insurance form for services provided by a supervisee when the psychiatrist has not examined the patient?</td>
<td>Exploitation occurs when the psychiatrist uses the therapeutic relationship for personal gain. This includes adopting or hiring a patient as well as sexual or financial relationships.</td>
</tr>
<tr>
<td>Fee splitting</td>
<td>What constitutes exploitation of the therapeutic relationship?</td>
<td>Exploitation occurs when the psychiatrist uses the therapeutic relationship for personal gain. This includes adopting or hiring a patient as well as sexual or financial relationships.</td>
</tr>
<tr>
<td>Exploitation</td>
<td>What is fee splitting?</td>
<td>Exploitation occurs when the psychiatrist uses the therapeutic relationship for personal gain. This includes adopting or hiring a patient as well as sexual or financial relationships.</td>
</tr>
<tr>
<td>Informed consent</td>
<td>Is it ethical to refuse to divulge information about a patient who has agreed to give this information to those requesting it?</td>
<td>No. If the patient is aware of the supervisory or teaching process and confidentiality is preserved.</td>
</tr>
<tr>
<td>Informed consent</td>
<td>Is informed consent needed when presenting or writing about case material?</td>
<td>Not if the patient is aware of the supervisory or teaching process and confidentiality is preserved.</td>
</tr>
<tr>
<td>Moonlighting</td>
<td>Can psychiatric residents ethically “moonlight”?</td>
<td>They can if their duties are not beyond their ability, if they are properly supervised, and if the moonlighting does not interfere with their residency training.</td>
</tr>
<tr>
<td>Reporting</td>
<td>Should psychiatrists expose or report unethical behavior of a colleague or colleague? Can a spouse bring an ethical complaint?</td>
<td>Psychiatrists are obligated to report colleagues’ unethical behavior. A spouse with knowledge of unethical behavior can bring an ethical complaint as well.</td>
</tr>
<tr>
<td>Reporting</td>
<td>How can ethical research be performed with subjects who cannot give informed consent?</td>
<td>Consent can be given by a legal guardian or via a living will. Incompetent persons have the right to withdraw from the research project at any time.</td>
</tr>
<tr>
<td>Research</td>
<td>See Abandonment.</td>
<td>The psychiatrist must spend sufficient time to ensure that proper care is given and that the supervisee is not providing services that are outside the scope of his or her training. It is ethical to charge a fee for supervision.</td>
</tr>
<tr>
<td>Informed consent</td>
<td>Is it ethical to refuse to divulge information about a patient who has agreed to give this information to those requesting it?</td>
<td>No. If the patient is aware of the supervisory or teaching process and confidentiality is preserved.</td>
</tr>
<tr>
<td>Informed consent</td>
<td>Is informed consent needed when presenting or writing about case material?</td>
<td>Not if the patient is aware of the supervisory or teaching process and confidentiality is preserved.</td>

Health Insurance Portability and Accountability Act

The Health Insurance Portability and Accountability Act (HIPAA) was passed in 1996 to address the medical delivery system’s mounting complexity and its rising dependence on electronic communication. The act orders that the federal Department of Health and Human Services (HHS) develop rules protecting the transmission and confidentiality of patient information, and all units under HIPAA must comply with such rules. The Privacy Rule, administered by the Office of Civil Rights (OCR) at HHS, protects the confidentiality of patient information (Table 36.2-3).
**Table 36.2-3**

<table>
<thead>
<tr>
<th>Patients’ Rights under the Privacy Rule</th>
</tr>
</thead>
<tbody>
<tr>
<td>Physicians must give the patient a written notice of his or her privacy rights; the privacy policies of the practice; and how patient information is used, kept, and disclosed. A written acknowledgment should be taken from the patient verifying that he or she has seen such notice.</td>
</tr>
<tr>
<td>Patients should be able to obtain copies of their medical records and to request revisions to those records within a stated amount of time (usually 30 days). Patients do not have the right to see psychotherapy notes.</td>
</tr>
<tr>
<td>Physicians must provide the patient with a history of most disclosures of their medical history on request. Some exceptions exist. The APA Committee on Confidentiality has developed a model document for this requirement.</td>
</tr>
<tr>
<td>Physicians must obtain authorization from the patient for disclosure of information other than for treatment, payment, and health care operations (these three are considered to be routine uses, for which consent is not required). The APA Committee on Confidentiality has developed a model document for this requirement.</td>
</tr>
<tr>
<td>Patients may request another means of communication of their protected information (e.g., request that the physician contact them at a specific phone number or address).</td>
</tr>
<tr>
<td>Physicians cannot generally limit treatment to obtaining patient authorization for disclosure of their information for nonroutine uses.</td>
</tr>
<tr>
<td>Patients have the right to complain about Privacy Rule violations to the physician, their health plan, or to the Secretary of HHS.</td>
</tr>

**References**

Mental disorders are highly prevalent in all regions of the world and represent a major source of disability and social burden worldwide. Treatments for all of these disorders are available and have been found to be efficacious in both developed and developing countries. However, mental disorders are remarkably undertreated worldwide, especially in low-income countries. National mental health policies are lacking in several countries, especially low-income ones. Resources for mental health care are scarce and unequally distributed. World psychiatry focuses on these and other issues such as the stigma attached to mental disorders, the relationships between mental and physical diseases, and the ethics of mental health care.

**PREVALENCE AND BURDEN OF MENTAL DISORDERS WORLDWIDE**

The World Health Organization (WHO) estimates that more than 25 percent of individuals worldwide develop one or more mental disorders during their lifetime. Among people seen by primary health care professionals, more than 20 percent have one or more current mental disorders. In a study carried out by the WHO at 14 sites in Africa, Asia, the Americas, and Europe, the average current prevalence of any mental disorder was 24 percent, without consistent differences between low- and high-income countries. The most common diagnoses were those of depression (average, 10.4 percent) and generalized anxiety disorder (average, 7.9 percent). Female rates were 1.89 times higher than male rates for depression, but male rates were higher for alcohol-related disorders, so that there was no sex difference in the proportion of people having at least one mental disorder. Physical ill health and educational disadvantage were both significantly associated with a diagnosis of mental disorder.

To quantify the burden of the various diseases and injuries, the WHO, in collaboration with the Harvard School of Public Health and the World Bank, introduced the disability-adjusted life year (DALY). DALYs for a given disease or injury are the sum of the years of life lost due to premature mortality plus the years lost due to disability for incident cases of that disease or injury in the general population. In the original estimates for the year 1990, mental and neurological disorders accounted for 10.5 percent of the total DALYs lost due to all diseases and injuries. The estimate for the year 2000 was 12.3 percent, with two mental disorders (depression and alcohol use disorders) and suicide ranking in the top 20 causes of DALYs for all ages.

In the estimates for the year 2005, mental and neurological disorders accounted for 13.5 percent of all DALYs in the world (27.4 percent in high-income countries, 17.7 percent in middle-income countries, and 9.1 percent in low-income countries), being the main contributor to burden among noncommunicable diseases (27.5 percent compared with 22 percent for cardiovascular diseases and 11 percent for cancer).

According to the updated estimates for the year 2030, mental and neurological disorders will account for 14.4 percent of all DALYs in the world and 25.4 percent of those due to noncommunicable diseases. Depression will rank number 2 in the percentage of total DALYs in that year (5.7 percent), following HIV/AIDS and preceding ischemic heart disease (Table 37-1). It will be number 1 in high-income countries (9.8 percent), number 2 in middle-income countries (6.7 percent), and number 3 in low-income countries (4.7 percent).

The WHO estimates that one of four families worldwide has at least one member with a mental disorder. The objective and subjective burden related to caring for people with severe mental disorders (in terms of disruption of family relationships; constraints in social, leisure, and work activities; financial difficulties; negative effect on physical health; feelings of loss, depression, and embarrassment in social situations; and the stress of coping with disturbing behaviors) has been reported to be substantial and significantly higher than that related to caring for people with long-term physical diseases such as diabetes and heart, kidney, or lung diseases. Cross-cultural differences have been reported in some dimensions of family burden.

Suicide is among the ten leading causes of death for all ages in most of the countries for which information is available. In some countries (e.g., China), it is the leading cause of death for people between 15 and 34 years of age.

According to WHO estimates, about 849,000 people died from suicide worldwide in the year 2001. In that year, the number of suicide deaths overtook the number of deaths by violence (500,000) and war (230,000). In 2020, approximately 1.53 million people will die from suicide worldwide based on current trends, and 10 to 20 times more people will attempt suicide. Reported suicide rates vary considerably across countries; for instance, annual suicide rates of 48.0 to 79.3 per 100,000 have been reported in many Eastern and Central European countries, and rates of less than 4.0 per 100,000 have been found in Islamic and several Latin American countries. More than 85 percent of suicides are reported to occur in low- or middle-income countries, but this figure may represent an underestimate due to the low reliability of official statistics in those countries: When surveillance with validated verbal autopsy was used in South India, the observed rates for suicide exceeded official national estimates tenfold. In the Asia-Pacific region, 300,000 cases of suicide per year are estimated to occur by self-poisoning with pesticides.

Suicide rates are higher in men than in women (3.2:1 in 1950, 3.6:1 in 1995, and an estimated 3.9:1 in 2020). China is the only country where suicide rates in women are consistently higher than in men, especially in rural areas. Over the past few decades, suicide rates have been reported to be stable.

TREATMENT GAP AND PROJECTED POPULATION-LEVEL TREATMENT EFFECTIVENESS WORLDWIDE

The efficacy of pharmacological and psychosocial treatments for mood, anxiety, psychotic, and substance-related disorders has been convincingly proved by clinical trials carried out in low- and middle-income, as well as in high-income, countries. However, the treatment gap is substantial for all mental disorders worldwide, particularly in low-income countries.

In the World Mental Health Surveys, failure and delays in treatment seeking were generally greater in low-income countries, older cohorts, men, and cases with earlier ages of onset. The earlier treatment contact of people with mood disorders might be partly due to the fact that these disorders have been targeted by educational campaigns and primary care quality improvement programs in several countries.

RESOURCES FOR MENTAL HEALTH CARE WORLDWIDE

According to the Mental Health Atlas 2005, only 62.1 percent of countries worldwide, accounting for 68.3 percent of the world population, have a mental health policy (i.e., a document of the government or ministry of health specifying the goals for improving the mental health situation of the country, the priorities among those goals, and the main directions for attaining them). A mental health policy is present in 58.8 percent of low-income and 70.5 percent of high-income countries. In Africa, only 50 percent of countries have a mental health policy. In Southeast Asia, only 54.5 percent of countries have a mental health policy, and 76.4 percent of the population is not covered by such a policy (Table 37-2).

Community care facilities exist in only 68.1 percent of the countries (51.7 percent of low-income and 93 percent of high-income countries). Only 60.9 percent of the countries report providing treatment facilities for severe mental disorders at the primary care level (55.2 percent of low-income and 79.5 percent of high-income countries). About one fourth of low-income countries do not provide even basic antidepressant medications in primary care settings. In many others, the supply does not cover all regions of the country or is very irregular. Because medicines are often not available in health care facilities, patients and families are forced to pay for them out of pocket.

Whereas 61.5 percent of European countries spend more than 5 percent of their health budget on mental health care, 70 percent of countries in Africa and 50 percent of countries in Southeast Asia spend less than 1 percent. Out-of-pocket payment is the most important method of financing mental health care in 38.6 percent of countries in Africa and 30 percent of countries in Southeast Asia, but it is not the primary method of financing mental health care in any European country (Table 37-3). All countries with out-of-pocket payment as the dominant method of financing mental health care belong to low-income or lower middle-income categories, but almost all countries with social insurance as the dominant method of financing belong to high-income or upper middle-income categories.

The median number of psychiatrists per 100,000 population ranges from 0.04 in Africa and 0.2 in Southeast Asia to 9.8 in Europe (Table 37-4). It is 0.1 in low-income countries compared with 9.2 in high-income countries. Two thirds of low-income countries have less than one psychiatrist per 100,000 population. Chad, Eritrea, and Liberia (with populations of 9, 4.2 and 3.5 million, respectively) each has just one psychiatrist per 100,000 population. Afghanistan, Rwanda, and Togo (with populations of 25, 8.5, and 5 million respectively) each has just two psychiatrists per 100,000 population. Large-scale migration of psychiatrists from low- and middle-income to high-income countries, as part of the larger picture of migration, has been consistently documented. India and some sub-Saharan African countries are the most important contributors to the mental health workforce in the United Kingdom, although the United Kingdom has 110 psychiatrists per million population, but India has 2 per million and sub-Saharan Africa less than 1 per million. The median number of psychologists working in mental health care per 100,000 population ranges from 0.03 in Southeast Asia and 0.05 in Africa to 3.1 in Europe. Approximately 69 percent of low-income countries have less than one psychologist per 100,000 population. The median number of psychiatric nurses per 100,000 population ranges from 0.1 in Southeast Asia and 0.2 in Africa to 24.8 in Europe.

From these figures, it is clear that resources for mental health care are grossly inadequate compared with the needs, and that inequalities across countries are substantial, especially between low- and high-income countries. Moreover, resources tend to be concentrated in urban areas, especially in low-income countries, leaving vast regions without any form of mental health care.

Even worse is the situation concerning child and adolescent mental health care. According to the WHO, only 7 percent of countries worldwide have a specific child and adolescent mental health policy. In less than one third of all countries is it possible to identify an institution or a governmental entity with an overall responsibility for child mental health. School-based services are almost exclusively present in high-income countries, and even in Europe only 17 percent of countries have a sufficient number of these services. There are no pediatric beds for mental health identified in low-income countries, but such beds are identified in 50 percent of high-income countries. In all African countries outside South Africa, fewer than 10 psychiatrists could be found who were trained to work with children. In European countries, the number of child psychiatrists ranges from one per 5,300 to one per 51,800. In more than 70 percent of countries worldwide, there is no list of essential psychotropic medications for children. In 45 percent of countries worldwide, psychostimulants are either prohibited or unavailable for use in children with attention-deficit/hyperactivity disorder.

### STIGMATIZING ATTITUDES TOWARD PEOPLE WITH MENTAL DISORDERS

Stigmatizing attitudes toward people with mental disorders are widespread in the general public and even among mental health professionals. Although it has been suggested that stigma may be less severe in Asian and African countries, a study carried out in India within the Stigma Programme of the World Psychiatric Association (WPA), in which 463 persons with schizophrenia and 651 family members were interviewed in four cities, reported that two thirds of the respondents had experienced discrimination. Women and people living in urban areas were more stigmatized. Whereas men experienced greater discrimination in the job area, women experienced more problems in the family and social areas.
Unlike people with physical disabilities, those with mental disorders are often perceived by the public to be in control of their disabilities and responsible for causing them. The view that “weakness,” “laziness,” or “lack of willpower” contributes to the development of mental disorders has been reported in several countries, including Turkey, Mongolia, and South Africa. The stigmatization of people with mental disorders may result in public avoidance, systematic discrimination, and reduced help-seeking behavior. In a survey carried out in 1996 in a probability sample of 1,444 adults in the United States, more than half of the respondents reported to be unwilling to spend an evening socializing with, work next to, or have a family member marry a person with mental illness. Although most countries have some provision for disability benefits, people with mental illness are often specifically excluded from such entitlements. Moreover, mental disorders are frequently not considered in social and private insurance schemes for health care. Shame is reported to be one of the main barriers from seeking help for mental disorders in both developed and developing countries.

Strategies for addressing stigmatization of people with mental disorders have been subdivided into three groups: protest, education, and contact. There is some evidence that protest campaigns may be effective in reducing stigmatizing behaviors against people with mental disorders. Education may promote a better understanding of mental illness, and educated people may be less likely to endorse stigma and discrimination. An inverse relationship between having contact with a person with mental illness and endorsing stigmatizing behaviors has been documented.

**RELATIONSHIPS BETWEEN MENTAL AND PHYSICAL DISEASES**

Mortality due to physical illness is significantly increased in people with severe mental disorders compared with the general population. In a follow-up study carried out in the United Kingdom, the standardized mortality ratio (SMR) for natural causes in people with schizophrenia was 2.32 (i.e., death was more than twice higher than in the general population). The SMR for causes “avoidable by appropriate treatment” was 4.68. The highest SMRs were those for endocrine, nervous, respiratory, circulatory, and gastrointestinal diseases. Increased non-suicide all-cause mortality has been also reported for bipolar disorder (SMR 1.9 for men and 2.1 for women) and dementia (relative risk [RR] 2.63; 95 percent confidence interval [CI] 2.17 to 3.21). A meta-analysis of 15 population-based studies of the effect of a diagnosis of depression on subsequent all-cause mortality yielded a pooled odds ratio of 1.7 (CI 1.5 to 2.0). Evidence from low-income countries is limited, but a large population study conducted in Ethiopia found high mortality rates for major depression (SMR 3.55, 95 percent CI 1.97 to 6.39) and schizophrenia (almost 5 percent per year).

The prevalence of several physical diseases is increased in people with mental disorders compared with the general population. In a study carried out in the United States, people with psychotic disorders were found to be more likely than other people to develop diabetes, hypertension, heart disease, asthma, gastrointestinal disorders, skin infections, malignant neoplasms, and acute respiratory disorders. The rate was increased even when only patients without a concomitant substance use disorder were considered. In a study conducted in Nigeria, 55.2 percent of persons with schizophrenia-spectrum disorders referred for the first time to a psychiatric clinic had at least one physical disease, but in persons with neurotic disorders, the rate was 11.8 percent. A strong prospective association has been documented between depression and coronary heart disease outcomes, including fatal myocardial infarction; on the other hand, the incidence of depression is increased after myocardial infarction, especially in the first month after the event. Depression also increases the risk for type II diabetes. In South Asia, an association between maternal perinatal depression and infant malnutrition and stunting at 6 months has been repeatedly reported.

People with severe mental disorders are at increased risk of contracting HIV infection, although prevalence rates vary substantially worldwide. A large multicenter study conducted in sub-Saharan Africa, Asia, Latin America, Europe, and the United States reported a higher prevalence of depressive disorder among symptomatic HIV-seropositive people than in asymptomatic HIV-seropositive cases and seronegative control participants. Evidence from both developed and developing countries shows that adherence to highly active antiretroviral therapy (HAART) is negatively affected by depression, cognitive impairment, and substance abuse.

In a study carried out in the United Kingdom, people with severe mental illness were significantly more likely to be obese (body mass index higher than 30) and morbidly obese (body mass index higher than 40) than the general population: The respective figures were 35.0 versus 19.4 percent and 3.7 versus 1.3 percent. When these figures were broken down by age and sex, 28.7 percent of men with severe mental illness between 18 and 44 years of age were obese compared with 13.6 percent in the general population, and 3.7 versus 0.4 percent were morbidly obese. Even more striking were the figures concerning women of the same age: 50.6 versus 16.6 percent and 7.4 versus 2.0 percent, respectively.

In a meta-analysis of worldwide studies, a highly significant association between schizophrenia and current smoking was confirmed: The weighted average odds ratio was 5.9; it was 7.2 in men and 3.3 in women. The association remained significant when controls with severe mental illness were used (odds ratio, 1.9). Heavy smoking and high nicotine dependence were also more frequent in people with schizophrenia than in the general population.

The quality of physical health care received by patients with severe mental illness is often worse than the general population. A study conducted in the United States found that adverse events during medical and surgical hospitalizations were significantly more frequent in patients with schizophrenia than in the other people, including infections due to medical care, postoperative respiratory failure, postoperative deep vein thrombosis or pulmonary embolism, and postoperative sepsis. All of these adverse events were associated with a significantly increased odds of admission to an intensive care unit and of death.

The decreased access of people with mental disorders to medical services has been related to several factors concerning the health care system. The effect of lack of insurance and cost of care is well documented. In a study carried out in the United States, people with mental disorders were twice as likely as those without mental disorders to have been denied
insurance because of a preexisting condition (odds ratio, 2.18). Having a mental disorder conferred a greater risk of having delayed seeking care because of cost (odds ratio, 1.76) and of having been unable to obtain needed medical care (odds ratio, 2.30).

Even when people with mental illness are seen by a doctor, their physical diseases often remain undiagnosed. Primary care providers may misperceive the medical complaints of people with mental disorders as “psychosomatic” or be unskilled or feel uncomfortable in dealing with this population. An underlying stigmatization may be involved. Moreover, during hospitalizations in medical and surgical wards, health care professionals may not be experienced in dealing with the special needs of patients with schizophrenia, may minimize or misinterpret their somatic symptoms, and may make an inappropriate use of restraints or sedative drugs or fail to consider possible interactions of psychotropic drugs with other medications. On the other hand, many psychiatrists are unable or unwilling to perform physical and even neurological examinations or are not up to date on the management of even common physical diseases.

To address this situation, the first step is raising awareness of the problem among mental health care professionals, primary care providers, and patients with schizophrenia and their families. Education and training of mental health professionals and primary care providers is a further essential step. Mental health professionals should be trained to perform at least basic medical tasks. They should be educated about the importance of recognizing physical illness in people with severe mental disorders and encouraged to become familiar with the most common reasons for underdiagnosis or misdiagnosis of physical illness in these patients. On the other hand, primary care providers should overcome their reluctance to treat people with severe mental illness and learn effective ways to interact and communicate with them; it is not only an issue of knowledge and skills but also most of all one of attitudes.

Another essential step is the development of an appropriate integration between mental health and physical health care. A well-identified professional should be responsible for physical health care in each person with a severe mental disorder. Mental health services should be able to provide at least a standard routine assessment of their patients to identify or at least suspect the presence of physical health problems. Guidelines about the management of patients receiving antipsychotic drugs should be known and applied by all mental health services. Patients should be involved as much as possible; for instance, mental health professionals should encourage patients to monitor and chart their weight. Dietary and exercise programs should be routinely provided by mental health services. Flexible smoking cessation programs, which have shown some degree of success, could be considered in some settings.

ETHICAL ISSUES IN MENTAL HEALTH CARE

The protection and promotion of the human rights of people with mental disorders are emerging as a priority worldwide. In 1991, the United Nations (UN) issued Resolution 46/119 for the Protection of Persons with Mental Illness and the Improvement of Mental Health Care. In that resolution, the human rights of people with mental disorders and their right to treatment were codified for the first time in a UN document. The 25 principles covered the following areas: definition of mental illness; protection of confidentiality; standards of care and treatment, including involuntary admission and consent to treatment; rights of persons with mental disorders in mental health facilities; protection of minors; provision of resources for mental health facilities; role of community and culture; review mechanisms providing for the protection of the rights of offenders with mental disorders; and procedural safeguards protecting rights of persons with mental disorders. National governments were invited to promote the principles of the resolution by appropriate legislative, juridical, administrative, educational, and other provisions. However, violations of the human rights of people with mental disorders are still reported in many countries, and in a substantial number of low- and middle-income countries, patients in mental hospitals are physically restrained or secluded for long periods.

In Latin America, an influential document has been the Declaration of Caracas, adopted in 1990 by the Regional Conference on Restructuring Psychiatric Care in Latin America, which states that resources, care, and treatment for people with mental disorders should safeguard their dignity and human and civil rights and strive to maintain them in their communities. The Declaration also states that mental health legislation should safeguard the human rights of people with mental disorders and that services should be organized so that these rights can be enforced.

In Africa, the Banjul Charter on Human and People’s Rights, a legally binding document supervised by the African Commission on Human and People’s Rights, in Article 5 addresses the right to respect for the dignity inherent in human beings and the prohibition of all forms of degradation, including cruel, inhuman, or degrading treatment.

According to the WHO, mental health legislation should cover the following issues: access to basic mental health care, least restrictive care, informed consent to treatment, voluntary and involuntary admission to treatment, competence issues, periodical review mechanism, confidentiality, rehabilitation, accreditation of professionals and facilities, and rights of families and caregivers. Specific legislation in the field of mental health is present in 74 percent of low-income countries versus 92.7 percent of high-income countries.

In 1996, the WPA released the Madrid Declaration, which contains the ethical principles by which all national psychiatric societies are expected to abide. The Declaration includes seven general guidelines focusing on the aims of psychiatry: (1) psychiatrists must serve patients by providing the best therapy available consistent with accepted scientific knowledge and ethical principles and should devise therapeutic interventions that are the least restrictive to the freedom of the patient; (2) it is the duty of psychiatrists to keep abreast of scientific developments of their specialty and to convey updated knowledge to others; (3) the patient should be accepted as a partner by right in the therapeutic process, and the therapist–patient relationship must be based on mutual trust and respect, to allow the patient to make free and informed decisions; (4) treatment must always be in the best interest of the patient, and no treatment should be provided against the patient’s will, unless withholding treatment would endanger life of the patient or those who surround him or her; (5) when psychiatrists are requested to assess a person, it is their duty to inform the person being assessed about the purpose of the intervention; (6) information contained in the therapeutic relationship should be kept in confidence and used exclusively for the
purpose of improving the mental health of the patient; and (7) because psychiatric patients are particularly vulnerable research subjects, extra caution should be taken to safeguard their autonomy, as well as their mental and physical integrity.

INTERNATIONAL ORGANIZATIONS ACTIVE IN THE MENTAL HEALTH FIELD

Many international organizations are active in the mental health field. They include the WHO, which is the world's leading public health agency; some professional associations, among which the largest is the WPA, representing the psychiatric profession worldwide; and several organizations with a membership of users and families (such as the World Fellowship for Schizophrenia and the Global Alliance of Mental Illness Advocacy Networks [GAMIAN]) or of both mental health professionals and users and families (such as the World Federation for Mental Health [WFMH]).

The WHO is a UN agency with 192 member states, grouped into six regions (Africa, the Americas, European Mediterranean, Europe, Southeast Asia, and Western Pacific). It has a Department of Mental Health and Substance Abuse at its headquarters in Geneva and advisors for mental health in each of its regional offices. Its main functions are direction and coordination of international health work and technical cooperation with countries. Among the numerous recent WHO activities in the mental health field, of special interest are the release of the World Health Report 2001 and the development of the report Mental Health: New Understanding, New Hope, which was completely devoted to mental health. It provided a summary of the current and projected impact of mental disorders and of the principles of mental health policy and service provision, as well as a set of recommendations for future action that can be adapted to the needs and resources of the various countries. Project Atlas aims to collect information on mental health resources around the world. Global and regional analyses of those resources were first published in 2001 and updated in 2005. Volumes focusing on resources for child and adolescent mental health and on psychiatric education and training worldwide (the latter in collaboration with the WPA) were released in 2005.

The WPA is an association of national psychiatric societies aimed at increasing knowledge and skills necessary for work in the field of mental health and the care for the mentally ill. Its member societies number 134, spanning 122 countries and representing more than 200,000 psychiatrists. The WPA organizes the World Congress of Psychiatry every 3 years. It also organizes international and regional congresses and meetings and thematic conferences. It has 65 scientific sections, which are aimed at disseminating information and promoting collaborative work in specific domains of psychiatry. It has produced several educational programs and series of books and consensus statements (including the Declaration of Madrid on ethical principles for psychiatric practice). It has an official journal, World Psychiatry, which is produced in English, Spanish, and Chinese and is indexed in PubMed and Current Contents and reaches more than 33,000 psychiatrists worldwide.

The WFMH is a multidisciplinary advocacy and education organization aimed at promoting the advancement of mental health awareness, prevention, advocacy, and best-practice recovery-focused interventions worldwide. Among its activities is the organization of the World Mental Health Day, observed every year on October 10, each time with a different theme.

FUTURE PERSPECTIVES

Several statements have been made by various groups and organizations about priorities for future action in the mental health field at the international level. Of special interest is a document produced by 39 leaders comprising the so-called Lancet Global Mental Health Group. In this document, five main goals are identified: (1) placing mental health on the public health priority agenda, (2) improving the organization of mental health services, (3) integrating the availability of mental health into general health care, (4) developing human resources for mental health, and (5) strengthening public mental health leadership.

Among the strategies proposed to place mental health on the public health priority agenda are the development and use of uniform and clearly understandable messages for mental health advocacy and the education of decision makers within governments and donor agencies on the evidence concerning the public health significance of mental disorders and the cost-effectiveness of mental health care. Strategies suggested to improve the organization of mental health services include, among others, the provision of incentive arrangements to overcome vested interests blocking change and the organization of international technical support to learn from countries that have experienced successful mental health reform. To integrate the availability of mental health in general health care, it is proposed that mental health professionals be appointed and trained specifically for supporting and supervising primary health care staff. To promote the development of human resources for mental health, it is suggested that the professional and specialist workforce be increased and diversified and that the quality of mental health training be improved to ensure that it is practical and occurs also in community or primary care settings.

REFERENCES

This page intentionally left blank.
abreaction: A process by which repressed material, particularly a painful experience or a conflict, is brought back to consciousness; in this process, the person not only recalls but also relives the repressed material, which is accompanied by the appropriate affective response.

abstract thinking: Thinking characterized by the ability to grasp the essentials of a whole, to break a whole into its parts, and to discern common properties. To think symbolically.

abulia: Reduced impulse to act and to think, associated with indifference about consequences of action. Occurs as a result of neurological deficit, depression, and schizophrenia.

acalculia: Loss of ability to do calculations; not caused by anxiety or impairment in concentration. Occurs with neurological deficit and learning disorder.

acaphasia: Disordered speech in which statements are incorrectly formulated. Patients may express themselves with words that sound like the ones intended but are not appropriate to the thoughts, or they may use totally inappropriate expressions.

acathexis: Lack of feeling associated with an ordinarily emotionally charged subject; in psychoanalysis, it denotes the patient's detaching or transferring of emotion from thoughts and ideas. Also called decathexis. Occurs in anxiety, dissociative, schizophrenic, and bipolar disorders.

acesthesia: Loss of sensation of physical existence.

acrophobia: Dread of high places.

acting out: Behavioral response to an unconscious drive or impulse that brings about temporary partial relief of inner tension; relief is attained by reacting to a present situation as if it were the situation that originally gave rise to the drive or impulse. Common in borderlines states.

aculalia: Nonsense speech associated with marked impairment of comprehension. Occurs in mania, schizophrenia, and neurological deficit.

adiadochokinesia: Inability to perform rapid alternating movements. Occurs with neurological deficit and cerebellar lesions.

adynamia: Weakness and fatigability, characteristic of neurasthenia and depression.

aerophagia: Excessive swallowing of air. Seen in anxiety disorder.

affect: The subjective and immediate experience of emotion attached to ideas or mental representations of objects. Affect has outward manifestations that may be classified as restricted, blunted, flattened, broad, labile, appropriate, or inappropriate. See also mood.

ageusia: Lack or impairment of the sense of taste. Seen in depression and neurological deficit.

aggression: Forceful, goal-directed action that may be verbal or physical; the motor counterpart of the affect of rage, anger, or hostility. Seen in neurological deficit, temporal lobe disorder, impulse-control disorders, mania, and schizophrenia.

agitation: Severe anxiety associated with motor restlessness.

agnosia: Inability to understand the import or significance of sensory stimuli; cannot be explained by a defect in sensory pathways or cerebral lesion; the term has also been used to refer to the selective loss or disuse of knowledge of specific objects because of emotional circumstances, as seen in certain schizophrenic, anxious, and depressed patients. Occurs with neurological deficit. For types of agnosia, see the specific term.

agoraphobia: Morbid fear of open places or leaving the familiar setting of the home. May be present with or without panic attacks.

agrammatism: Speech in which the patient forms words into a sentence without regard for grammatical rules. Seen in Alzheimer's and Pick's disease.

agrafia: Loss or impairment of a previously possessed ability to write.

ailurophobia: Dread of cats.

akataphasia: A form of disordered speech in which thoughts cannot be expressed directly but are expressed indirectly such as by making a similar sound (displacement paralalia) or by being derailed into another thought (derailment paralalia). See also derailment.

akathisia: Subjective feeling of motor restlessness manifested by a compelling need to be in constant movement; may be seen as an extrapyramidal adverse effect of antipsychotic medication. May be mistaken for psychogenic agitation.

akinesia: Lack of physical movement, in the extreme immobility of catatonic schizophrenia; may also occur as an extrapyramidal effect of antipsychotic medication.

akinetic mutism: Absence of voluntary motor movement or speech in a patient who is apparently alert (as evidenced by eye movements). Seen in psychotic depression and catatonic states.

alexia: Loss of a previously possessed reading facility; not explained by defective visual acuity. Compare with dyslexia.

alexithymia: Inability or difficulty in describing or being aware of one's emotions or moods; elaboration of fantasies associated with depression, substance abuse, and posttraumatic stress disorder (PTSD).

algophobia: Dread of pain.
alogy: Inability to speak because of a mental deficiency or an episode of dementia.
ambivalence: Coexistence of two opposing impulses toward the same thing in the same person at the same time. Seen in schizophrenia, borderline states, and obsessive–compulsive disorders (OCDs).
amnesia: Partial or total inability to recall past experiences; may be organic (amnestic disorder) or emotional (dissociative amnesia) in origin.
amnestic aphasia: Disturbed capacity to name objects, even though they are known to the patient. Also called anomic aphasia.
analgesia: Lack of the ability to make gestures or to comprehend those made by others.
amnesia: Partial or total inability to recall past experiences; may be organic (amnestic disorder) or emotional (dissociative amnesia) in origin.
amnestic aphasia: Disturbed capacity to name objects, even though they are known to the patient. Also called anomic aphasia.
analgesia: Lack of the ability to make gestures or to comprehend those made by others.
amnesia: Partial or total inability to recall past experiences; may be organic (amnestic disorder) or emotional (dissociative amnesia) in origin.
amnestic aphasia: Disturbed capacity to name objects, even though they are known to the patient. Also called anomic aphasia.
analgesia: Lack of the ability to make gestures or to comprehend those made by others.
amnesia: Partial or total inability to recall past experiences; may be organic (amnestic disorder) or emotional (dissociative amnesia) in origin.
amnestic aphasia: Disturbed capacity to name objects, even though they are known to the patient. Also called anomic aphasia.
analgesia: Lack of the ability to make gestures or to comprehend those made by others.
amnesia: Partial or total inability to recall past experiences; may be organic (amnestic disorder) or emotional (dissociative amnesia) in origin.
amnestic aphasia: Disturbed capacity to name objects, even though they are known to the patient. Also called anomic aphasia.
analgesia: Lack of the ability to make gestures or to comprehend those made by others.
amnesia: Partial or total inability to recall past experiences; may be organic (amnestic disorder) or emotional (dissociative amnesia) in origin.
amnestic aphasia: Disturbed capacity to name objects, even though they are known to the patient. Also called anomic aphasia.
analgesia: Lack of the ability to make gestures or to comprehend those made by others.
bradykinesia: Slowness of motor activity, with a decrease in normal spontaneous movement.

bradyphasia: Abnormally slow speech. Common in depression.

bradylexia: Inability to read at normal speed.

bruxism: Grinding or gnashing of the teeth, typically occurring during sleep. Seen in anxiety disorder.

carebia: Sensation of discomfort or pressure in the head.

catalepsy: Condition in which persons maintain the body position into which they are placed; observed in severe cases of catatonic schizophrenia. Compare with waxy flexibility and cerea flexibility. See also command automatism.

catastrophic reaction: Extreme emotional state characterized by restlessness, irritability, crying, anxiety, and uncooperativeness. Seen in patients who have had a stroke.

catatonic excitement: Excited, uncontrolled motor activity seen in catatonic schizophrenia. Patients in catatonic state may suddenly erupt into an excited state and may be violent.

catatonic posturing: Voluntary assumption of an inappropriate or bizarre posture, generally maintained for long periods of time. May switch unexpectedly with catatonic excitement.

catatonic rigidity: Fixed and sustained motoric position that is resistant to change.

catatonic stupor: Stupor in which patients ordinarily are well aware of their surroundings.

cathexis: In psychoanalysis, a conscious or unconscious investment of psychic energy in an idea, concept, object, or person. Compare with aca­thesis.

causalgia: Burning pain that may be organic or psychic in origin.

cenesthesia: Change in the normal quality of feeling tone in a part of the body.

cephalagia: Headache.

cerea flexibilitas: Condition of a person who can be molded into a position that is then maintained; when an examiner moves the person’s limb, the limb feels as if it were made of wax. Also called waxy flexibility. Seen in schizophrenia.

chorea: Movement disorder characterized by random and involuntary quick, jerky, purposeless movements. Seen in Huntington’s disease.

circumstantiality: Disturbance in the associative thought and speech processes in which a patient digresses into unnecessary details and inappropriate thoughts before communicating the central idea. Observed in schizophrenia, obsessional disturbances, and certain cases of dementia. See also tangentiality.

clang association: Association or speech directed by the sound of a word rather than by its meaning; words have no logical connection; punning and rhyming may dominate the verbal behavior. Seen most frequently in schizophrenia or mania.

claustrophobia: Abnormal fear of closed or confining spaces.

clonic convulsion: An involuntary, violent muscular contraction or spasm in which the muscles alternately contract and relax. Characteristic phase in grand mal epileptic seizure.

clouding of consciousness: Any disturbance of consciousness in which the person is not fully awake, alert, and oriented. Occurs in delirium, dementia, and cognitive disorder.

cluttering: Disturbance of fluency involving an abnormally rapid rate and erratic rhythm of speech that impedes intelligibility; the affected individual is usually unaware of communicative impairment.

cognition: Mental process of knowing and becoming aware; function is closely associated with judgment.

coma: State of profound unconsciousness from which a person cannot be roused, with minimal or no detectable responsiveness to stimuli; seen in injury or disease of the brain, in systemic conditions such as diabetic ketoacidosis and uremia, and in intoxications with alcohol and other drugs. Coma may also occur in severe catatonic states and in conversion disorder.

coma vigil: Coma in which a patient appears to be asleep but can be aroused (also known as akinetic mutism).

command automatism: Condition in which suggestions are followed automatically.

command hallucination: False perception of orders that a person may feel obliged to obey or unable to resist.

complex: A feeling-toned idea.

complex partial seizure: A seizure characterized by alterations in consciousness that may be accompanied by complex hallucinations (sometimes olfactory) or illusions. During the seizure, a state of impaired consciousness resembling a dreamlike state may occur, and the patient may exhibit repetitive, automatic, or semipurposeful behavior.

compulsion: Pathological need to act on an impulse that, if resisted, produces anxiety; repetitive behavior in response to an obsession or performed according to certain rules, with no true end in itself other than to prevent something from occurring in the future.

conation: That part of a person’s mental life concerned with cravings, strivings, motivations, drives, and wishes as expressed through behavior or motor activity.

concrete thinking: Thinking characterized by actual things, events, and immediate experience rather than by abstractions; seen in young children, in those who have lost or never developed the ability to generalize (as in certain cognitive mental disorders), and in schizophrenic persons. Compare with abstract thinking.

condensation: Mental process in which one symbol stands for a number of components.

confabulation: Unconscious filling of gaps in memory by imagining experiences or events that have no basis in fact, commonly seen in amnestic syndromes; should be differentiated from lying. See also paramnesia.

confusion: Disturbances of consciousness manifested by a disordered orientation in relation to time, place, or person.

consciousness: State of awareness, with response to external stimuli.

constipation: Inability to defecate or difficulty in defecating.

constricted affect: Reduction in intensity of feeling tone that is less severe than that of blunted affect.

constructual apraxia: Inability to copy a drawing, such as a cube, clock, or pentagon, as a result of a brain lesion.

conversion phenomena: The development of symbolic physical symptoms and distortions involving the voluntary muscles or special sense organs; not under voluntary control and not explained by any physical disorder. Most common in conversion disorder but also seen in a variety of mental disorders.
**convulsion**: An involuntary, violent muscular contraction or spasm. See also **clonic convulsion** and **tonic convulsion**.

**coprolalia**: Involuntary use of vulgar or obscene language. Observed in some cases of schizophrenia and in Tourette's syndrome.

**coprophagia**: Eating of filth or feces.

**cryptographia**: A private written language.

**cryptolalia**: A private spoken language.

**cycloplegia**: Paralysis of the muscles of accommodation in the eye; observed, at times, as an autonomic adverse effect (anti-cholinergic effect) of antipsychotic or antidepressant medication.

**derealization**: False feeling of unreality concerning oneself, parts of oneself, or one's environment that occurs under extreme stress or fatigue. Seen in schizophrenia, depersonalization disorder, and schizotypal personality disorder.

**delusion**: False belief that a person's will, thoughts, or feelings are being controlled by external forces.

**delusion of control**: False belief that a person's will, thoughts, or feelings are being controlled by external forces.

**delusion of grandeur**: Exaggerated conception of one's importance, power, or identity.

**delusion of infidelity**: False belief that one's lover is unfaithful. Sometimes called pathological jealousy.

**delusion of persecution**: False belief of being harassed or persecuted; often found in litigious patients who have a pathological tendency to take legal action because of imagined mistreatment. Most common delusion.

**delusion of poverty**: False belief that one is bereft or will be deprived of all material possessions.

**delusion of reference**: False belief that the behavior of others refers to oneself or that events, objects, or other people have a particular and unusual significance, usually of a negative nature; derived from idea of reference, in which persons falsely feel that others are talking about them (e.g., belief that people on television or radio are talking to or about the person). See also **thought broadcasting**.

**delirium**: Acute reversible mental disorder characterized by confusion and some impairment of consciousness; generally associated with emotional lability, hallucinations or illusions, and inappropriate, impulsive, irrational, or violent behavior.

**delirium tremens**: Acute and sometimes fatal reaction to withdrawal from alcohol, usually occurring 72 to 96 hours after the cessation of heavy drinking; distinctive characteristics are marked autonomic hyperactivity (tachycardia, fever, hyperhidrosis, and dilated pupils), usually accompanied by tremulousness, hallucinations, illusions, and delusions. Called alcohol withdrawal with perceptual disturbance in DSM-5. See also **formication**.

**delusion of self-accusation**: False feeling of remorse and guilt. Seen in depression with psychotic features.

**dementia**: Mental disorder characterized by general impairment in intellectual functioning without clouding of consciousness; characterized by falling memory, difficulty with calculations, distractibility, alterations in mood and affect, impaired judgment and abstraction, reduced facility with language, and disturbance of orientation. Although irreversible because of underlying progressive degenerative brain disease, dementia may be reversible if the cause can be treated. Also known as major neurocognitive disorder in DSM-5.

**denial**: Defense mechanism in which the existence of unpleasant realities is disavowed; refers to keeping out of conscious awareness any aspects of external reality that, if acknowledged, would produce anxiety.

**depersonalization**: Sensation of unreality concerning oneself, parts of oneself, or one's environment that occurs under extreme stress or fatigue. Seen in schizophrenia, depersonalization disorder, and schizotypal personality disorder.

**depression**: Mental state characterized by feelings of sadness, loneliness, despair, low self-esteem, and self-reproach; accompanying signs include psychomotor retardation or, at times, agitation, withdrawal from interpersonal contact, and vegetative symptoms, such as insomnia and anorexia. The term refers to a mood that is so characterized or a mood disorder.

**derailment**: Gradual or sudden deviation in train of thought without blocking; sometimes used synonymously with loosening of association.

**derealization**: Sensation of changed reality or that one's surroundings have altered. Usually seen in schizophrenia, panic attacks, and dissociative disorders.

**dereism**: Mental activity that follows a totally subjective and idiosyncratic system of logic and fails to take the facts of reality or experience into consideration. Characteristic of schizophrenia. See also **autistic thinking**.

**detachment**: Characterized by distant interpersonal relationships and lack of emotional involvement.

**devaluation**: Defense mechanism in which a person attributes excessively negative qualities to self or others. Seen in depression and paranoid personality disorder.

**diminished libido**: Decreased sexual interest and drive. (Increased libido is often associated with mania.)

**dipsomania**: Compulsion to drink alcoholic beverages.

**disinhibition**: (1) Removal of an inhibitory effect, as in the reduction of the inhibitory function of the cerebral cortex by alcohol. (2) In psychiatry, a greater freedom to act in accordance with inner drives or feelings and with less regard for restraints dictated by cultural norms or one's superego.

**disorientation**: Confusion; impairment of awareness of time, place, and person (the position of the self in relation to other persons). Characteristic of cognitive disorders.

**displacement**: Unconscious defense mechanism by which the emotional component of an unacceptable idea or object is transferred to a more acceptable one. Seen in phobias.

**dissociation**: Unconscious defense mechanism involving the segregation of any group of mental or behavioral processes from the rest of the person's psychic activity; may entail the separation of an idea from its accompanying emotional tone, as seen in dissociative and conversion disorders.
distractibility: Inability to focus one's attention; the patient does not respond to the task at hand but attends to irrelevant phenomena in the environment.
dread: Massive or pervasive anxiety, usually related to a specific danger.
dreamy state: Altered state of consciousness, likened to a dream situation that develops suddenly and usually lasts a few minutes; accompanied by visual, auditory, and olfactory hallucinations. Commonly associated with temporal lobe lesions.
drowsiness: State of impaired awareness associated with a desire or inclination to sleep.
dysarthria: Difficulty in articulation, the motor activity of shaping phonated sounds into speech, not in word finding or in grammar.
dyscalculia: Difficulty in performing calculations.
dysgeusia: Impaired sense of taste.
dysgraphia: Difficulty in writing.
dyskinesia: Difficulty in performing movements. Seen in extrapyramidal disorders.
dystalia: Faulty articulation caused by structural abnormalities of the articulatory organs or impaired hearing.
dyslexia: Specific learning disability syndrome involving an impairment of the previously acquired ability to read; unrelated to the person's intelligence. Compare with alexia.
dysmegalamia: A distortion in which the size and shape of objects is misperceived, sometimes called the "Alice in Wonderland" effect. See also illusion.
dynametry: Impaired ability to gauge distance relative to movements. Seen in neurological deficit.
dysmnesia: Impaired memory.
dyspareunia: Physical pain in sexual intercourse, usually emotionally caused and more commonly experienced by women; may also result from cystitis, urethritis, or other medical conditions.
dysphagia: Difficulty in swallowing.
dysphasia: Difficulty in comprehending oral language (reception dysphasia) or in trying to express verbal language (expressive dysphasia).
dysphonia: Difficulty or pain in speaking.
dysphoria: Feeling of unpleasantness or discomfort; a mood of general dissatisfaction and restlessness. Occurs in depression and anxiety.
dysprosody: Loss of normal speech melody (prosody). Common in depression.
dystonia: Extrapyramidal motor disturbance consisting of slow, sustained contractions of the axial or appendicular musculature; one movement often predominates, leading to relatively sustained postural deviations; acute dystonic reactions (facial grimacing and torticollis) are occasionally seen with the initiation of antipsychotic drug therapy.
echolalia: Psychopathological repeating of words or phrases of one person by another; tends to be repetitive and persistent. Seen in certain kinds of schizophrenia, particularly the catatonic types.
ego-allen: Denoting aspects of a person's personality that are viewed as repugnant, unacceptable, or inconsistent with the rest of the personality. Also called ego-dystonia. Compare with ego-syntonic.
egocentric: Self-centered; selfishly preoccupied with one's own needs; lacking interest in others.
ego-dystonic: See ego-alien.
egomania: Morbid self-preoccupation or self-centeredness. See also narcissism.
ego-syntonic: Denoting aspects of a personality that are viewed as acceptable and consistent with that person's total personality. Personality traits are usually ego-syntonic. Compare with ego-alien.
edetic image: Unusually vivid or exact mental image of objects previously seen or imagined.
elation: Mood consisting of feelings of joy, euphoria, triumph, and intense self-satisfaction or optimism. Occurs in mania when not grounded in reality.
elated mood: Air of confidence and enjoyment; a mood more cheerful than normal but not necessarily pathological.
emotion: Complex feeling state with psychic, somatic, and behavioral components; external manifestation of emotion is affect.
emotional insight: A level of understanding or awareness that one has emotional problems. It facilitates positive changes in personality and behavior when present.
emotional liability: Excessive emotional responsiveness characterized by unstable and rapidly changing emotions.
encopresis: Involuntary passage of feces, usually occurring at night or during sleep.
enuresis: Incontinence of urine during sleep.
erotomania: Delusional belief, more common in women than in men, that someone is deeply in love with them (also known as de Clérambault syndrome).
erythrophobia: Abnormal fear of blushing.
euphoria: Exaggerated feeling of well-being that is inappropriate to real events. Can occur with drugs such as opiates, amphetamines, and alcohol.
euthymia: Normal range of mood, implying absence of depressed or elevated mood.
evaporation: Act of not facing up to, or strategically eluding, something; consists of suppressing an idea that is next in a thought series and replacing it with another idea closely related to it. Also called paralogia and perverted logic.
exaltation: Feeling of intense elation and grandeur.
excited: Agitated, purposeless motor activity uninfluenced by external stimuli.
expansive mood: Expression of feelings without restraint, frequently with an overestimation of their significance or importance. Seen in mania and grandiose delusional disorder.
expressive aphasia: Disturbance of speech in which understanding remains, but ability to speak is grossly impaired; halting, laborious, and inaccurate speech (also known as Broca's, nonfluent, and motor aphasias).
expressive dysphasia: Difficulty in expressing verbal language; the ability to understand language is intact.
externalization: More general term than projection that refers to the tendency to perceive in the external world and in external objects elements of one's own personality, including instinctual impulses, conflicts, moods, attitudes, and styles of thinking.
extroversion: State of one's energies being directed outside oneself. Compare with introversion.
false memory: A person’s recollection and belief by the patient of an event that did not actually occur. In false memory syndrome, persons erroneously believe that they sustained an emotional or physical (e.g., sexual) trauma in early life.

fantasy: Daydream; fabricated mental picture of a situation or chain of events. A normal form of thinking dominated by unconscious material that seeks wish fulfillment and solutions to conflicts; may serve as the matrix for creativity. The content of the fantasy may indicate mental illness.

fatigue: A feeling of weariness, sleepiness, or irritability after a period of mental or bodily activity. Seen in depression, anxiety, neurasthenia, and somatoform disorders.

fausse reconnaissance: False recognition, a feature of paranoia. Can occur in delusional disorders.

fear: Unpleasurable emotional state consisting of psychophysiological changes in response to a realistic threat or danger. Compare with anxiety.

flat affect: Absence or near absence of any signs of affective expression.

flight of ideas: Rapid succession of fragmentary thoughts or speech in which content changes abruptly and speech may be incoherent. Seen in mania.

floccillation: Aimless plucking or picking, usually at bedclothes or clothing, commonly seen in dementia and delirium.

fluent aphasia: Aphasia characterized by inability to understand the spoken word; fluent but incoherent speech is present. Also called Wernicke’s, sensory and receptive aphasias.

folie à deux: Mental illness shared by two persons, usually involving a common delusional system; if it involves three persons, it is referred to as folie à trois, etc. Also called shared psychotic disorder.

formal thought disorder: Disturbance in the form of thought rather than the content of thought; thinking characterized by loosened associations, neologisms, and illogical constructs; thought process is disordered, and the person is defined as psychotic. Characteristic of schizophrenia.

formication: Tactile hallucination involving the sensation that tiny insects are crawling over the skin. Seen in cocaine addiction and delirium tremens.

free-floating anxiety: Severe, pervasive, generalized anxiety that is not attached to any particular idea, object, or event. Observed particularly in anxiety disorders, although it may be seen in some cases of schizophrenia.

fugue: Dissociative disorder characterized by a period of almost complete amnesia, during which a person actually flees from an immediate life situation and begins a different life pattern; apart from the amnesia, mental faculties and skills are usually unimpaired.

galactorrhea: Abnormal discharge of milk from the breast; may result from the endocrine influence (e.g., prolactin) of dopamine receptor antagonists, such as phenothiazines.

generalized tonic-clonic seizure: Generalized onset of tonic-clonic movements of the limbs, tongue biting, and incontinence followed by slow, gradual recovery of consciousness and cognition; also called grand mal seizure.

global aphasia: Combination of grossly nonfluent aphasia and severe fluent aphasia.

glossolalia: Unintelligible jargon that has meaning to the speaker but not to the listener. Occurs in schizophrenia.

grandiosity: Exaggerated feelings of one’s importance, power, knowledge, or identity. Occurs in delusional disorder and manic states.

grief: Alteration in mood and affect consisting of sadness appropriate to a real loss; normally, it is self-limited. See also depression and mourning.

guilt: Emotional state associated with self-reproach and the need for punishment. In psychoanalysis, refers to a feeling of culpability that stems from a conflict between the ego and the superego (conscience). Guilt has normal psychological and social functions, but special intensity or absence of guilt characterizes many mental disorders, such as depression and antisocial personality disorder, respectively. Psychiatrists distinguish shame as a less internalized form of guilt that relates more to others than to the self. See also shame.

gustatory hallucination: Hallucination primarily involving taste.

gyneomastia: Female-like development of the male breasts; may occur as an adverse effect of antipsychotic and antidepressant drugs because of increased prolactin levels or anabolic-androgenic steroid abuse.

hallucination: False sensory perception occurring in the absence of any relevant external stimulation of the sensory modality involved. For types of hallucinations, see the specific term.

hallucinosis: State in which a person experiences hallucinations without any impairment of consciousness.

haptic hallucination: Hallucination of touch.

hebephrenia: Complex of symptoms, considered a form of schizophrenia, characterized by wild or silly behavior or mannerisms, inappropriate affect, and delusions and hallucinations that are transient and unsystematized. Hebephrenic schizophrenia is now called disorganized schizophrenia.

holoplastic: Using a single word to express a combination of ideas. Seen in schizophrenia.

hyperactivity: Increased muscular activity. The term is commonly used to describe a disturbance found in children that is manifested by constant restlessness, overactivity, distractibility, and difficulties in learning. Seen in attention-deficit/hyperactivity disorder (ADHD).

hyperacusis: Extreme sensitivity to sounds.

hyperalgesia: Excessive sensitivity to pain. Seen in somatoform disorder.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.

hyperesthesia: Increased sensitivity to tactile stimulation.
**hypervigilance:** Excessive attention to and focus on all internal and external stimuli; usually seen in delusional or paranoid states.

**hypesthesia:** Diminished sensitivity to tactile stimulation.

**hypnagogic hallucination:** Hallucination occurring while falling asleep, not ordinarily considered pathological.

**hypnopompic hallucination:** Hallucination occurring while awakening from sleep, not ordinarily considered pathological.

**hypnosis:** Artificially induced alteration of consciousness characterized by increased suggestibility and receptivity to direction.

**hypoactivity:** Decreased motor and cognitive activity, as in psychomotor retardation; visible slowing of thought, speech, and movements. Also called hypokinesis.

**hypochondria:** Exaggerated concern about health that is based not on real medical pathology but on unrealistic interpretations of physical signs or sensations as abnormal.

**hypomania:** Mood abnormality with the qualitative characteristics of mania but somewhat less intense. Seen in cyclothymic disorder.

**idea of reference:** Misinterpretation of incidents and events in the outside world as having direct personal reference to oneself; occasionally observed in normal persons, but frequently seen in paranoid patients. If present with sufficient frequency or intensity or if organized and systematized, they constitute delusions of reference.

**illogical thinking:** Thinking containing erroneous conclusions or internal contradictions; psychopathological only when it is marked and not caused by cultural values or intellectual deficit.

**illusion:** Perceptual misinterpretation of a real external stimulus. Compare with hallucination.

**immediate memory:** Reproduction, recognition, or recall of perceived material within seconds after presentation. Compare with long-term memory and short-term memory.

**impaired insight:** Diminished ability to understand the objective reality of a situation.

**impaired judgment:** Diminished ability to understand a situation correctly and to act appropriately.

**impulse control:** Ability to resist an impulse, drive, or temptation to perform some action.

**inappropriate affect:** Emotional tone out of harmony with the idea, thought, or speech accompanying it. Seen in schizophrenia.

**incoherence:** Communication that is disconnected, disorganized, or incomprehensible. See also word salad.

**incorporation:** Primitive unconscious defense mechanism in which the psychic representation of another person or aspects of another person are assimilated into oneself through a figurative process of symbolic oral ingestion; represents a special form of introjection and is the earliest mechanism of identification.

**increased libido:** Increase in sexual interest and drive.

**ineffability:** Ecstatic state in which persons insist that their experience is inexpressible and indescribable and that it is impossible to convey what it is like to one who never experienced it.

**initial insomnia:** Falling asleep with difficulty; usually seen in anxiety disorder. Compare with middle insomnia and terminal insomnia.

**insight:** Conscious recognition of one’s own condition. In psychiatry, it refers to the conscious awareness and understanding of one’s own psychodynamics and symptoms of maladaptive behavior; highly important in effecting changes in the personality and behavior of a person.

**insomnia:** Difficulty in falling asleep or difficulty in staying asleep. It can be related to a mental disorder, can be related to a physical disorder or an adverse effect of medication, or can be primary (not related to a known medical factor or another mental disorder). See also initial insomnia, middle insomnia, and terminal insomnia.

**intellectual insight:** Knowledge of the reality of a situation without the ability to use that knowledge successfully to effect an adaptive change in behavior or to master the situation. Compare with true insight.

**intelligence:** Capacity for learning and ability to recall, to integrate constructively, and to apply what one has learned; the capacity to understand and to think rationally.

**intoxication:** Mental disorder caused by recent ingestion or presence in the body of an exogenous substance producing maladaptive behavior by virtue of its effects on the central nervous system (CNS). The most common psychiatric changes involve disturbances of perception, wakefulness, attention, thinking, judgment, emotional control, and psychomotor behavior; the specific clinical picture depends on the substance ingested.

**intropunitive:** Turning anger inward toward oneself. Commonly observed in depressed patients.

**introspection:** Contemplating one’s own mental processes to achieve insight.

**introduction:** State in which a person’s energies are directed inward toward the self, with little or no interest in the external world.

**irrelevant answer:** Answer that is not responsive to the question.

**irritability:** Abnormal or excessive excitability, with easily triggered anger, annoyance, or impatience.

**irritable mood:** State in which one is easily annoyed and provoked to anger. See also irritability.

**jamais vu:** Paramnestic phenomenon characterized by a false feeling of unfamiliarity with a real situation that one has previously experienced.

**jargon aphasia:** Aphasia in which the words produced are neologistic; that is, nonsense words created by the patient.

**judgment:** Mental act of comparing or evaluating choices within the framework of a given set of values for the purpose of electing a course of action. If the course of action chosen is consonant with reality or with mature adult standards of behavior, then judgment is said to be intact or normal; judgment is said to be impaired if the chosen course of action is frankly maladaptive, results from impulsive decisions based on the need for immediate gratification, or is otherwise not consistent with reality as measured by mature adult standards.

**kleptomania:** Pathological compulsion to steal.

**la belle indifférence:** Inappropriate attitude of calm or lack of concern about one’s disability. May be seen in patients with conversion disorder.
magical thinking: A form of dereistic thought; thinking similar to that of the preoperational phase in children (Jean Piaget), in which thoughts, words, or actions assume power (e.g., to cause or to prevent events).

malingering: Feigning disease to achieve a specific goal, for example, to avoid an unpleasant responsibility.

mania: Mood state characterized by elation, agitation, hyperactivity, hypersexuality, and accelerated thinking and speaking (flight of ideas). Seen in bipolar I disorder. See also hypomania.

manipulation: Maneuvering by patients to get their own way, characteristic of antisocial personalities.

mannerism: Ingrained, habitual involuntary movement.

melancholia: Severe depressive state. Used in the term involutional melancholia as a descriptive term and also in reference to a distinct diagnostic entity.

memory: Process whereby what is experienced or learned is established as a record in the CNS (registration), where it persists with a variable degree of permanence (retention) and can be recollected or retrieved from storage at will (recall). For types of memory, see immediate memory, long-term memory, and short-term memory.

mental disorder: Psychiatric illness or disease whose manifestations are characterized primarily by behavioral or psychological impairment of function, measured in terms of deviation from some normative concept; associated with distress or disease, not just an expected response to a particular event or limited to relations between a person and society.

mental retardation: Subaverage general intellectual functioning that originates in the developmental period and is associated with impaired maturation and learning and social maladjustment. Retardation is commonly defined in terms of intelligence quotient (IQ): mild (between 50 and 55 to 70), moderate (between 35 and 40 to between 50 and 55), severe (between 20 and 25 to between 35 and 40), and profound (below 20 to 25).

metonymy: Speech disturbance common in schizophrenia in which the affected person uses a word or phrase that is related to the proper one but is not the one ordinarily used; for example, the patient speaks of consuming a menu rather than a meal or refers to losing the piece of string of the conversation rather than the thread of the conversation. See also paraphasia and word approximation.

microcephaly: Condition in which the head is unusually small as a result of defective brain development and premature ossification of the skull.

micropsia: False perception that objects are smaller than they really are. Sometimes called lilliputian hallucination. Compare with macropsia.

middle insomnia: Waking up after falling asleep without difficulty and then having difficulty in falling asleep again. Compare with initial insomnia and terminal insomnia.

mimicry: Simple, imitative motion activity of childhood.

monomania: Mental state characterized by preoccupation with one subject.

mood: Pervasive and sustained feeling tone that is experienced internally and that, in the extreme, can markedly influence virtually all aspects of a person’s behavior and perception of the world. Distinguished from affect, the external expression of the internal feeling tone. For types of mood, see the specific term.

mood-congruent delusion: Delusion with content that is mood appropriate (e.g., depressed patients who believe that they are responsible for the destruction of the world).

mood-congruent hallucination: Hallucination with content that is consistent with a depressed or manic mood (e.g., depressed patients hearing voices telling them that they are bad persons and manic patients hearing voices telling them that they have inflated worth, power, or knowledge).

mood-incongruent hallucination: Hallucination not associated with real external stimuli, with content that is not consistent with depressed or manic mood (e.g., in depression, hallucinations not involving such themes as guilt, undeserved punishment, or inadequacy; in mania, not involving such themes as inflated worth or power).

mood swings: Oscillation of a person’s emotional feeling tone between periods of elation and periods of depression.

motor aphasia: Aphasias in which understanding is intact, but the ability to speak is lost. Also called Broca’s, expressive, or nonfluent aphasias.

mourning: Syndrome following loss of a loved one, consisting of preoccupation with the lost individual, weeping, sadness,
and repeated reliving of memories. See also bereavement and grief.

**muscle rigidity**: State in which the muscles remain immovable; seen in schizophrenia.

**mutism**: Organic or functional absence of the faculty of speech. See also stupor.

**mydriasis**: Dilation of the pupil; sometimes occurs as an autonomic (anticholinergic) or atropine-like adverse effect of some antipsychotic and antidepressant drugs.

**narcissism**: In psychoanalytic theory, divided into primary and secondary types: primary narcissism, the early infantile phase of object relationship development, when the child has not differentiated the self from the outside world, and all sources of pleasure are unrealistically recognized as coming from within the self, giving the child a false sense of omnipotence; secondary narcissism, when the libido, once attached to external love objects, is redirected back to the self. See also autistic thinking.

**needle phobia**: The persistent, intense, pathological fear of receiving an injection.

**negative signs**: In schizophrenia: flat affect, alogia, abulia, and apathy.

**negativism**: Verbal or nonverbal opposition or resistance to outside suggestions and advice; commonly seen in catatonic schizophrenia in which the patient resists any effort to be moved or does the opposite of what is asked.

**neologism**: New word or phrase whose derivation cannot be understood; often seen in schizophrenia. It has also been used to mean a word that has been incorrectly constructed but whose origins are nonetheless understandable (e.g., head shoe to mean hat), but such constructions are more properly referred to as word approximations.

**neurological amnesia**: (1) Auditory amnesia: loss of ability to comprehend sounds or speech. (2) Tactile amnesia: loss of ability to judge the shape of objects by touch. See also aste-reognosis. (3) Verbal amnesia: loss of ability to remember words. (4) Visual amnesia: loss of ability to recall or to recognize familiar objects or printed words.

**nihilism**: Delusion of the nonexistence of the self or part of the self; also refers to an attitude of total rejection of established values or extreme skepticism regarding moral and value judgments.

**nihilistic delusion**: Depressive delusion that the world and everything related to it have ceased to exist.

**noesis**: Revelation in which immense illumination occurs in association with a sense that one has been chosen to lead and command. Can occur in manic or dissociative states.

**nominal aphasia**: Aphasia characterized by difficulty in giving the correct name of an object. See also anomia and amnes-tic aphasia.

**nymphomania**: Abnormal, excessive, insatiable desire in a woman for sexual intercourse. Compare with satyrism.

**obsession**: Persistent and recurrent idea, thought, or impulse that cannot be eliminated from consciousness by logic or reasoning; obsessions are involuntary and ego-dystonic. See also compulsion.

**olfactory hallucination**: Hallucination primarily involving smell or odors; most common in medical disorders, especially in the temporal lobe.

**orientation**: State of awareness of oneself and one’s surroundings in terms of time, place, and person.

**overactivity**: Abnormality in motor behavior that can manifest itself as psychomotor agitation, hyperactivity (hypermobility), tics, sleepwalking, or compulsions.

**overvalued idea**: False or unreasonable belief or idea that is sustained beyond the bounds of reason. It is held with less intensity or duration than a delusion but is usually associated with mental illness.

**panic**: Acute, intense attack of anxiety associated with personality disorganization; the anxiety is overwhelming and accompanied by feelings of impending doom.

**panphobia**: Overwhelming fear of everything.

**pantomime**: Gesticulation; psychodrama without the use of words.

**paramnesia**: Disturbance of memory in which reality and fantasy are confused. It is observed in dreams and in certain types of schizophrenia and organic mental disorders; it includes phenomena such as déjà vu and déjà entendu, which may occur occasionally in normal persons.

**paranoia**: Rare psychiatric syndrome marked by the gradual development of a highly elaborate and complex delusional system, generally involving persecutory or grandiose delusions, with few other signs of personality disorganization or thought disorder.

**paranoid delusions**: Includes persecutory delusions and delusions of reference, control, and grandeur.

**paranoid ideation**: Thinking dominated by suspicious, persecu-tory, or grandiose content of less than delusional proportions.

**paraphasia**: Abnormal speech in which one word is substituted for another, the irrelevant word generally resembling the required one in morphology, meaning, or phonetic composition; the inappropriate word may be a legitimate one used incorrectly, such as clover instead of hand, or a bizarre nonsense expression, such as green instead of train. Paraphasic speech may be seen in organic aphasias and in mental disorders such as schizophrenia. See also metonymy and word approximation.

**parapraxis**: Faulty act, such as a slip of the tongue or the misplacement of an article. Freud ascribed paraprases to unconscious motives.

**paresis**: Weakness or partial paralysis of organic origin.

**paresthesia**: Abnormal spontaneous tactile sensation, such as a burning, tingling, or pins-and-needles sensation.

**perception**: Conscious awareness of elements in the environment by the mental processing of sensory stimuli; sometimes used in a broader sense to refer to the mental process by which all kinds of data, intellectual, emotional, and sensor-y, are meaningfully organized. See also apperception.

**perseveration**: (1) Pathological repetition of the same response to different stimuli, as in a repetition of the same verbal response to different questions. (2) Persistent repetition of specific words or concepts in the process of speaking. Seen in cognitive disorders, schizophrenia, and other mental illness. See also verbigeration.

**phantom limb**: False sensation that an extremity that has been lost is, in fact, present.

**phobia**: Persistent, pathological, unrealistic, intense fear of an object or situation; the phobic person may realize that the
fear is irrational but, nonetheless, cannot dispel it. For types of phobias, see the specific term.

**Pica:** Craving and eating of nonfood substances, such as paint and clay.

**Polyphagia:** Pathological overeating.

**Positive signs:** In schizophrenia: hallucinations, delusions, and thought disorder.

**Posturing:** Strange, fixed, and bizarre bodily positions held by a patient for an extended time. See also *catatonia*.

**Poverty of content of speech:** Speech that is adequate in amount but conveys little information because of vagueness, emptiness, or stereotyped phrases.

**Poverty of speech:** Restriction in the amount of speech used; replies may be monosyllabic. See also *laconic speech*.

**Preoccupation of thought:** Centering of thought content on a particular idea, associated with a strong affective tone, such as a paranoid trend or a suicidal or homicidal preoccupation.

**Pressured speech:** Increase in the amount of spontaneous speech; rapid, loud, accelerated speech, as occurs in mania, schizophrenia, and cognitive disorders.

**Primary process thinking:** In psychoanalysis, the mental activity related directly to the functions of the id and characteristic of unconscious mental processes; marked by primitive, prelogical thinking and by the tendency to seek immediate discharge and gratification of instinctual demands. Includes thinking that is dereistic, illogical, magical; normally found in dreams, abnormally in psychosis. Compare with *secondary process thinking*.

**Projection:** Unconscious defense mechanism in which persons attribute to another those generally unconscious ideas, thoughts, feelings, and impulses that are in themselves undesirable or unacceptable as a form of protection from anxiety arising from an inner conflict; by externalizing whatever is unacceptable, they deal with it as a situation apart from themselves.

**Protopagnosia:** Inability to recognize familiar faces that is not due to impaired visual acuity or level of consciousness.

**Pseudocyesis:** Rare condition in which a nonpregnant patient has the signs and symptoms of pregnancy, such as abdominal distention, breast enlargement, pigmentation, cessation of menses, and morning sickness.

**Pseudodementia:** (1) Dementia-like disorder that can be reversed by appropriate treatment and is not caused by organic brain disease. (2) Condition in which patients show exaggerated indifference to their surroundings in the absence of a mental disorder; also occurs in depression and factitious disorders.

**Pseudologia phantastica:** Disorder characterized by uncontrollable lying in which patients elaborate extensive fantasies that they freely communicate and act on.

**Psychomotor agitation:** Physical and mental overactivity that is usually nonproductive and is associated with a feeling of inner turmoil, as seen in agitated depression.

**Psychosis:** Mental disorder in which the thoughts, affective response, ability to recognize reality, and ability to communicate and relate to others are sufficiently impaired to interfere grossly with the capacity to deal with reality; the classical characteristics of psychosis are impaired reality testing, hallucinations, delusions, and illusions.

**Psychotic:** (1) Person experiencing psychosis. (2) Denoting or characteristic of psychosis.

**Rationalization:** An unconscious defense mechanism in which irrational or unacceptable behavior, motives, or feelings are logically justified or made consciously tolerable by plausible means.

**Reaction formation:** Unconscious defense mechanism in which a person develops a socialized attitude or interest that is the direct antithesis of some infantile wish or impulse that is harbored consciously or unconsciously. One of the earliest and most unstable defense mechanisms, closely related to repression; both are defenses against impulses or urges that are unacceptable to the ego.

**Reality testing:** Fundamental ego function that consists of tentative actions that test and objectively evaluate the nature and limits of the environment; includes the ability to differentiate between the external world and the internal world and to accurately judge the relation between the self and the environment.

**Recall:** Process of bringing stored memories into consciousness. See also *memory*.

**Recent memory:** Recall of events over the past few days.

**Recent past memory:** Recall of events over the past few months.

**Receptive aphasia:** Organic loss of ability to comprehend the meaning of words; fluid and spontaneous, but incoherent and nonsensical, speech. See also *fluent aphasia* and *sensory aphasia*.

**Receptive dysphasia:** Difficulty in comprehending oral language; the impairment involves comprehension and production of language.

**Regression:** Unconscious defense mechanism in which a person undergoes a partial or total return to earlier patterns of adaptation; observed in many psychiatric conditions, particularly schizophrenia.

**Remote memory:** Recall of events in the distant past.

**Repression:** Freud’s term for an unconscious defense mechanism in which unacceptable mental contents are banished or kept out of consciousness; important in normal psychological development and in neurotic and psychotic symptom formation. Freud recognized two kinds of repression: (1) repression proper, in which the repressed material was once in the conscious domain, and (2) primal repression, in which the repressed material was never in the conscious realm. Compare with *suppression*.

**Restricted affect:** Reduction in intensity of feeling tone that is less severe than in blunted affect but clearly reduced. See also *constricted affect*.

**Regressive amnesia:** Loss of memory for events preceding the onset of the amnesia. Compare with *anterograde amnesia*.

**Retrospective falsification:** Memory becomes unintentionally (unconsciously) distorted by being filtered through a person’s present emotional, cognitive, and experiential state.

**Rigidity:** In psychiatry, a person's resistance to change, a personality trait.

**Ritual:** (1) Formalized activity practiced by a person to reduce anxiety, as in OCD. (2) Ceremonial activity of cultural origin.

**Rumination:** Constant preoccupation with thinking about a single idea or theme, as in OCD.
satyríasis: Morbid, insatiable sexual need or desire in a man. Compare with nymphomania.
socoma: (1) In psychiatry, a figurative blind spot in a person’s psychological awareness. (2) In neurology, a localized visual field defect.
secondary process thinking: In psychoanalysis, the form of thinking that is logical, organized, reality oriented, and influenced by the demands of the environment; characterizes the mental activity of the ego. Compare with primary process thinking.
seizure: An attack or sudden onset of certain symptoms, such as convulsions, loss of consciousness, and psychic or sensory disturbances; seen in epilepsy and can be substance induced. For types of seizures, see the specific term.
sensorium: Hypothetical sensory center in the brain that is involved with clarity of awareness about oneself and one’s surroundings, including the ability to perceive and to process ongoing events in light of past experiences, future options, and current circumstances; sometimes used interchangeably with consciousness.
sensory aphasia: Organic loss of ability to comprehend the meaning of words; fluid and spontaneous, but incoherent and nonsensical, speech. See also fluent aphasia and receptive aphasia.
sensory extinction: Neurological sign operationally defined as failure to report one of two simultaneously presented sensory stimuli, despite the fact that either stimulus alone is correctly reported. Also called sensory inattention.
shame: Failure to live up to self-expectations; often associated with fantasy of how person will be seen by others. See also guilt.
short-term memory: Reproduction, recognition, or recall of perceived material within minutes after the initial presentation. Compare with immediate memory and long-term memory.
simultanagnosia: Impairment in the perception or integration of visual stimuli appearing simultaneously.
somatic delusion: Delusion pertaining to the functioning of one’s body.
somatic hallucination: Hallucination involving the perception of a physical experience localized within the body.
somatopagnosia: Inability to recognize a part of one’s body as one’s own (also called ignorance of the body and autotopagnosia).
somnolence: Pathological sleepiness or drowsiness from which one can be aroused to a normal state of consciousness.
spatial agnosia: Inability to recognize spatial relations.
speaking in tongues: Expression of a revelatory message through unintelligible words; not considered a disorder of thought if associated with practices of specific Pentecostal religions. See also glossolalia.
stereotypy: Continuous mechanical repetition of speech or physical activities; observed in catatonic schizophrenia.
stupor: (1) State of decreased reactivity to stimuli and less than full awareness of one’s surroundings; as a disturbance of consciousness, it indicates a condition of partial coma or semicoma. (2) In psychiatry, used synonymously with mutism and does not necessarily imply a disturbance of consciousness; in catatonic stupor, patients are ordinarily aware of their surroundings.
stuttering: Frequent repetition or prolongation of a sound or syllable, leading to markedly impaired speech fluency.
sublimation: Unconscious defense mechanism in which the energy associated with unacceptable impulses or drives is diverted into personally and socially acceptable channels; unlike other defense mechanisms, it offers some minimal gratification of the instinctual drive or impulse.
substitution: Unconscious defense mechanism in which a person replaces an unacceptable wish, drive, emotion, or goal with one that is more acceptable.
suggestibility: State of uncritical compliance with influence or of uncritical acceptance of an idea, belief, or attitude; commonly observed among persons with hysterical traits.
suicidal ideation: Thoughts or act of taking one’s own life.
suppression: Conscious act of controlling and inhibiting an unacceptable impulse, emotion, or idea; differentiated from repression in that repression is an unconscious process.
symbolization: Unconscious defense mechanism in which one idea or object comes to stand for another because of some common aspect or quality in both; based on similarity and association; the symbols formed protect the person from the anxiety that may be attached to the original idea or object.
synesthesia: Condition in which the stimulation of one sensory modality is perceived as sensation in a different modality, as when a sound produces a sensation of color.
syntactical aphasia: Aphasia characterized by difficulty in understanding spoken speech, associated with gross disorder of thought and expression.
systematized delusion: Group of elaborate delusions related to a single event or theme.
tactile hallucination: Hallucination primarily involving the sense of touch. Also called haptic hallucination.
tangentiality: Oblique, digressive, or even irrelevant manner of speech in which the central idea is not communicated.
tension: Physiological or psychic arousal, uneasiness, or pressure toward action; an unpleasurable alteration in mental or physical state that seeks relief through action.
terminal insomnia: Early morning awakening or waking up at least 2 hours before planning to wake up. Compare with initial insomnia and middle insomnia.
thought broadcasting: Feeling that one’s thoughts are being broadcast or projected into the environment. See also thought withdrawal.
thought disorder: Any disturbance of thinking that affects language, communication, or thought content; the hallmark feature of schizophrenia. Manifestations range from simple blocking and mild circumstantiality to profound loosening of associations, incoherence, and delusions; characterized by a failure to follow semantic and syntactic rules that is inconsistent with the person’s education, intelligence, or cultural background.
thought insertion: Delusion that thoughts are being implanted in one’s mind by other people or forces.
thought latency: The period of time between a thought and its verbal expression. Increased in schizophrenia (see blocking) and decreased in mania (see pressured speech).
thought withdrawal: Delusion that one's thoughts are being removed from one's mind by other people or forces. See also thought broadcasting.

tic disorders: Predominantly psychogenic disorders characterized by involuntary, spasmodic, stereotyped movement of small groups of muscles; seen most predominantly in moments of stress or anxiety, rarely as a result of organic disease.

tinnitus: Noises in one or both ears, such as ringing, buzzing, or clicking; an adverse effect of some psychotropic drugs.

tonic convulsion: Convulsion in which the muscle contraction is sustained.

trailing phenomenon: Perceptual abnormality associated with hallucinogenic drugs in which moving objects are seen as a series of discrete and discontinuous images.

trace: Sleeplike state of reduced consciousness and activity.

tremor: Rhythmical alteration in movement, which is usually faster than one beat a second; typically, tremors decrease during periods of relaxation and sleep and increase during periods of anger and increased tension.

true insight: Understanding of the objective reality of a situation coupled with the motivational and emotional impetus to master the situation or change behavior.

twilight state: Disturbed consciousness with hallucinations.

twirling: Sign present in autistic children who continually rotate in the direction in which their head is turned.

unconscious: (1) One of three divisions of Freud's topographic theory of the mind (the others being the conscious and the preconscious) in which the psychic material is not readily accessible to conscious awareness by ordinary means; its existence may be manifest in symptom formation, in dreams, or under the influence of drugs. (2) In popular (but more ambiguous) usage, any mental material not in the immediate field of awareness. (3) Denoting a state of unawareness, with lack of response to external stimuli, as in a coma.

undoing: Unconscious primitive defense mechanism, repetitive in nature, by which a person symbolically acts out in reverse something unacceptable that has already been done or against which the ego must defend itself; a form of magical expiatory action, commonly observed in OCD.

unio mystica: Feeling of mystic unity with an infinite power.

vegetative signs: In depression, denoting characteristic symptoms such as sleep disturbance (especially early morning awakening), decreased appetite, constipation, weight loss, and loss of sexual response.

verbigeration: Meaningless and stereotyped repetition of words or phrases, as seen in schizophrenia. Also called cataphasia. See also perseveration.

vertigo: Sensation that one or the world around one is spinning or revolving; a hallmark of vestibular dysfunction, not to be confused with dizziness.

visual agnosia: Inability to recognize objects or persons.

visual amnesia: See neurological amnesia.

visual hallucination: Hallucination primarily involving the sense of sight.

waxy flexibility: Condition in which a person maintains the body position into which they are placed with slight resistance to movement giving it a waxy feel. See also cerea flexibilitis.

word approximation: Use of conventional words in an unconventional or inappropriate way (metonymy or of new words that are developed by conventional rules of word formation) (e.g., hand shoes for gloves and time measure for clock); distinguished from a neologism, which is a new word whose derivation cannot be understood. See also paraphasia.

word salad: Incoherent, essentially incomprehensible, mixture of words and phrases commonly seen in far-advanced cases of schizophrenia. See also incoherence.

xenophobia: Abnormal fear of strangers.

zoophobia: Abnormal fear of animals.

1991 (with H.I. Kaplan)
This guide contains color reproductions of some commonly prescribed psychotherapeutic drugs. This guide mainly illustrates proprietary tablets and capsules. A † preceding the name of a drug indicates that other doses are available. Check directly with the manufacturer.

(Although the photos are intended as accurate reproductions of the drug, this guide should be used only as a quick identification aid.)

*Lippincott Williams & Wilkins*
Emotional facial expressions.\(^1\) In the 1960s, Paul Ekman demonstrated that facial expressions of emotion are universal and thus, presumably, biological in origin as Charles Darwin once theorized (Ekman & Friesen, 1975). Since Ekman’s discovery, photographs of emotional expressions have been widely used in psychological research to understand how people recognize another’s emotions. Neuroimaging research has focused on two areas that are involved in emotion recognition: (A) The amygdala, known to be involved in fear conditioning, is most active when recognizing fear compared to other facial expressions (Whalen, 1998). (B) The anterior insula, associated with taste processing, subserves the recognition of another’s disgust (Calder, Lawrence, & Young, 2001). (From Sadock BJ, Sadock VA, Ruiz P. Kaplan & Sadock’s Comprehensive Textbook of Psychiatry. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009.)

\(^1\)Development of the MacBrain Face Stimulus Set was overseen by Nim Tottemham and supported by the John D. and Catherine T. MacArthur Foundation Research Network on Early Experience and Brain Development.
This figure from the Human Connectome Project is a resting-state functional magnetic resonance (fMRI) spatial map of functional connectivity of cortical signals, which show strong and distinct patterns of activation. The term "connectome" refers to the mapping of connectivity throughout the brain using imaging modalities such as fMRI and diffusion MRI. fMRI is used to study connectivity in the brain by acquiring fMRI data from a subject lying "at rest" in the scanner, and utilizing the fact that the spontaneous time series from functionally related brain regions are correlated. (Courtesy of Stephen M. Smith, M.D.)
COLOR PLATE 5.8-4
Functional MRI during rhyming tasks in normal people and people with dyslexia. The left hemisphere is depicted in green. Normal (top) and dyslexic (bottom) subjects were shown two letters and asked to determine whether the letters rhymed (B-T) or not (B-K). To perform the task, the subjects had to translate the letters into sounds, or phonemes (/bee/, /lee/), then compare only the rhyming part of the phonemes (/ee/). In normals, three contiguous areas were activated, including Broca’s area, Wernicke’s area, and the intervening insula. In those with dyslexia, only Broca’s area was activated. Dyslexic patients required much more time to complete the task and were more prone to make errors. (Reprinted with permission from Frith C, Frith U. A biological marker for dyslexia. Nature. 1996;382:19.)

COLOR PLATE 1.8-5
Topographic quantitative electroencephalography map of theta absolute power (z score departures from normative database mean). The patient is a male 24 years of age with a closed head injury. The focus of increased theta voltage is at the locus of an earlier head injury that occurred approximately 2 years before the recording. After recording and quantification, the color bar scale was adjusted to maximize the bullseye localization effect. Theta voltage was also elevated to a lesser extent over a wide, right frontal area and even spread somewhat across the midline. Theta relative power (not shown) was also elevated over the right frontal region, but mapping did not produce a sharp relative power focus at the locus of injury. Important note: A very sharply defined bull’s eye can also be produced by artifact from a faulty electrode, and it is imperative to monitor electrical impedance and check the integrity of the electrode in the event that deviant activity appears confined to only one lead with no spread to adjoining electrodes. (From Sadock BJ, Sadock VA, Ruiz P. Kaplan & Sadock’s Comprehensive Textbook of Psychiatry. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009.)
Stages of the superimposition of a single photon emission computed tomography cerebral blood flow image (A), which has been redefined (B), and a magnetic resonance T1-weighted image (C), to produce a combination (D). (Reprinted from Besson JAO. Magnetic resonance imaging and its application in neuropsychiatry. Br J Psychiatry. 1990;(9 Suppl):25–37, with permission.)

Exophthalmos. This patient has Graves' disease. Note the lid retraction and proptosis.

Statistical map of functional magnetic resonance imaging (fMRI) blood oxygenation level–dependent signal intensity differences demonstrating significantly increased activity in the right amygdale in subjects with posttraumatic stress disorder (PTSD) compared with traumatized subjects without PTSD. The response to masked, fearful faces in PTSD and non-PTSD groups were compared after normalizing to masked, happy faces. fMRI data are displayed in Talairach template space and are co-registered with structural magnetic resonance imaging data.

Facitial ulcerations. These were created by the patient. Note their geometric appearance.

Erythema multiforme minor caused by hypersensitivity to certain antiepileptic drugs in psychiatry (e.g. lamotrigine).
