Before the development of the PAC, determining cardiac output (QT) at the bedside required careful measurements of oxygen consumption (Fick method) or spectrophotometric determination of indocyanine green dye dilution curves. Measurements of QT using the thermodilution technique are simple and reasonably accurate. The measurements can be performed repetitively, and the principle is straightforward. If a bolus of an indicator is rapidly and thoroughly mixed with a moving fluid upstream from a detector, then the concentration of the indicator at the detector will increase sharply and then exponentially diminish back to zero. The area under the resulting time-concentration curve is a function of the volume of indicator injected and the flow rate of the moving stream of fluid. Larger volumes of indicator result in greater areas under the curve, and faster flow rates of the mixing fluid result in smaller areas under the curve. When QT is measured by thermodilution, the indicator is heat and the detector is a temperature-sensing thermistor at the distal end of the PAC. The relationship used for calculating QT is called the Stewart-Hamilton equation:

\[
Q_T = \frac{V K_1 K_2 (T_B - T_I)}{\int T_B(t) dt}
\]

where V is the volume of the indicator injected, TB is the temperature of blood (i.e., core body temperature), TI is the temperature of the indicator, K1 is a constant that is the function of the specific heats of blood and the indicator, K2 is an empirically derived constant that accounts for several factors (the dead space volume of the catheter, heat lost from the indicator as it traverses the catheter, and the injection rate of the indicator), and \(\int T_B(t) dt\) is the area under the time-temperature curve. In clinical practice, the Stewart-Hamilton equation is solved by a microprocessor.

Determination of cardiac output by the thermodilution method is generally quite accurate, although it tends to systematically overestimate QT at low values. Changes in blood temperature and QT during the respiratory cycle can influence the measurement. Therefore, results generally should be recorded as the mean of two or three determinations obtained at random points in the respiratory cycle. Using cold injectate widens the difference between TB and TI and thereby increases signal-to-noise ratio. Nevertheless, most authorities recommend using room temperature injectate (normal saline or 5% dextrose in water) to minimize errors resulting from warming of the fluid as it transferred from its reservoir to a syringe for injection.

Technologic innovations have been introduced that permit continuous measurement of QT by thermodilution. In this approach, thermal transients are not generated by injecting a bolus of a cold indicator, but rather by heating the blood with a tiny filament located on the PAC upstream from the thermistor. By correlating the amount of current supplied to the heating element with the downstream temperature of the blood, it is possible to estimate the average blood flow across the filament and thereby calculate QT. Based upon the results of several studies, continuous determinations of QT using this approach agree well with data generated by conventional measurements using bolus injections of a cold indicator. Information is lacking regarding the clinical value of being able to monitor QT continuously.

**Mixed Venous Oximetry**

The Fick equation can be written as

\[
Q_T = \frac{\text{VO}_2}{(\text{CaO}_2 - \text{CvO}_2)}
\]

where \(\text{C}_a\text{O}_2\) is the content of oxygen in arterial blood and \(\text{C}_v\text{O}_2\) is the content of oxygen in mixed venous blood. The oxygen content in both arterial and venous blood is a function of the hemoglobin concentration in the blood, the hemoglobin saturation, and the partial pressure of oxygen:

\[
\text{C}_a\text{O}_2 = (1.36 \times \text{Hgb} \times \frac{\text{S}_a\text{O}_2}{100}) + 0.0031 \times P_a\text{O}_2
\]

\[
\text{C}_v\text{O}_2 = (1.36 \times \text{Hgb} \times \frac{\text{S}_v\text{O}_2}{100})
\]

where \(\text{S}_a\text{O}_2\) is the fractional saturation of hemoglobin in either arterial or venous blood, Hgb is the concentration of hemoglobin...
in blood, and \( P_{a}O_2 \) is the partial pressure of oxygen in the arterial or venous blood. Under most circumstances the contribution of dissolved oxygen to both \( C_{a}O_2 \) and \( C_{v}O_2 \) is negligible, allowing the second portion of equation to be functionally eliminated (see previous equation). Given that, if the Fick equation is rearranged to the following:

\[
C_{a}O_2 = C_{v}O_2 - \frac{VO_2}{Q_T}
\]

Oxygen saturation can replace oxygen content, yielding the final clinically valuable equation:

\[
S_{O_2} = S_{a}O_2 - \frac{VO_2}{(Q_T \times Hgb \times 1.36)}
\]

where \( S_{O_2} \) is the fractional saturation of hemoglobin in mixed venous blood, \( S_{a}O_2 \) is the fractional saturation of hemoglobin in arterial blood, and \( Hgb \) is the concentration of hemoglobin in blood. Thus, it can be seen that \( S_{O_2} \) is a function of \( VO_2 \) (i.e., metabolic rate), \( Q_T \), \( S_{a}O_2 \), and \( Hgb \). Accordingly, subnormal values of \( S_{O_2} \) can be caused by a decrease in \( Q_T \) (due, for example, to heart failure or hypovolemia), a decrease in \( S_{a}O_2 \) (due, for example, to intrinsic pulmonary disease), a decrease in \( Hgb \) (i.e., anemia), or an increase in metabolic rate (due, for example, to seizures or fever). With a conventional PAC, measurements of \( S_{O_2} \) require aspirating a sample of blood from the distal (i.e., pulmonary arterial) port of the catheter and injecting the sample into a blood gas analyzer. Therefore, for practical purposes, measurements of \( S_{O_2} \) can be performed only intermittently.

By adding a fifth channel to the PAC, it is possible to monitor \( S_{O_2} \) continuously. The fifth channel contains two fiber-optic bundles, which are used to transmit and receive light of the appropriate wavelengths to permit measurements of hemoglobin saturation by reflectance spectrophotometry. Continuous \( S_{O_2} \) devices provide measurements of \( S_{O_2} \) that agree quite closely with those obtained by conventional analyses of blood aspirated from the pulmonary artery. Despite the theoretical value of being able to monitor \( S_{O_2} \) continuously, data are lacking to show that this capability favorably improves outcomes. In a prospective, observational study of 3265 patients undergoing cardiac surgery with either a standard PAC or a PAC with continuous \( S_{O_2} \) monitoring, the oximetric catheter was associated with fewer arterial blood gases and thermodilution cardiac output determinations but no difference in patient outcome. Since pulmonary artery catheters that permit continuous monitoring of \( S_{O_2} \) are more expensive than conventional PACs, the routine use of these devices cannot be recommended.

The saturation of oxygen in the right atrium or superior vena cava (\( S_{a}O_2 \)) correlates closely with \( S_{O_2} \) over a wide range of conditions, although the correlation between \( S_{a}O_2 \) and \( S_{O_2} \) has been questioned. Since measurement of \( S_{a}O_2 \) requires placement of a central venous catheter rather than a PAC, it is somewhat less invasive and easier to carry out. By using a central venous catheter equipped to permit fiber-optic monitoring of \( S_{a}O_2 \), it may be possible to titrate the resuscitation of patients with shock using a less invasive device than the PAC. The Surviving Sepsis Campaign international guidelines for the management of severe sepsis and septic shock recommends that during the first 6 hours of resuscitation, the goals of initial resuscitation of sepsis-induced hypoperfusion should include all of the following: CVP 8 to 12 mm Hg, MAP \( \geq 65 \) mm Hg, urine output \( \geq 0.5 \) mL/kg per hour, and \( S_{a}O_2 \) of 70% or \( S_{v}O_2 \) 65%.20

**EFFECT OF PULMONARY ARTERY CATHETERIZATION ON OUTCOME**

Despite initial enthusiasm for using the PAC in the management of critically ill patients, several studies have failed to show improved outcomes with their use. Connors and colleagues reported results of a major observational study evaluating the value of pulmonary artery catheterization in critically ill patients. These researchers compared two groups of patients: those who did undergo placement of a PAC during their first 24 hours of stay and those who did not. The investigators recognized that the value of their intended analysis was completely dependent on the robustness of their methodology for case-matching because sicker patients (i.e., those at greater risk of mortality based upon the severity of their illness) were presumably more likely to undergo pulmonary artery catheterization. Accordingly, the authors used sophisticated statistical methods for generating a cohort of study (i.e., PAC) patients, each one having a paired control matched carefully for severity of illness. Connors and associates concluded that placement of a pulmonary artery catheter during the first 24 hours of stay in an ICU is associated with a significant increase in the risk of mortality, even when statistical methods are used to account for severity of illness.

A number of prospective, randomized controlled trials of pulmonary artery catheterization are summarized in Table 13-2. The study by Pearson and associates was underpowered with only 226 patients enrolled. In addition, the attending anesthesiologists were permitted to exclude patients from the CVP group at their discretion; thus randomization was compromised. The study by Tuman and coworkers was large (1094 patients were enrolled), but different anesthesiologists were assigned to the different groups. Furthermore, 39 patients in the CVP group underwent placement of a PAC because of hemodynamic complications. All of the individual single-institution studies of vascular surgery patients were relatively underpowered, and all excluded at least certain categories of patients (e.g., those with a history of recent myocardial infarction).24,25

In the largest randomized controlled trial of the PAC, Sandham and associates randomized nearly 2000 American Society of Anesthesiologists (ASA) classes III and IV patients undergoing major thoracic, abdominal, or orthopedic surgery to placement of a PAC or CVP catheter. In the patients assigned to receive a PAC, physiologic goal-directed therapy was implemented by protocol. There were no differences in mortality at 30 days, 6 months, or 12 months between the two groups, and ICU length of stay was similar. There was a significantly higher rate of pulmonary emboli in the PAC group (0.9% vs. 0%). This study has been criticized because most of the patients enrolled were not in the highest risk category.

In the “PAC-Man” trial, a multicenter, randomized trial in 65 UK hospitals, over 1000 ICU patients were managed with or without a PAC. The specifics of the clinical management were then left up to the treating clinicians. There was no difference in hospital mortality between the 2 groups (with PAC 68% vs. without PAC 66%, \( P = 0.39 \)). However, a 9.5% complication rate was associated with the insertion or use of the PAC, although none of these complications were fatal. Clearly, these were critically ill patients, as noted by the high hospital mortality rates. Supporters of the PAC may cite methodology problems with this study, such as loose inclusion criteria and the lack of a defined treatment protocol.

ALI = acute lung injury; CHF = congestive heart failure; CO = cardiac output; CVC = central venous catheter; ICU = intensive care unit; PAC = pulmonary artery catheter; Sv–O2 = fractional mixed venous (pulmonary artery) hemoglobin saturation.

A meta-analysis of 13 randomized studies of the PAC that included over 5000 patients was published in 2005.\(^{28}\) A broad spectrum of critically ill patients was included in these heterogeneous trials, and the hemodynamic goals and treatment strategies varied. While the use of the PAC was associated with an increased use of inotropes and vasodilators, there were no differences in mortality or hospital length of stay between the patients managed with a PAC and those managed without a PAC. The ESCAPE trial (which was one of the studies included in the previous meta-analysis)\(^{29}\) evaluated 433 patients with severe or recurrent congestive heart failure (CHF) admitted to the ICU. Patients were randomized to management by clinical assessment and a PAC or clinical assessment without a PAC. The goal in both groups was resolution of CHF, with additional PAC targets of a pulmonary capillary occlusion pressure of 15 mmHg and a right atrial pressure of 8 mmHg. There was no formal treatment protocol, but inotropic support was discouraged. Substantial reduction in symptoms, jugular venous pressure, and edema was noted in both groups. There was no significant difference in the primary end point of days alive and out of the hospital during the first 6 months, or hospital mortality (PAC 10% vs without PAC 9%). Adverse events
were more common among patients in the PAC group (21.9% vs 11.5%; *P* = 0.04).

Finally, the Fluids and Catheters Treatment Trial (FACTTT) conducted by the Acute Respiratory Distress Syndrome (ARDS) Clinical Trials Network was published in 2006. The risks and benefits of PAC compared with central venous catheters (CVC) were evaluated in 1000 patients with acute lung injury. Patients were randomly assigned to receive either a PAC or a CVC to guide management for 7 days via an explicit protocol. Patients also were randomly assigned to a conservative or liberal fluid strategy in a 2 × 2 factorial design (outcomes based on the fluid management strategy were published separately). Mortality during the first 60 days was similar in the PAC and CVC groups (27% and 26%, respectively; *P* = .69). The duration of mechanical ventilation and ICU length of stay also were not influenced by the type of catheter used. The type of catheter employed did not affect the incidence of shock, respiratory or renal failure, ventilator settings, or requirement for hemodialysis or vasopressors. There was a 1% rate of crossover from CVC-guided therapy to PAC-guided therapy. The catheter used did not affect the administration of fluids or diuretics, and the fluid balance was similar in the two groups. The PAC group had approximately twice as many catheter-related adverse events (mainly arrhythmias).

Few subjects in critical care medicine have historically generated more emotional responses among experts in the field than the use of the PAC. As these studies demonstrate, it is not possible to show that therapy directed by use of the PAC saves lives when it is evaluated in a large population of patients. Certainly, given the available evidence, routine use of the PAC cannot be justified.

Whether selective use of the device in a few relatively uncommon clinical situations is warranted or valuable remains a controversial issue. Consequently, a marked decline in the use of the PAC from 5.66 per 1000 medical admissions in 1993 to 1.99 per 1000 medical admissions in 2004 has been seen. Based upon the results and exclusion criteria in these prospective randomized trials, reasonable criteria for perioperative monitoring without use of a PAC are presented in Table 13-3.

One of the reasons for using a PAC to monitor critically ill patients is to optimize cardiac output and systemic oxygen delivery. Defining what constitutes the optimum cardiac output, however, has proven to be difficult. A number of randomized trials evaluating the effect on outcome of goal-directed as compared to conventional hemodynamic resuscitation have been published. Some studies provide support for the notion that interventions designed to achieve supraphysiologic goals for DO₂, VO₂, and Qₜ improve outcome. However, other published studies do not support this view, and a meta-analysis concluded that interventions designed to achieve supraphysiologic goals for oxygen transport do not significantly reduce mortality rates in critically ill patients. At this time, supraphysiologic resuscitation of patients in shock cannot be endorsed.

There is no simple explanation for the apparent lack of effectiveness of pulmonary artery catheterization, although several concurrent possibilities exist. First, even though bedside pulmonary artery catheterization is quite safe, the procedure is associated with a finite incidence of serious complications, including ventricular arrhythmias, catheter-related sepsis, central venous thrombosis, pulmonary arterial perforation, and pulmonary embolism. The adverse effects of these complications on outcome may equal or even outweigh any benefits associated with using a PAC to guide therapy. Second, the data generated by the PAC may be inaccurate, leading to inappropriate therapeutic interventions. Third, the measurements, even if accurate, are often misinterpreted. Furthermore, the current state of understanding is primitive when it comes to deciding what is the best management for certain hemodynamic disturbances, particularly those associated with sepsis or septic shock. Taking all of this into consideration, it may be that interventions prompted by measurements obtained with a PAC are actually harmful to patients. As a result, the marginal benefit now available by placing a PAC may be quite small. Less invasive modalities are available that may provide clinically useful hemodynamic information.

It may be true that aggressive hemodynamic resuscitation of patients, guided by various forms of monitoring, is valuable only during certain critical periods, such as the first few hours after presentation with septic shock or during surgery. For example, Rivers and colleagues reported that survival of patients with septic shock is significantly improved when resuscitation in the emergency department is guided by a protocol that seeks to keep ScvO₂ greater than 70%. Similarly, a study using an ultrasound-based device (see “Doppler Ultrasonography”) to assess cardiac filling and SV showed that maximizing SV intraoperatively results in fewer postoperative complications and shorter hospital length of stay.

**MINIMALLY INVASIVE ALTERNATIVES TO THE PULMONARY ARTERY CATHETER**

Because of the cost, risks, and questionable benefit associated with bedside pulmonary artery catheterization, there has been interest in the development of practical means for less invasive monitoring of hemodynamic parameters. Several approaches have been developed that have achieved variable degrees of success. None of these methods render the standard thermodilution technique of the pulmonary artery catheter obsolete. However, these strategies may contribute to improvements in the hemodynamic monitoring of critically ill patients.

**Transpulmonary Thermodilution**

In the standard PAC thermodilution technique, measurements rely on the detection of temperature changes in a relatively small area from the injection port to the thermistor on the same catheter. In contrast, the transpulmonary thermodilution (TPTD) technique measures temperature changes from cold
bolus solution injected centrally, then measured using an arterial thermistor on a special arterial line, generally placed in the femoral artery. Both standard PAC thermodilution and TPTD make use of the Stewart-Hamilton equation to subsequently calculate cardiac output. Studies have demonstrated that this technique provides comparable estimates of cardiac output when compared to routine PAC thermodilution and can accurately detect changes in cardiac output as small as 12%. However, due to the large blood circuit between the central injection point and the thermistor, data can be challenging to interpret in certain pathophysiologic conditions (e.g., in pulmonary edema, as excess lung water serves as a temperature sink). On the other hand, thoughtful application of TPTD data allows clinicians access to several additional variables that the traditional PAC does not provide, such as estimation of the global end-diastolic volume (GEDV) and the extravascular lung water volume (EVLW). While these variables are of scientific interest, they are not yet in widespread use, and further studies are required to determine their utility. However, TPTD does currently play a prominent role in the real-time calibration of pulse contour analysis, described in greater detail later in this chapter.

**Doppler Ultrasoundography**

When ultrasonic sound waves are reflected by moving erythrocytes in the bloodstream, the frequency of the reflected signal is increased or decreased, depending on whether the cells are moving toward or away from the ultrasonic source. This change in frequency is called the Doppler shift, and its magnitude is determined by the velocity of the moving red blood cells. Therefore, measurements of the Doppler shift can be used to calculate red blood cell velocity. With knowledge of both the cross-sectional area of a vessel and the mean red blood cell velocity of the blood flowing through it, one can calculate blood flow rate. If the vessel in question is the aorta, then Q_T can be calculated as:

\[
Q_T = HR \times A \times \int V(t) \, dt
\]

where A is the cross-sectional area of the aorta and \( \int V(t) \, dt \) is the red blood cell velocity integrated over the cardiac cycle.

Two approaches have been developed for using Doppler ultrasonography to estimate Q_T. The first approach uses an ultrasonic transducer, which is manually positioned in the suprasternal notch and focused on the root of the aorta. Aortic cross-sectional area can be estimated using a nomogram, which factors in age, height, and weight, back-calculated if an independent measure of Q_T is available, or by using two-dimensional transthoracic or transesophageal ultrasonography. While this approach is completely noninvasive, it requires a highly-skilled operator in order to obtain meaningful results and is labor-intensive. Moreover, unless Q_T measured using thermodilution is used to back-calculate aortic diameter, accuracy using the suprasternal notch approach is not acceptable. Accordingly, the method is useful only for obtaining very intermittent estimates of Q_T, and it has not been widely adopted by clinicians.

A more promising, albeit more invasive, approach has been introduced. In this method blood flow velocity is continuously monitored in the descending thoracic aorta using a continuous-wave Doppler transducer introduced into the esophagus. The probe is connected to a monitor which continuously displays the blood flow velocity profile in the descending aorta as well as the calculated Q_T. In order to maximize the accuracy of the device, the probe position must be adjusted to obtain the peak velocity in the aorta. In order to transform blood flow in the descending aorta into Q_T, a correction factor is applied that is based on the assumption that only 70% of the flow at the root of the aorta is still present in the descending thoracic aorta. Aortic cross-sectional area is estimated using a nomogram based on the patient’s age, weight, and height. Results using these methods appear to be reasonably accurate across a broad spectrum of patients. A meta-analysis of the available data shows a good correlation between cardiac output estimates obtained by transesophageal Doppler and PAC in critically ill patients. The ultrasonic device also calculates a derived parameter termed flow time corrected (FTc), which is the systolic flow time in the descending aorta corrected for heart rate. FTc is a function of preload, contractility, and vascular input impedance. Although it is not a pure measure of preload, Doppler-based estimates of SV and FTc have been used successfully to guide volume resuscitation in high-risk surgical patients undergoing major operations.

**Impedance Cardiography**

The impedance to flow of alternating electrical current in regions of the body is commonly called bioimpedance. In the thorax, changes in the volume and velocity of blood in the thoracic aorta lead to detectable changes in bioimpedance. The first derivative of the oscillating component of thoracic bioimpedance (dZ/dt) is linearly related to aortic blood flow. On the basis of this relationship, empirically derived formulas have been developed to estimate SV, and subsequently Q_T, noninvasively. This methodology is called impedance cardiography. The approach is attractive because it is noninvasive, provides a continuous readout of Q_T, and does not require extensive training. Despite these advantages, measurements of Q_T obtained by impedance cardiography are not sufficiently reliable to be used for clinical decision making and have poor correlation with thermodilution.

Because of the limitations of bioimpedance devices, a newer approach for processing the impedance signal was developed and commercialized. This approach is based on the recognition that the impedance signal has two components: amplitude and phase. Whereas the amplitude of the thoracic impedance signal is determined by all of the components of the thoracic cavity (bone, blood, muscle, and other soft tissues), phase shifts are determined entirely by pulsatile flow. The vast majority of pulsatile flow is related to blood moving within the aorta. Therefore, the “bioreactance” signal correlates closely with aortic flow, and cardiac output determined using this approach agrees closely with cardiac output measured using conventional indicator dilution techniques.

**Pulse Contour Analysis**

Another method for determining cardiac output is an approach called pulse contour analysis for estimating SV on a beat-to-beat basis. The mechanical properties of the arterial tree and SV determine the shape of the arterial pulse waveform. The pulse contour method of estimating Q_T uses the arterial pressure waveform as an input for a model of the systemic circulation in order to determine beat-to-beat flow through the circulatory system. The parameters of resistance, compliance, and impedance are initially estimated based on the patient’s age and sex and can be subsequently refined by using a reference standard measurement of Q_T. The reference standard estimation of Q_T is obtained periodically using the indicator dilution approach by injecting the indicator into a central venous catheter and
detecting the transient increase in indicator concentration in the blood using an arterial catheter. In one commercially available embodiment of this approach, the lithium ion (Li+) is the indicator used for the periodic calibrations of the device. The lithium carbonate indicator can be injected into a peripheral vein, and the doses do not exert pharmacologically relevant effects in adult patients. The Li+ indicator dilution method has shown to be at least as reliable as other thermodilution methods over a broad range of CO in a variety of patients. An improved method uses the indicator for calibration, via TPTD approaches as described previously. When the pulse contour analysis is combined with intermittent TPTD in this fashion, the continuous data provided by contour analysis is more precise than TPTD alone.

Measurements of QT based on pulse contour monitoring using these two approaches are comparable in accuracy to standard pulmonary artery catheter (PAC)-thermodilution methods, but they are less invasive because transcardiac catheterization is not needed. Using online pressure waveform analysis, the computerized algorithms can calculate SV, QT, SVR, and an estimate of myocardial contractility, the rate of rise of the arterial systolic pressure (dP/dT). The use of pulse contour analysis has been applied using noninvasive photoplethysmographic measurements of arterial pressure. However, the accuracy of this technique has been questioned, and its clinical utility remains to be determined.

One commercially available device that can be used for estimating cardiac output does not require external calibration. Instead, the relationship between pulse pressure and stroke volume is determined using a proprietary algorithm that uses biometric data, such as age, gender and height, as inputs. Although this methodology is gaining fairly wide acceptance in critical care medicine, reported accuracy (in comparison to “gold standard” approaches) is not very good.

Partial Carbon Dioxide Rebreathing

Partial carbon dioxide (CO₂) rebreathing uses the Fick principle to estimate Qₜ noninvasively. By intermittently altering the dead space within the ventilator circuit via a rebreathing valve, changes in CO₂ production (VCO₂) and end-tidal CO₂ (ETCO₂) are used to determine cardiac output using a modified Fick equation:

\[
Q_T = \frac{\Delta V_{CO_2}}{\Delta ET_{CO_2}}
\]

Commercially available devices use this Fick principle to calculate Qₜ using intermittent partial CO₂ rebreathing through a disposable rebreathing loop. These devices consist of a CO₂ sensor based on infrared light absorption, an airflow sensor, and a pulse oximeter. Changes in intrapulmonary shunt and hemodynamic instability impair the accuracy of Qₜ estimated by partial CO₂ rebreathing. Continuous inline pulse oximetry and inspiration of inspired O₂ (FiO₂) are used to estimate shunt fraction to correct Qₜ.

Some studies of the partial CO₂ rebreathing approach suggest that this technique is not as accurate as thermodilution, the gold standard for measuring Qₜ. However, other studies suggest that the partial CO₂ rebreathing method for determination of Qₜ compares favorably to measurements made using a PAC in critically ill patients.

Transesophageal Echocardiography

Transesophageal echocardiography (TEE) has made the transition from operating room to intensive care unit. TEE requires that the patient be sedated and usually intubated for airway protection. Using this powerful technology, global assessments of LV and RV function can be made, including determinations of ventricular volume, EF, and QT. Segmental wall motion abnormalities, pericardial effusions, and tamponade can be readily identified with TEE. Doppler techniques allow estimation of atrial filling pressures. The technique is somewhat cumbersome and requires considerable training and skill in order to obtain reliable results. Recently, a TEE probe has been introduced into practice that is small enough in diameter that it can be left in place for as long as 72 hours. While only limited data are currently available with this probe, it seems like it will be a useful cardiac monitoring tool for use in selected, complex patients.

Assessing Preload Responsiveness

Although pulse contour analysis or partial CO₂ rebreathing may be able to provide estimates of SV and QT, these approaches alone can offer little or no information about the adequacy of preload. Thus, if QT is low, some other means must be employed to estimate preload. Many clinicians assess the adequacy of cardiac preload by determining CVP or PAOP. However, neither CVP nor PAOP correlate well with the true parameter of interest, left ventricular end-diastolic volume (LVEDV). Extremely high or low CVP or PAOP results are informative, but readings in a large middle zone (i.e., 5 to 20 mmHg) are less useful. Furthermore, changes in CVP or PAOP fail to correlate well with changes in stroke volume. Echocardiography can be used to estimate LVEDV, but this approach is dependent on the skill and training of the individual using it, and isolated measurements of LVEDV fail to predict the hemodynamic response to alterations in preload.

When intrathoracic pressure increases during the application of positive airway pressure in mechanically ventilated patients, venous return decreases, and as a consequence, left ventricular stroke volume (LVSV) also decreases. Therefore, pulse pressure variation (PPV) during a positive pressure episode can be used to predict the responsiveness of cardiac output to changes in preload. PPV is defined as the difference between the maximal pulse pressure and the minimum pulse pressure divided by the average of these two pressures (Fig. 13-4). This approach has validated this by comparing PPV, CVP, PAOP, and systolic pressure variation as predictors of preload responsiveness in a cohort of critically ill patients. Patients were classified as being “preload responsive” if their cardiac index increased by at least 15% after rapid infusion of a standard volume of intravenous fluid. Receiver-operating characteristic (ROC) curves demonstrated that PPV was the best predictor of preload responsiveness. Although atrial arrhythmias can interfere with the usefulness of this technique, PPV remains a useful approach for assessing preload responsiveness in most patients because of its simplicity and reliability.

Near-Infrared Spectroscopic Measurement of Tissue Hemoglobin Oxygen Saturation

Near-infrared spectroscopy (NIRS) allows continuous, noninvasive measurement of tissue hemoglobin oxygen saturation (StO₂) using near-infrared wave lengths of light (700–1000 nm). This technology is based on Beer’s law, which states that the transmission of light through a solution with a dissolved
solute decreases exponentially as the concentration of the solute increases. In mammalian tissue, three compounds change their absorption pattern when oxygenated: cytochrome aa3, myoglobin, and hemoglobin. Because of the distinct absorption spectra of oxyhemoglobin and deoxyhemoglobin, Beer’s law can be used to detect their relative concentrations within tissue. Thus, the relative concentrations of the types of hemoglobin can be determined by measuring the change in light intensity as it passes through the tissue. Since about 20% of blood volume is intra-arterial and the StO2 measurements are taken without regard to systole or diastole, spectroscopic measurements are primarily indicative of the venous oxyhemoglobin concentration.

NIRS has been evaluated to assess the severity of traumatic shock in animal models and in trauma patients. Studies have shown that peripheral muscle StO2, as determined by NIRS, is as accurate as other endpoints of resuscitation (i.e., base deficit, mixed venous oxygen saturation) in a porcine model of hemorrhagic shock. Continuously measured StO2 has been evaluated in blunt trauma patients as a predictor of the development of multiple organ dysfunction syndrome (MODS) and mortality. 383 patients were prospectively studied at seven level I trauma centers. StO2 was monitored for 24 hours after admission along with vital signs and other endpoints of resuscitation such as base deficit (BD). Minimum StO2 (using a minimum StO2 ≤75% as a cutoff) had a similar sensitivity and specificity in predicting the development of MODS as BD ≥6 mEq/L. StO2 and BD were also comparable in predicting mortality. Thus, NIRS-derived muscle StO2 measurements perform similarly to BD in identifying poor perfusion and predicting the development of MODS or death after severe torso trauma, yet have the additional advantages of being continuous and noninvasive. Ongoing prospective studies will help determine the clinical utility of continuous monitoring of StO2 in clinical scenarios such as trauma, hemorrhagic shock, sepsis, etc.

**RESPIRATORY MONITORING**

The ability to monitor various parameters of respiratory function is of utmost importance in critically ill patients. Many of these patients require mechanical ventilation. Monitoring of their respiratory physiology is necessary to assess the adequacy of oxygenation and ventilation, guide weaning and liberation from mechanical ventilation, and detect adverse events associated with respiratory failure and mechanical ventilation. These parameters include gas exchange, neuromuscular activity, respiratory mechanics, and patient effort.

**Arterial Blood Gases**

Blood gas analysis may provide useful information when caring for patients with respiratory failure. However, even in the absence of respiratory failure or the need for mechanical ventilation, blood gas determinations also can be valuable to detect alterations in acid-base balance due to low Qs, sepsis, renal failure, severe trauma, medication or drug overdose, or altered mental status. Arterial blood can be analyzed for pH, Po2, Pco2, HCO3– concentration and calculated base deficit. When indicated, carboxyhemoglobin and methemoglobin levels also can be measured. In recent years, efforts have been made to decrease the unnecessary use of arterial blood gas analysis. Serial arterial blood gas determinations are not necessary for routine weaning from mechanical ventilation in the majority of postoperative patients.

Most bedside blood gas analyses still involve removal of an aliquot of blood from the patient, although continuous bedside arterial blood gas determinations are now possible without sampling via an indwelling arterial catheter that contains a biosensor. In studies comparing the accuracy of continuous arterial blood gas and pH monitoring with a conventional laboratory blood gas analyzer, excellent agreement between the two methods has been demonstrated. Continuous monitoring can reduce the volume of blood loss due to phlebotomy and dramatically decrease the time necessary to obtain blood gas results. Continuous monitoring, however, is expensive and is not widely employed.

**Determinants of Oxygen Delivery**

The primary goal of the cardiovascular and respiratory systems is to deliver oxygenated blood to the tissues. DO2 is dependent to a greater degree on the oxygen saturation of hemoglobin (Hgb) in arterial blood (Sao2) than on the partial pressure of oxygen in arterial blood (Pao2). DO2 also is dependent on Qs and Hgb. As discussed earlier and illustrated mathematically by previous equations, the dissolved oxygen in blood makes only a negligible contribution to DO2. Sao2 in mechanically ventilated patients depends on the mean airway pressure, the fraction of inspired oxygen (Fio2), and S O2. Thus, when Sao2 is low, the clinician has only a limited number of ways to improve this parameter. The clinician can increase mean airway pressure by increasing positive-end expiratory pressure (PEEP) or inspiratory time. Fio2 can be increased to a maximum of 1.0 by decreasing the amount of room air mixed with the oxygen supplied to the ventilator. S O2 can be increased by increasing Hgb
Peak and Plateau Airway Pressure

Airway pressures are routinely monitored in mechanically ventilated patients. The peak airway pressure measured at the end of inspiration (P\text{peak}) is a function of the tidal volume, the resistance of the airways, lung/chest wall compliance, and peak inspiratory flow. The airway pressure measured at the end of inspiration when the inhaled volume is held in the lungs by briefly closing the expiratory valve is termed the plateau airway pressure (P\text{plateau}). As a static parameter, plateau airway pressure is independent of the airway resistance and peak airway flow and is related to the lung/chest wall compliance and delivered tidal volume. Mechanical ventilators monitor P\text{peak} with each breath and can be set to trigger an alarm if the P\text{peak} exceeds a predetermined threshold. P\text{plateau} is not measured routinely with each delivered tidal volume but rather is measured intermittently by setting the ventilator to close the exhalation circuit briefly at the end of inspiration and record the airway pressure when airflow is zero.

If both P\text{peak} and P\text{plateau} are increased (and tidal volume is not excessive), then the problem is a decrease in the compliance in the lung/chest wall unit. Common causes of this problem include pneumothorax, hemotorax, lobar atelectasis, pulmonary edema, pneumonia, acute respiratory distress syndrome (ARDS), active contraction of the chest wall or diaphragmatic muscles, abdominal distention, and intrinsic PEEP, such as occurs in patients with bronchospasm and insufficient expiratory times. When P\text{peak} is increased but P\text{plateau} is relatively normal, the primary problem is an increase in airway resistance, such as occurs with bronchospasm, use of a small-caliber endotracheal tube, or kinking or obstruction of the endotracheal tube. A low P\text{peak} also should trigger an alarm, as it suggests a discontinuity in the airway circuit involving the patient and the ventilator. These scenarios are outlined in Table 13-4.

Ventilator-induced lung injury (VILI) is now an established clinical entity of great relevance to the care of critically ill patients. Excessive airway pressure and tidal volume adversely affect pulmonary and possibly systemic responses to critical illness. Subjecting the lung parenchyma to excessive pressure, known as barotrauma, can result in parenchymal lung injury, diffuse alveolar damage similar to ARDS, and pneumothorax, and can impair venous return and therefore limit cardiac output. Lung-protective ventilation strategies have been developed to prevent the development of VILI and improve patient outcomes.

In a large, multicenter, randomized trial of patients with ARDS from a variety of etiologies, limiting plateau airway pressure to less than 30 cm H\text{2}O and tidal volume to less than 6 mL/kg of ideal body weight reduced 28-day mortality by 22% relative to a ventilator strategy that used a tidal volume of 12 mL/kg. For this reason, monitoring of plateau pressure and using a low tidal volume strategy in patients with ARDS is now the standard of care. Recent data also suggest that a lung-protective ventilation strategy is associated with improved clinical outcomes in ventilated patients without ARDS. Importantly, this strategy also has been shown to have benefit for high-risk patients undergoing general anesthesia for surgical procedures, leading to a reduced overall rate of pulmonary complications in the perioperative period as well as a reduced length of stay following surgery.

Pulse Oximetry

The pulse oximeter is a microprocessor-based device that integrates oximetry and plethysmography to provide continuous noninvasive monitoring of the oxygen saturation of arterial blood (Sao\text{2}). It is considered one of the most important and useful technologic advances in patient monitoring. Continuous, noninvasive monitoring of arterial oxygen saturation is possible using light-emitting diodes and sensors placed on the skin. Pulse oximetry employs two wavelengths of light (i.e., 660 nm and 940 nm) to analyze the pulsatile component of blood flow between the light source and sensor. Because oxyhemoglobin and deoxyhemoglobin have different absorption spectra, differential absorption of light at these two wavelengths can be used to calculate the fraction of oxygen saturation of hemoglobin. Under normal circumstances, the contributions of carboxyhemoglobin and methemoglobin are minimal. However, if carboxyhemoglobin levels are elevated, the pulse oximeter will incorrectly interpret carboxyhemoglobin as oxyhemoglobin and the arterial saturation displayed will be falsely elevated. When the concentration of methemoglobin is markedly increased, the Sao\text{2} will be displayed as 85%, regardless of the true arterial saturation. The accuracy of pulse oximetry begins to decline at Sao\text{2} values less than 92% and tends to be unreliable for values less than 85%.

Several studies have assessed the frequency of arterial oxygen desaturation in hospitalized patients and its effect on outcome. Monitoring pulse oximetry in surgical patients is associated with a reduction in unrecognized deterioration, rescue events, and transfers to the ICU. Because of its clinical relevance, ease of use, noninvasive nature, and cost-effectiveness, pulse oximetry has become a routine monitoring strategy in patients with respiratory disease, intubated patients, and those undergoing surgical intervention under sedation or general anesthesia. Pulse oximetry is especially useful in the titration of Fio\text{2} and PEEP for patients receiving mechanical ventilation, and during weaning from mechanical ventilation. The widespread use of pulse oximetry has decreased the need for arterial blood gas determinations in critically ill patients.

Pulse CO-Oximetry

While simple pulse oximeters such as those described previously are helpful for determination of the Sao\text{2}, extensions of the technology may prove valuable for determination of total hemoglobin concentration as well. Through the use of multiple additional wavelengths of light, clinicians can leverage the different spectrophotometric properties of the multiple different
oxidative states of hemoglobin to get a complete readout of the total hemoglobin present in a given volume, leading to a noninvasive measurement of Hgb. These devices are referred to as pulse CO-Oximeters, as opposed to pulse oximeters, to differentiate that they are capable of measuring other hemoglobin moieties. Currently, there are two such devices that are commercially available for clinical use.

Theoretically, the capacity to noninvasively measure Hgb concentration in real time would offer significant clinical benefit. These include obviating the need for serial blood draws, the early detection of potential postsurgical hemorrhage, and more judicious usage of blood transfusions. In practice, there are multiple factors that currently affect the accuracy of the technique. Multiple studies have demonstrated that biases with noninvasive Hgb monitoring are inversely correlated with hemoglobin concentration in a variety of monitoring scenarios; with decreasing hemoglobin values the noninvasive approaches tend to overestimate the true Hgb.62-64 This poses a significant challenge for monitoring the critically ill patient, as frequently anemia is a common comorbid condition. On the other hand, if the continuous monitoring capacity afforded by these monitors can provide usable trend data, that may still provide clinical utility despite less accuracy at low hemoglobin levels. To date, there have been relatively few studies validating the trending capacity of noninvasive Hgb monitoring compared to serial blood draws, with limited agreement due to differences in analysis and study design.65 Further studies are required to evaluate the clinical utility of this potentially useful technology.

**Capnometry**

Capnometry is the measurement of carbon dioxide in the airway throughout the respiratory cycle. Capnometry is most commonly measured by infrared light absorption. CO₂ absorbs infrared light at a peak wavelength of approximately 4.27 µm. Capnometry works by passing infrared light through a sample chamber to a detector on the opposite side. More infrared light passing through the sample chamber (i.e., less CO₂) causes a larger signal in the detector relative to the infrared light passing through a reference cell. Capnometric determination of the partial pressure of CO₂ in end-tidal exhaled gas (PetCO₂) is used as a surrogate reference cell. Capnometric determination of the partial pressure of CO₂ in end-tidal exhaled gas (PetCO₂) is used as a surrogate reference cell. Capnometry is most commonly measured by infrared light absorption. CO₂ absorbs infrared light at a peak wavelength of approximately 4.27 µm. Capnometry works by passing infrared light through a sample chamber to a detector on the opposite side. More infrared light passing through the sample chamber (i.e., less CO₂) causes a larger signal in the detector relative to the infrared light passing through a reference cell. Capnometric determination of the partial pressure of CO₂ in end-tidal exhaled gas (PetCO₂) is used as a surrogate reference cell. Capnometry is most commonly measured by infrared light absorption. CO₂ absorbs infrared light at a peak wavelength of approximately 4.27 µm. Capnometry works by passing infrared light through a sample chamber to a detector on the opposite side. More infrared light passing through the sample chamber (i.e., less CO₂) causes a larger signal in the detector relative to the infrared light passing through a reference cell. Capnometric determination of the partial pressure of CO₂ in end-tidal exhaled gas (PetCO₂) is used as a surrogate reference cell.

**Urine Output**

Bladder catheterization with an indwelling catheter allows the monitoring of urine output, usually recorded hourly by the nursing staff. With a patent Foley catheter, urine output is a gross indicator of renal perfusion. The generally accepted normal urine output is 0.5 mL/kg per hour for adults and 1 to 2 mL/kg per hour for neonates and infants. Oliguria may reflect inadequate renal artery perfusion due to hypotension, hypovolemia, or low Qs. Low urine flow also can be a sign of intrinsic renal dysfunction. It is important to recognize that normal urine output does not exclude the possibility of impending renal failure.

**Bladder Pressure**

The triad of oliguria, elevated peak airway pressures, and elevated intra-abdominal pressure is known as abdominal compartment syndrome (ACS). This syndrome, first described in patients after repair of ruptured abdominal aortic aneurysm, is associated with interstitial edema of the abdominal organs, resulting in elevated intra-abdominal pressure (IAP). When IAP exceeds venous or capillary pressures, perfusion of the kidneys and other intra-abdominal viscera is impaired. Oliguria is a cardinal sign. While the diagnosis of ACS is a clinical one, measuring IAP is useful to confirm the diagnosis. Ideally, a catheter inserted into the peritoneal cavity could measure IAP to substantiate the diagnosis. In practice, transurethral bladder pressure measurement reflects IAP and is most often used to confirm the presence of ACS. After instilling 50 to 100 mL of sterile saline into the bladder via a Foley catheter, the tubing is connected to a transducing system to measure bladder pressure in the supine position at end-expiration.

Intra-abdominal hypertension is defined as an IAP ≥12 mmHg recorded on three standard measurements conducted 4 to 6 hours apart and is separated into several grades. The diagnosis of ACS is the presence of an IAP ≥20 mmHg recorded by three measurements 1 to 6 hours apart, along with new onset of organ dysfunction (Table 13-5).67-69 Less commonly, gastric or inferior vena cava pressures can be monitored with appropriate catheters to detect elevated intra-abdominal pressures.

**Intracranial Pressure**

Because the brain is rigidly confined within the bony skull, cerebro spinal fluid or mass lesions increase intracranial pressure (ICP). Monitoring of ICP is currently recommended in patients with severe traumatic brain injury (TBI), defined as a Glasgow Coma Scale (GCS) score less than or equal to 8 with an abnormal computed tomography (CT) scan, and in patients with severe TBI and a normal CT scan if two or more of the following are present: age >40 years, unilateral or bilateral motor posturing,
or systolic blood pressure <90 mmHg. ICP monitoring also is indicated in patients with acute subarachnoid hemorrhage with coma or neurologic deterioration, intracranial hemorrhage with intraventricular blood, ischemic middle cerebral artery stroke, fulminant hepatic failure with coma and cerebral edema on CT scan, and global cerebral ischemia or anoxia with cerebral edema on CT scan. The goal of ICP monitoring is to ensure that cerebral perfusion pressure (CPP) is adequate to support perfusion of the brain. CPP is equal to the difference between MAP and ICP: CPP = MAP – ICP.

One type of ICP measuring device, the ventriculostomy catheter, consists of a fluid-filled catheter inserted into a cerebral ventricle and connected to an external pressure transducer. This device permits measurement of ICP but also allows drainage of cerebrospinal fluid (CSF) as a means to lower ICP and sample CSF for laboratory studies. Other devices locate the pressure transducer within the central nervous system and are used only to monitor ICP. These devices can be placed in the intraventricular, parenchymal, subdural, or epidural spaces. Ventriculostomy catheters are the accepted standard for monitoring ICP in patients with TBI due to their accuracy, ability to drain CSF, and low complication rate. The associated complications include infection (5%), hemorrhage (1.1%), catheter malfunction or obstruction (6.3–10.5%), and malposition with injury to cerebral tissue.

The purpose of ICP monitoring is to detect and treat abnormal elevations of ICP that may be detrimental to cerebral perfusion and function. In TBI patients, ICP greater than 20 mmHg is associated with unfavorable outcomes. However, few studies have shown that treatment of elevated ICP improves clinical outcomes in human trauma patients. In a randomized, controlled, double-blind trial, Eisenberg and colleagues demonstrated that maintaining ICP less than 25 mmHg in patients without craniectomy and less than 15 mmHg in patients with craniectomy is associated with improved outcome. In patients with low CPP, therapeutic strategies to correct CPP can be directed at increasing MAP or decreasing ICP. While it has been recommended that CPP be maintained between 50 and 70 mmHg, the evidence to support this recommendation are not overly compelling. Furthermore, a retrospective cohort study of patients with severe TBI found that ICP/CPP-targeted neurointensive care was associated with prolonged mechanical ventilation and increased therapeutic interventions, without evidence for improved outcome in patients who survive beyond 24 hours.

### Electroencephalogram and Evoked Potentials

Electroencephalography offers the capacity to monitor global neurologic electrical activity, while evoked potential monitoring can assess pathways not detected by the conventional EEG. Continuous EEG (CEEG) monitoring in the intensive care unit permits ongoing evaluation of cerebral cortical activity. It is especially useful in obtunded and comatose patients. CEEG also is useful for monitoring of therapy for status epilepticus and detecting early changes associated with cerebral ischemia. CEEG can be used to adjust the level of sedation, especially if high-dose barbiturate therapy is being used to manage elevated ICP. Somatosensory and brain stem evoked potentials are less affected by the administration of sedatives than is the EEG. Evoked potentials are useful for localizing brain stem lesions or proving the absence of such structural lesions in cases of metabolic or toxic coma. They also can provide prognostic data in posttraumatic coma.

An advance in EEG monitoring is the use of the bispectral index (BIS) to titrate the level of sedative medications. While sedative drugs are usually titrated to the clinical neurologic examination, the BIS device has been used in the operating room to continuously monitor the depth of anesthesia. The BIS is an empiric measurement statistically derived from a database of over 5000 EEGs. The BIS is derived from bifrontal EEG recordings and analyzed for burst suppression ratio, relative alpha to beta ratio, and bicoherence. Using a multivariate regression model, a linear numeric index (BIS) is calculated, ranging from 0 (isoelectric EEG) to 100 (fully awake). Its use has been associated with lower consumption of anesthetics during surgery and earlier awakening and faster recovery from anesthesia. The BIS also has been validated as a useful approach for monitoring the level of sedation for ICU patients, using the revised Sedation-Agitation Scale as a gold standard.

### Transcranial Doppler Ultrasonography

This modality provides a noninvasive method for evaluating cerebral hemodynamics. Transcranial Doppler (TCD) measurements of middle and anterior cerebral artery blood flow velocity are useful for the diagnosis of cerebral vasospasm after subarachnoid hemorrhage. Qureshi and associates demonstrated that an increase in the middle cerebral artery mean flow velocity as assessed by TCD is an independent predictor of symptomatic vasospasm in a prospective study of patients with aneurysmal subarachnoid hemorrhage. In addition, while some have proposed using TCD to estimate ICP, studies have shown that TCD is not a reliable method for estimating ICP and CPP and currently cannot be endorsed for this purpose. TCD also is useful to confirm the clinical examination for determining brain death in patients with confounding factors such as the presence of CNS depressants or metabolic encephalopathy.

### Jugular Venous Oximetry

When the arterial oxygen content, hemoglobin concentration, and the oxyhemoglobin dissociation curve are constant, changes in jugular venous oxygen saturation (S_jo2) reflect changes in the difference between cerebral oxygen delivery and demand.
Generally, a decrease in Sj o2 reflects cerebral hypoperfusion, whereas an increase in Sj o2 indicates the presence of hyperemia. Sj o2 monitoring cannot detect decreases in regional cerebral blood flow if overall perfusion is normal or above normal. This technique requires the placement of a catheter in the jugular bulb, usually via the internal jugular vein. Catheters that permit intermittent aspiration of jugular venous blood for analysis or continuous oximetry catheters are available.

Low Sj o2 is associated with poor outcomes after TBI. Nevertheless, the value of monitoring Sj o2 remains unproven. If it is employed, it should not be the sole monitoring technique, but rather should be used in conjunction with ICP and CPP monitoring. By monitoring ICP, CPP, and Sj o2, early intervention with volume, vasopressors, and hyperventilation has been shown to prevent ischemic events in patients with TBI.

**Transcranial Near-Infrared Spectroscopy**

Transcranial near-infrared spectroscopy (NIRS) is a noninvasive continuous monitoring method to determine cerebral oxygenation. It employs technology similar to that of pulse oximetry to determine the concentrations of oxy- and deoxyhemoglobin with near-infrared light and sensors and takes advantage of the relative transparency of the skull to light in the near-infrared region of the spectrum. Continuous monitoring of cerebral perfusion via transcranial NIRS may provide a method to detect early cerebral ischemia in patients with traumatic brain injury. Nevertheless, this form of monitoring remains largely a research tool at the present time.

Recently, some authors have reported its use as a potential triage tool for prehospital care in the management of TBI, as NIRS allows for rapid screening for intracranial hematoma. Two small EMS studies demonstrated that handheld NIRS devices may be feasible adjunct tools in this setting, particularly when CT scanners may not be readily available.

**Brain Tissue Oxygen Tension**

While the standard of care for patients with severe TBI includes ICP and CPP monitoring, this strategy does not always prevent secondary brain injury. Growing evidence suggests that monitoring local brain tissue oxygen tension (PbtO2) may be a useful adjunct to ICP monitoring in these patients. Normal values for PbtO2 are 20 to 40 mmHg, and critical levels are 8 to 10 mmHg. A recent clinical study sought to determine whether the addition of a PbtO2 monitor to guide therapy in severe traumatic brain injury was associated with improved patient outcomes. Twenty-eight patients with severe traumatic brain injury (GCS score ≤8) were enrolled in an observational study at a level I trauma center. These patients received invasive ICP and PbtO2 monitoring and were compared with 25 historical controls matched for age, injuries, and admission GCS score that had undergone ICP monitoring alone. Goals of therapy in both groups included maintaining an ICP <20 mmHg and a CPP >60 mmHg. Among patients with PbtO2 monitoring, therapy also was directed at maintaining PbtO2 >25 mmHg. The groups had similar mean daily ICP and CPP levels. The mortality rate in the historical controls treated with standard ICP and CPP management was 44%. Mortality was significantly lower in the patients who had therapy guided by PbtO2 monitoring in addition to ICP and CPP (25%; P < .05). The benefits of PbtO2 monitoring may include the early detection of brain tissue ischemia despite normal ICP and CPP. In addition, PbtO2-guided management may reduce potential adverse effects associated with therapies to maintain ICP and CPP.

**Conclusions**

Modern intensive care is predicated by the need and ability to continuously monitor a wide range of physiologic parameters. This capability has dramatically improved the care of critically ill patients and advanced the development of the specialty of critical care medicine. In some cases, the technological ability to measure such variables has surpassed our understanding of the significance or the knowledge of the appropriate intervention to ameliorate such pathophysiologic changes. In addition, the development of less invasive monitoring methods has been promoted by the recognition of complications associated with invasive monitoring devices. The future portends the continued development of noninvasive monitoring devices along with their application in an evidenced-based strategy to guide rational therapy.

# INTRODUCTION

Minimally invasive surgery describes an area of surgery that crosses all traditional disciplines, from general surgery to neurosurgery. It is not a discipline unto itself, but more a philosophy of surgery, a way of thinking. Minimally invasive surgery is a means of performing major operations through small incisions, often using miniaturized, high-tech imaging systems, to minimize the trauma of surgical exposure. Some believe that the term minimal access surgery more accurately describes the small incisions generally necessary to gain access to surgical sites in high-tech surgery, but John Wickham’s term minimally invasive surgery (MIS) is widely used because it describes the paradox of postmodern high-tech surgery—small holes, big operations.

Robotic surgery today is practiced using a single platform (Intuitive, Inc, Sunnyvale, CA) and should better be termed computer-enhanced surgery because the term robotics assumes autonomous action that is not a feature of the da Vinci robotic system. Instead, the da Vinci robot couples an ergonomic workstation that features stereoscopic video imaging and intuitive micromanipulators (surgeon side) with a set of arms delivering specialized laparoscopic instruments enhanced with more degrees of freedom than are allowed by laparoscopic surgery alone (patient side). A computer between the surgeon side and patient side removes surgical tremor and scales motion to allow precise microsurgery, which is helpful for microdissection and difficult anastomoses.

Single-incision laparoscopic surgery (SILS), also called laparoendoscopic single-site surgery (LESS), is a recent addition to the armamentarium of the minimally invasive surgeon. As public awareness has grown, so too has its spread outside of larger institutions. SILS challenges the well-established paradigm of standard laparoscopic surgery by placing multiple trocars within the fascia at the umbilicus or through a single multichannel trocar at the umbilicus. The manipulation of tightly spaced instruments across the fulcrum of the abdominal wall requires that the surgeon either operate in a crossed hands fashion or use specialized curved instruments to avoid clashing outside the body while working intra-abdominally. The primary advantage of SILS is the reduction to one surgical scar. Greater efficacy, safety, and cost savings have yet to be fully elucidated in the increasing number of procedures that are being attempted in this manner. The advent of a robotic SILS platform now enables the computer reassignment of the surgeon’s hands, thus eliminating the difficult ergonomic challenges making the technique far more accessible.

Natural orifice transluminal endoscopic surgery (NOTES) is an extension of interventional endoscopy. Using the mouth, anus, vagina, and urethra (natural orifices), flexible endoscopes are passed through the wall of the esophagus, stomach, colon,
bladder, or vagina entering the mediastinum, the pleural space, or the peritoneal cavity. The advantage of this method of minimal access is principally the elimination of the scar associated with laparoscopy or thoracoscopy. Other advantages have yet to be elucidated, including pain reduction, need for hospitalization, and cost savings.

HISTORICAL BACKGROUND

Although the term minimally invasive surgery is relatively recent, the history of its component parts is nearly 100 years old. What is considered the newest and most popular variety of MIS, laparoscopy, is in fact the oldest. Primitive laparoscopy, placing a cystoscope within an inflated abdomen, was first performed by Kelling in 1901. Illumination of the abdomen required hot elements at the tip of the scope and was dangerous. In the late 1950s, Hopkins described the rod lens, a method of transmitting light through a solid quartz rod with no heat and little light loss. Around the same time, thin quartz fibers were discovered to be capable of trapping light internally and conducting it around corners, opening the field of fiber optics and allowing the rapid development of flexible endoscopes. In the 1970s, the application of flexible endoscopy grew faster than that of rigid endoscopy except in a few fields such as gynecology and orthopedics. By the mid-1970s, rigid and flexible endoscopes made a rapid transition from diagnostic instruments to therapeutic ones. The explosion of video-assisted surgery in the past 20 years was a result of the development of compact, high-resolution, charge-coupled devices (CCDs) that could be mounted on the internal end of flexible endoscopes or on the external end of a Hopkins telescope. Coupled with bright light sources, fiber-optic cables, and high-definition video monitors, the videolaparoscope has changed our understanding of surgical anatomy and reshaped surgical practice.

Flexible endoscopic imaging started in the 1960s with the first bundling of many quartz fibers into bundles, one for illumination and one for imaging. The earliest upper endoscopes revolutionized the diagnosis and treatment of gastroesophageal reflux and peptic ulcer disease and made possible early detection of upper and lower gastrointestinal (GI) cancer at a stage that could be cured. The first endoscopic surgical procedure was the colonoscopic polypectomy, developed by Shinya and Wolfe, two surgeons from New York City. The percutaneous endoscopic gastrostomy (PEG) invented by Gauderer and Ponsky may have been the first NOTES procedure, reported in 1981. Endoscopic pancreatic pseudocyst drainage is thought to be the next NOTES procedure developed; however, there was little energy and money put into the development of NOTES until a number of gastroenterologists claimed the ability to remove the gallbladder with a flexible endoscope, using a transgastric technique. With this pronouncement, the surgical community took notice and seized the momentum for NOTES research and development. Today most intra-abdominal NOTES procedures remain within the realm of research or incorporate a hybrid laparoscopic technique outside of highly specialized centers. Clinically the transvaginal approach has been studied the most extensively. Evaluation of 551 female patients from the German NOTES registry has shown conversion and complication rates similar to conventional laparoscopic surgery for cholecystectomy and appendectomy procedures. Endoscopic mucosal resection (EMR) of early-stage esophageal and gastric lesions has revolutionized the management of these malignancies. The peroral endoscopic myotomy (POEM) procedure for achalasia is showing clinical efficacy and gaining popularity.

As the race to minimize the size and increase the functionality of laparoscopic instruments progressed, the notion of using fewer access points to accomplish the same operations resulted in the development of single-incision laparoscopic surgery (SILS), synonymously termed laparoendoscopic single-site surgery (LESS). Viewed as a progression of laparoscopic surgery, SILS has recently garnered greater enthusiasm over its transvical NOTES counterpart. Currently the single-incision technique is used regularly across a wide variety of surgical areas including general, urologic, gynecologic, colorectal, and bariatric surgery. Although optical imaging produced the majority of MIS procedures, other (traditionally radiologic) imaging technologies allowed the development of innovative procedures in the 1970s. Fluoroscopic imaging allowed the adoption of percutaneous vascular procedures, the most revolutionary of which was balloon angioplasty. Balloon-based procedures spread into all fields of medicine used to open clogged lumens with minimal access. Stents were then developed that were used in many disciplines to keep the newly ballooned segment open. The culmination of fluoroscopic balloon and stent proficiency is exemplified by the transvenous intrahepatic portosystemic shunt and by the aortic stent graft, which has nearly replaced open elective abdominal aortic aneurysm repair.

MIS procedures using ultrasound imaging have been limited to fairly crude exercises, such as fragmenting kidney stones and freezing liver tumors, because of the relatively low...
resolution of ultrasound devices. Newer, high-resolution ultrasound methods with high-frequency crystals may act as a guide while performing minimally invasive resections of individual layers of the intestinal wall.

Axial imaging, such as computed tomography (CT), has allowed the development of an area of MIS that often is not recognized because it requires only a CT scanner and a long needle. CT-guided drainage of abdominal fluid collections and percutaneous biopsy of abnormal tissues are minimally invasive means of performing procedures that previously required a celiotomy. CT-guided percutaneous radiofrequency (RF) ablation has emerged as a useful treatment for primary and metastatic liver tumors. This procedure also is performed laparoscopically under ultrasound guidance.9

A powerful, noninvasive method of imaging that will allow the development of the least invasive—and potentially noninvasive—surgery is magnetic resonance imaging (MRI). MRI is an extremely valuable diagnostic tool, but it is only slowly coming to be of therapeutic value. One obstacle to the use of MRI for MIS is that image production and refreshment of the image as a procedure progresses are slow. Another is that all instrumentation must be nonmetallic when working with the powerful magnets of an MRI scanner. Moreover, MRI magnets are bulky and limit the surgeon’s access to the patient. Open magnets have been developed that allow the surgeon to stand between two large MRI coils, obtaining access to the portion of the patient being scanned. The advantage of MRI, in addition to the superb images produced, is that there is no radiation exposure to patient or surgeon. Some neurosurgeons are accumulating experience using MRI to perform frameless stereotactic surgery.

Robotic surgery has been dreamed about for some time, and many science fiction–like devices have been developed over the years to provide mechanical assistance for the surgeon. The first computer-assisted robot was designed to accurately drill femoral shaft bone for wobble-free placement of hip prostheses. Although the concept was appealing, the robot proved no better than a skilled orthopedic surgeon and was a good deal slower. Following this, the first and only two commercially successful robots for laparoscopic surgery were developed in California. Computer Motion, founded by Yulun Wang in Santa Barbara, used National Science Foundation funds to create a mechanical arm, the Aesop robot, which held and moved the laparoscope with voice, foot, or hand control. In Northern California, a master-slave system first developed for surgery on the multinational space station by Philip Green was purchased by Fred Moll and Lonnie Smith, and then reengineered with the surgeon in mind to create a remarkably intuitive computer-enhanced surgical platform. The company, Intuitive Surgical, was aptly named, and their primary product, the da Vinci robot, is currently the only major robotic platform on the market, although competitors are rapidly emerging in the horizon. Although eschewed by many experienced laparoscopists, the da Vinci achieved a toehold among many skilled surgeons who found that the robot could facilitate MIS procedures that were difficult with standard laparoscopic procedures. The latest iteration of the da Vinci Xi platform released in 2014 features high-definition, three-dimensional vision and a dual-console capability allowing greater visualization, assistance, and instruction capabilities. Additionally, the new overhead boom design facilitates anatomical access from virtually any position enabling complex multiquadrant surgeries.

### PHYSIOLOGY AND PATHOPHYSIOLOGY OF MINIMALLY INVASIVE SURGERY

Even with the least invasive of the MIS procedures, physiologic changes occur. Many minimally invasive procedures require minimal or no sedation, and there are few adverse consequences to the cardiovascular, endocrinologic, or immunologic systems. The least invasive of such procedures include stereotactic biopsy of breast lesions and flexible GI endoscopy. Minimally invasive procedures that require general anesthesia have a greater physiologic impact because of the anesthetic agent, the incision (even if small), and the induced pneumoperitoneum.

#### Laparoscopy

The unique feature of laparoscopic surgery is the need to lift the abdominal wall from the abdominal organs. Two methods have been devised for achieving this.10 The first, used by most surgeons, is a pneumoperitoneum. Throughout the early 20th century, intraperitoneal visualization was achieved by inflating the abdominal cavity with air, using a sphygmomanometer bulb.11 The problem with using air insufflation is that nitrogen is poorly soluble in blood and is slowly absorbed across the peritoneal surfaces. Air pneumoperitoneum was believed to be more painful than nitrous oxide (N2O) pneumoperitoneum, but less painful than carbon dioxide (CO2) pneumoperitoneum. Subsequently, CO2 and N2O were used for inflating the abdomen. N2O had the advantage of being physiologically inert and rapidly absorbed. It also provided better analgesia for laparoscopy performed under local anesthesia when compared with CO2 or air.12 Despite initial concerns that N2O would not suppress combustion, controlled clinical trials have established its safety within the peritoneal cavity.13 In addition, N2O has been shown to reduce the intraoperative end-tidal CO2 and minute ventilation required to maintain homeostasis when compared to CO2 pneumoperitoneum.13 The effect of N2O on tumor biology and the development of port site metastasis are unknown. As such, caution should be exercised when performing laparoscopic cancer surgery with this agent. Finally, the safety of N2O pneumoperitoneum in pregnancy has yet to be elucidated.

The physiologic effects of CO2 pneumoperitoneum can be divided into two areas: (a) gas-specific effects and (b) pressure-specific effects (Fig. 14-1). CO2 is rapidly absorbed across the peritoneal membrane into the circulation. In the circulation,
CO₂ creates a respiratory acidosi by the generation of carbonic acid.¹⁴ Body buffers, the largest reserve of which lies in bone, absorb CO₂ (up to 120 L) and minimize the development of hypercapnia or respiratory acidosis during brief endoscopic procedures.¹⁴ Once the body buffers are saturated, respiratory acidosis develops rapidly, and the respiratory system assumes the burden of keeping up with the absorption of CO₂ and its release from these buffers.

In patients with normal respiratory function, this is not difficult; the anesthesiologist increases the ventilatory rate or vital capacity on the ventilator. If the respiratory rate required exceeds 20 breaths per minute, there may be less efficient gas exchange and increasing hypercapnia.¹⁵ Conversely, if vital capacity is increased substantially, there is a greater opportunity for barotrauma and greater respiratory motion—induced disruption of the upper abdominal operative field. In some situations, it is advisable to evacuate the pneumoperitoneum or reduce the intra-abdominal pressure to allow time for the anesthesiologist to adjust for hypercapnia.¹⁶ Although mild respiratory acidosis probably is an insignificant problem, more severe respiratory acidosis leading to cardiac arrhythmias has been reported.¹⁷ Hypercapnia also causes tachycardia and increased systemic vascular resistance, which elevates blood pressure and increases myocardial oxygen demand.¹⁴,¹⁷

The pressure effects of the pneumoperitoneum on cardiovascular physiology also have been studied. In the hypovolemic individual, excessive pressure on the inferior vena cava and a reverse Trendelenburg position with loss of lower extremity muscle tone may cause decreased venous return and decreased cardiac output.¹⁴,¹⁸ This is not seen in the normovolemic patient. The most common arrhythmia created by laparoscopy is bradycardia. A rapid stretch of the peritoneal membrane often causes a vagovagal response with bradycardia and, occasionally, hypotension.¹⁹ The appropriate management of this event is desufflation of the abdomen, administration of vagolytic agents (e.g., atropine), and adequate volume replacement.²⁰

With the increased intra-abdominal pressure compressing the inferior vena cava, there is diminished venous return from the lower extremities. This has been well documented in the patient placed in the reverse Trendelenburg position for upper abdominal operations. Venous engorgement and decreased venous return promote venous thrombosis.²¹,²² Many series of advanced laparoscopic procedures in which deep venous thrombosis (DVT) prophylaxis was not used demonstrated the frequency of pulmonary embolus. This usually is an avoidable complication with the use of sequential compression stockings, subcutaneous heparin, or low molecular weight heparin.²³,²⁴ In short-duration laparoscopic procedures, such as appendectomy, hernia repair, or cholecystectomy, the risk of DVT may not be sufficient to warrant extensive DVT prophylaxis.

The increased pressure of the pneumoperitoneum is transmitted directly across the paralyzed diaphragm to the thoracic cavity, creating increased central venous pressure and increased filling pressures of the right and left sides of the heart. If the intra-abdominal pressures are kept under 20 mmHg, the cardiac output usually is well maintained.²²,²³ The direct effect of the pneumoperitoneum on increasing intrathoracic pressure increases peak inspiratory pressure, pressure across the chest wall, and also, the likelihood of barotrauma. Despite these concerns, disruption of blebs and consequent pneumothoraces are rare after uncomplicated laparoscopic surgery.²⁴ Pneumothoraces occurring with laparoscopic esophageal surgery may be very significant. The pathophysiology and management are discussed at the end of this section. Increased intra-abdominal pressure decreases renal blood flow, glomerular filtration rate, and urine output. These effects may be mediated by direct pressure on the kidney and the renal vein.²⁵,²⁶ The secondary effect of decreased renal blood flow is to increase plasma renin release, thereby increasing sodium retention. Increased circulating antidiuretic hormone levels also are found during the pneumoperitoneum, increasing free water reabsorption in the distal tubules.²⁷ Although the effects of the pneumoperitoneum on renal blood flow are immediately reversible, the hormonally mediated changes such as elevated antidiuretic hormone levels decrease urine output for up to 1 hour after the procedure has ended. Intraoperative oliguria is common during laparoscopy, but the urine output is not a reflection of intravascular volume status; intravenous (IV) fluid administration during an uncomplicated laparoscopic procedure should not be linked to urine output. Because insensible fluid losses through the open abdomen are eliminated with laparoscopy, the need for supplemental fluid during a laparoscopic surgical procedure should only keep up with venous pooling in the lower limbs, third-space losses into the bowel, and blood loss, which is generally less than occurs with an equivalent open operation.

The hemodynamic and metabolic consequences of pneumoperitoneum are well tolerated by healthy individuals for a prolonged period and by most individuals for at least a short period. Difficulties can occur when a patient with compromised cardiovascular function is subjected to a long laparoscopic procedure. It is during these procedures that alternative approaches should be considered or insufflation pressure reduced. Alternative gases that have been suggested for laparoscopy include the inert gases helium, neon, and argon. These gases are appealing because they cause no metabolic effects, but are poorly soluble in blood (unlike CO₂ and N₂O) and are prone to create gas emboli if the gas has direct access to the venous system.²² Gas emboli are rare but serious complications of laparoscopic surgery.²³,²⁴ They should be suspected if hypotension develops during insufflation. Diagnosis may be made by listening (with an esophageal stethoscope) for the characteristic “mill wheel” murmur. The treatment of gas embolism is to place the patient in a left lateral decubitus position with the head down to trap the gas in the apex of the right ventricle.²⁵ A rapidly placed central venous catheter then can be used to aspirate the gas out of the right ventricle.

In some situations, minimally invasive abdominal surgery can be performed without insufflation. This is possible with the assistance of an abdominal lift device that can be placed through a 10- to 12-mm trocar at the umbilicus.²⁷ These devices have the advantage of creating little physiologic derangement, but they are bulky and intrusive. The exposure and working room offered by lift devices also are inferior to those accomplished by pneumoperitoneum. Lifting the anterior abdominal wall reduces space available laterally and thereby displaces the bowel medially and anteriorly into the operative field. A pneumoperitoneum, with its well-distributed intra-abdominal pressure, provides better exposure. Abdominal lift devices also cause more postoperative pain, but they do allow the performance of MIS with standard (nonlaparoscopic) surgical instruments.

Endocrine responses to laparoscopic surgery are not always intuitive. Serum cortisol levels after laparoscopic operations are often higher than after the equivalent operation performed through an open incision.³⁰ The greatest difference
between the endocrine response of open and laparoscopic surgery is the more rapid equilibration of most stress-mediated hormone levels after laparoscopic surgery. Immune suppression also is less after laparoscopy than after open surgery. There is a trend toward more rapid normalization of cytokine levels after a laparoscopic procedure than after the equivalent procedure performed by celiotomy.31

Transhiatal mobilization of the distal esophagus is commonly performed as a component of many laparoscopic upper abdominal procedures. If there is compromise of the mediastinal pleura with resultant CO₂ pneumothorax, the defect should be enlarged so as to prevent a tension pneumothorax. Even with such a strategy, tension pneumothorax may develop, as mediastinal structures may seal the hole during inspiration, allowing the chest to fill during expiration. In addition to enlargement of the hole, a thoracostomy tube (chest tube) should be placed across the breach into the abdomen with intra-abdominal pressures reduced below 8 mmHg, or a standard chest tube may be placed. When a pneumothorax occurs with laparoscopic Nissen fundoplication or Heller myotomy, it is preferable to place an 18-French red rubber catheter with multiple side holes cut out of the distal end across the defect. At the end of the procedure, the distal end of the tube is pulled out a 10-mm port site (as the port is removed), and the pneumothorax is evacuated to a primitive water seal using a bowl of sterile water or saline. During laparoscopic esophagectomy, it is preferable to leave a standard chest tube, as residual intra-abdominal fluid will tend to be siphoned through the defect postoperatively if the tube is removed at the end of the case.

Thoracoscopy

The physiology of thoracic MIS (thoracoscopy) is different from that of laparoscopy. Because of the bony confines of the thorax, it is unnecessary to use positive pressure when working in the thorax.32 The disadvantages of positive pressure in the chest include decreased venous return, mediastinal shift, and the need to keep a firm seal at all trocar sites. Without positive pressure, it is necessary to place a double-lumen endotracheal tube so that the ipsilateral lung can be deflated when the operation starts. By collapsing the ipsilateral lung, working space within the thorax is obtained. Because insufflation is unnecessary in thoracoscopic surgery, it can be beneficial to use standard instruments via extended port sites in conjunction with thoracoscopic instruments. This approach is particularly useful when performing advanced procedures such as thoracoscopic anatomic pulmonary resection.

Extracavitary Minimally Invasive Surgery

Many MIS procedures create working spaces in extrathoracic and extraperitoneal locations. Laparoscopic inguinal hernia repair usually is performed in the anterior extraperitoneal Retzius space.33,34 Laparoscopic nephrectomy often is performed with retroperitoneal laparoscopy. Endoscopic retroperitoneal approaches to pancreatic necrosectomy have seen some limited use.35 Lower extremity vascular procedures and plastic surgical endoscopic procedures require the development of working space in unconventional planes, often at the level of the fascia, sometimes below the fascia, and occasionally in nonanatomic regions.36 Some of these techniques use insufflation of gas, but many use balloon inflation to develop the space, followed by low-pressure gas insufflation or lift devices to maintain the space (Fig. 14-2). These techniques produce fewer and less severe adverse physiologic consequences than does the pneumoperitoneum, but the insufflation of carbon dioxide into extraperitoneal locations can spread widely, causing subcutaneous emphysema and metabolic acidosis.

Anesthesia

Proper anesthesia management during laparoscopic surgery requires a thorough knowledge of the pathophysiology of the CO₂ pneumoperitoneum.20 The laparoscopic surgeon can influence cardiovascular performance by reducing or removing the CO₂ pneumoperitoneum. Insensible fluid losses are negligible, and therefore, IV fluid administration should not exceed that necessary to maintain circulating volume. MIS procedures are often outpatient procedures, so short-acting anesthetic agents are preferable. Because the factors that require hospitalization after laparoscopic procedures include the management of nausea, pain, and urinary retention, the anesthesiologist should minimize the use of agents that provoke these conditions and maximize the use of medications that prevent such problems. Critical to the anesthesia management of these patients is the use of nonnarcotic analgesics (e.g., ketorolac) when hemostasis allows it and the liberal use of antiemetic agents, including ondansetron and steroids.

The Minimally Invasive Team

From the beginning, the tremendous success of MIS was founded on the understanding that a team approach was
necessary. The many laparoscopic procedures performed daily range from basic to advanced complexity, and require that the surgical team have an intimate understanding of the operative conduct (Table 14-1). Minimally invasive procedures require complicated and fragile equipment that demands constant maintenance. In addition, multiple intraoperative adjustments to the equipment, camera, insufflator, monitors, and patient/surgeon position are made during these procedures. As such, a coordinated team approach is mandated to ensure patient safety and excellent outcomes. More and more, flexible endoscopes are used to guide or provide quality control for laparoscopic procedures. As NOTES, SILS, and robotic surgery become more common, hybrid procedures (laparoscopy and endoscopy) and complicated robotics cases will require a nursing staff capable of maintaining flexible endoscopes and understanding the operation of sophisticated technology.

A typical MIS team may consist of a laparoscopic surgeon and an operating room (OR) nurse with an interest in laparoscopic and endoscopic surgery. Adding dedicated assistants and circulating staff with an intimate knowledge of the equipment will add to and enhance team competency. Studies have demonstrated that having a designated laparoscopic team increases the efficiency and safety of laparoscopic surgery, which is translated into a benefit for the patient and the hospital.

**Room Setup and the Minimally Invasive Suite**

Nearly all MIS, whether using fluoroscopic, ultrasound, or optical imaging, incorporates a video monitor as a guide. Occasionally, two images are necessary to adequately guide the operation, as in procedures such as endoscopic retrograde cholangiopancreatography, laparoscopic common bile duct exploration, and laparoscopic ultrasonography. When two images are necessary, the images should be displayed on two adjacent video monitors or projected on a single screen with a picture-in-picture effect. The video monitor(s) should be set across the operating table from the surgeon. The patient should be interposed between the surgeon and the video monitor; ideally, the operative field also lies between the surgeon and the monitor. In pelviscopic surgery, it is best to place the video monitor at the patient’s feet, and in laparoscopic cholecystectomy, the monitor is placed at the 10 o’clock position (relative to the patient) while the surgeon stands on the patient’s left at the 4 o’clock position. The insufflating and patient-monitoring equipment ideally also is placed across the table from the surgeon so that the insufflating pressure and the patient’s vital signs and end-tidal CO₂ tension can be monitored.

The development of the minimally invasive surgical suite has been a tremendous contribution to the field of laparoscopy in that it has facilitated the performance of advanced procedures and techniques (Fig. 14-3). By having the core equipment (monitors, insufflators, and imaging equipment) located within mobile, ceiling-mounted consoles, the surgery team is able to accommodate and make small adjustments rapidly and continuously throughout the procedure. The specifically designed minimally invasive surgical suite serves to decrease equipment and cable disorganization, ease the movements of operative personnel around the room, improve ergonomics, and facilitate the use of advanced imaging equipment such as laparoscopic ultrasound. Although having a minimally invasive surgical suite available is very useful, it is not essential to successfully carry out advanced laparoscopic procedures.

**Patient Positioning**

Patients usually are placed in the supine position for laparoscopic surgery. When the operative field is the gastroesophageal junction or the left lobe of the liver, it is easiest to operate from between the legs. The legs may be elevated in Allen stirrups or abducted on leg boards to achieve this position. When pelvic procedures are performed, it usually is necessary to place the legs in Allen stirrups to gain access to the perineum. A lateral decubitus position with the table flexed provides the best access to the retroperitoneum when performing nephrectomy or adrenalectomy. For laparoscopic splenectomy, a 45° tilt of the patient provides excellent access to the lesser sac and the lateral peritoneal attachments to the spleen. For thoracoscopic surgery, the patient is placed in the lateral position with table flexion to open the intercostal spaces and the distance between the iliac crest and costal margin (Fig. 14-4). Additional consideration must be made in robotic operations to position the

**Figure 14-3.** An example of a typical minimally invasive surgery suite. All core equipment is located on easily movable consoles.
Figure 14-4. Proper padding and protection of pressure points is an essential consideration in laparoscopic and thoracoscopic approaches. In preparation for thoracoscopy, this patient is placed in left lateral decubitus position with the table flexed, which serves to open the intercostal spaces and increase the distance between the iliac crest and the inferior costal margin.

Patient appropriately before starting. Clashing of the robotic arms with surrounding equipment or each other can occur if not positioned correctly. This is more common in predecessors of the da Vinci Xi platform. Unless an operative table with integrated table motion is available, once the robot is docked to the patient the bed cannot be moved without undocking.

When the patient’s knees are to be bent for extended periods or the patient is going to be placed in a reverse Trendelenburg position for more than a few minutes, DVT prophylaxis should be used. Sequential compression devices should be placed on the lower extremities during laparoscopic procedures to increase venous return and provides inhibition of thromboplastin activation.

General Principles of Access
The most natural ports of access for MIS and NOTES are the anatomic portals of entry and exit. The nares, mouth, anus, vagina, and urethra are used to access the respiratory, GI, and urinary systems. The advantage of using these points of access is that no incision is required. The disadvantages lie in the long distances between the orifice and the region of interest. For NOTES procedures, the vagina may serve as point of access, entering the abdomen via the posterior cul-de-sac of the pelvis. Similarly, the peritoneal cavity may be reached through the side wall of the stomach or colon.

Access to the vascular system may be accomplished under local anesthesia by cutting down and exposing the desired vessel, usually in the groin. Increasingly, vascular access is obtained with percutaneous techniques using a small incision, a needle, and a guidewire, over which are passed a variety of different-sized access devices. This approach, known as the Seldinger technique, is most frequently used by general surgeons for placement of Hickman catheters, but it also is used to gain access to the arterial and venous system for performance of minimally invasive procedures. Guidewire-assisted, Seldinger-type techniques also are helpful for gaining access to the gut for procedures such as PEG, for gaining access to the biliary system through the liver, and for gaining access to the upper urinary tract.

In thoracoscopic surgery, the access technique is similar to that used for placement of a chest tube. In these procedures, general anesthesia and single lung ventilation are essential. A small incision is made over the top of a rib and, under direct vision, carried down through the pleura. The lung is collapsed, and a trocar is inserted across the chest wall to allow access with a telescope. Once the lung is completely collapsed, subsequent access may be obtained with direct puncture, viewing all entry sites through the videoendoscope. Because insufflation of the chest is unnecessary, simple ports that keep the small incisions open are all that is required to allow repeated access to the thorax.

Laparoscopic Access
The requirements for laparoscopy are more involved because the creation of a pneumoperitoneum requires that instruments of access (trocars) contain valves to maintain abdominal inflation.

Two methods are used for establishing abdominal access during laparoscopic procedures. The first, direct puncture laparoscopy, begins with the elevation of the relaxed abdominal wall with two towel clips or a well-placed hand. A small incision is made in the umbilicus, and a specialized spring-loaded (Veress) needle is placed in the abdominal cavity (Fig. 14-5).

Figure 14-5. A. Tip of spring loaded (Veress) needle. B. Veress needle held at its serrated collar with a thumb and forefinger. At the umbilicus, the abdominal wall is grasped with fingers or penetrating towel clip to elevate the abdominal wall away from the underlying structures.
With the Veress needle, two distinct pops are felt as the surgeon passes the needle through the abdominal wall fascia and the peritoneum. The umbilicus usually is selected as the preferred point of access because, in this location, the abdominal wall is quite thin, even in obese patients. The abdomen is inflated with a pressure-limited insufflator. CO₂ gas usually is used, with maximal pressures in the range of 14 to 15 mmHg. During the process of insufflation, it is essential that the surgeon observe the pressure and flow readings on the monitor to confirm an intraperitoneal location of the Veress needle tip (Fig. 14-6). Laparoscopic surgery can be performed under local anesthesia, but general anesthesia is preferable. Under local anesthesia, N₂O is used as the insufflating agent, and insufflation is stopped after 2 L of gas is insufflated or when a pressure of 10 mmHg is reached.

After peritoneal insufflation, direct access to the abdomen is obtained with a 5- or 10-mm trocar. This can be performed through a radially dilating sheath placed over the Veress needle or an optical viewing trocar. In the latter technique, a camera is placed inside of a clear pyramidal trocar. Direct puncture entry is observed as the trocar is passed through the abdominal wall. The critical issues for safe direct-puncture laparoscopy include the use of a vented stylet for the trocar, or a trocar with a safety shield or dilating tip. An optical viewing trocar can be used without prior insufflation; however, proper recognition of the abdominal wall layers is critical to avoid entry into the mesentery or underlying structures. In all direct puncture entry the trocar must be pointed away from the sacral promontory and the great vessels. Patient position should be surveyed before trocar placement to ensure a proper trajectory.

Occasionally, the direct peritoneal access (Hasson) technique is advisable. With this technique, the surgeon makes a small incision just below the umbilicus and under direct vision locates the abdominal fascia. Two Kocher clamps are placed on the fascia, and with curved Mayo scissors, a small incision is made through the fascia and underlying peritoneum. A finger is placed into the abdomen to make sure that there is no adherent bowel. A sturdy suture is placed on each side of the fascia and secured to the wings of a specialized trocar, which is then passed directly into the abdominal cavity (Fig. 14-7). Rapid insufflation can make up for some of the time lost with the initial dissection. This technique is preferable for the abdomen of patients who have undergone previous operations in which small bowel may be adherent to the undersurface of the abdominal wound. The close adherence of bowel to the peritoneum in the previously operated abdomen does not eliminate the possibility of intestinal injury but should make great vessel injury extremely unlikely. Because of the difficulties in visualizing the abdominal region immediately adjacent to the primary trocar, it is recommended that the telescope be passed through a secondary trocar to inspect the site of initial abdominal access. Secondary punctures are made with 5- and 10-mm trocars. For safe access to the abdominal cavity, it is critical to visualize all sites of trocar entry. At the completion of the operation, all trocars are removed under direct vision, and the insertion sites are inspected for bleeding. If bleeding occurs, direct pressure with an instrument from another trocar site or balloon tamponade with a Foley catheter placed through the trocar site generally stops the bleeding within 3 to 5 minutes. When this is not successful, a full-thickness abdominal wall suture has been used successfully to tamponade trocar site bleeding.

It is generally agreed that 5-mm trocars need no site suturing. Ten-millimeter trocars placed off the midline, through a radially dilating sheath or above the transverse mesocolon do not typically require repair. Conversely, if the fascia has been dilated to allow the passage of the gallbladder or other organ, it should be repaired at the fascial level with interrupted sutures. The port site may be closed with suture delivery systems similar to crochet needles enabling mass closure of the abdominal wall. This is especially helpful in obese patients where direct fascial closure may be challenging, through a small skin incision. Failure to close lower abdominal trocar sites that are 10 mm in diameter or larger can lead to an incarcerated hernia.

**Access for Subcutaneous and Extraperitoneal Surgery**

There are two methods for gaining access to nonanatomic spaces. For retroperitoneal locations, balloon dissection is effective. This access technique is appropriate for the extraperitoneal repair of inguinal hernias and for retroperitoneal surgery for adrenalectomy, nephrectomy, lumbar discectomy, pancreatic necrosectomy, or para-aortic lymph node dissection. The
initial access to the extraperitoneal space is performed in a way similar to direct puncture laparoscopy, except that the last layer (the peritoneum) is not traversed. Once the transversalis fascia has been punctured, a specialized trocar with a balloon on the end is introduced. The balloon is inflated in the extraperitoneal space to create a working chamber. The balloon then is deflated, and a Hasson trocar is placed. An insufflation pressure of 10 mmHg usually is adequate to keep the extraperitoneal space open for dissection and will limit subcutaneous emphysema. Higher gas pressures force CO₂ into the soft tissues and may contribute to hypercarbia. Extraperitoneal endosurgery provides less working space than laparoscopy but eliminates the possibility of intestinal injury, intestinal adhesion, herniation at the trocar sites, and ileus. These issues are important for laparoscopic hernia repair because extraperitoneal approaches prevent the small bowel from sticking to the prosthetic mesh.34

Subcutaneous surgery has been most widely used in cardiac, vascular, and plastic surgery.36 In cardiac surgery, subcutaneous access has been used for saphenous vein harvesting, and in vascular surgery for ligation of subfascial perforating veins (Linton procedure). With minimally invasive techniques, the entire saphenous vein above the knee may be harvested through a single incision (Fig. 14-8).45,46 Once the saphenous vein is located, a long retractor that holds a 5-mm laparoscope allows the coaxial dissection of the vein and coagulation or clipping of each side branch. A small incision above the knee also can be used to ligate perforating veins in the lower leg.

Subcutaneous access also is used for plastic surgery procedures.46 Minimally invasive approaches are especially well suited to cosmetic surgery, in which attempts are made to hide the incision. It is easier to hide several 5-mm incisions than one long incision. The technique of blunt dissection along fascial planes combined with lighted retractors and endoscope-holding retractors is most successful for extensive subcutaneous surgery. Some prefer gas insufflation of these soft tissue planes. The primary disadvantage of soft tissue insufflation is that subcutaneous emphysema can be created.

**Hand-Assisted Laparoscopic Access**

Hand-assisted laparoscopic surgery is thought to combine the tactile advantages of open surgery with the minimal access of laparoscopy and thoracoscopy. This approach commonly is used to assist with difficult cases before conversion to celiotomy is necessary. Additionally, hand-assisted laparoscopic surgery is used to help surgeons negotiate the steep learning curve associated with advanced laparoscopic procedures.47 This technology uses an entryway for the hand that preserves the pneumoperitoneum and enables laparoscopic visualization in combination with the use of minimally invasive instruments (Fig. 14-9). Formal investigation of this modality has been limited primarily to case reports and small series and has focused primarily on solid organ and colon surgery.

Intraperitoneal, intrathoracic, and retroperitoneal access for robotic surgery adheres to the principles of laparoscopic and thoracoscopic access; however, the port size for the primary puncture is 12 mm to allow placement of the stereo laparoscope. Remaining trocars are 8 mm.

**Natural Orifice Transluminal Endoscopic Surgery Access**

Multiple studies have shown safety in the performance of NOTES procedures. Transvaginal, transvesicle, transanal, transcolonic, transgastric, and transoral approaches have all been attempted with varying success. The ease of decontamination, entry, and closure of these structures create variable challenges. The transvaginal approach for resection of the uterus has been employed for many years by gynecologists and has been modified by laparoscopists with great success. Extraction of the gallbladder, kidney, bladder, large bowel, and stomach can be

**Figure 14-8.** With two small incisions, virtually the entire saphenous vein can be harvested for bypass grafting.

**Figure 14-9.** This is an example of hand-assisted laparoscopic surgery during left colectomy. The surgeon uses a hand to provide retraction and counter tension during mobilization of the colon from its retroperitoneal attachments, as well as during division of the mesocolon. This technique is particularly useful in the region of the transverse colon.
Figure 14-10. Submucosal tunnel technique for transesophageal mediastinoscopy. (Reproduced with permission from Khashab MA, Kalloo AN. NOTES: current status and new horizons, Gastroenterology. 2012 Apr;142(4):704-710.e1.)

performed via the vagina. The esophagus can be traversed to enter the mediastinum. Leaving the orifice or organ of entry with an endoscope requires the use of an endoscopic needle knife followed by submucosal tunneling or direct puncture and balloon dilation (Fig. 14-10). Closure has been performed using endoscopic clips or sutures with advanced endoscopic platforms.

**Single-Incision Laparoscopic Surgery Access**

There is no standardized approach for SILS, and access techniques vary by surgeon preference. Traditionally, a single skin incision is made directly through the umbilical scar ranging from 1 to 3 cm. Through this single incision, multiple low-profile trocars can be placed separately into the fascia to allow insufflation, camera, and working instruments. The advantage of this technique is that conventional laparoscopic tools can be employed. The disadvantage becomes apparent when an extraction site is needed. A variety of specialized multilumen trocars are on the market that can be placed through the umbilical ring (Fig. 14-11A,B). The advantages of these devices include faster access, improved safety, minimization of air leaks, and platform-derived instrument triangulation. The major disadvantage is cost.

**Port Placement**

Trocars for the surgeon’s left and right hand should be placed at least 10 cm apart. For most operations, it is possible to orient the telescope between these two trocars and slightly back from them. The ideal trocar orientation creates an equilateral triangle between the surgeon’s right hand, left hand, and the telescope, with 10 to 15 cm on each leg. If one imagines the target of the operation (e.g., the gallbladder or gastroesophageal junction) oriented at the apex of a second equilateral triangle built on the first, these four points of reference create a diamond (Fig. 14-12). The surgeon stands behind the telescope, which provides optimal ergonomic orientation but frequently requires that a camera operator (or mechanical camera holder) reach between the surgeon’s hands to guide the telescope. SILS is challenging for even the experienced laparoscopist because it violates most of the aforementioned ergonomic principles. Having only a single point of entry into the abdominal cavity creates an inherently crowded port and hand position. The inability to space trocars severely limits the ability to triangulate the left- and right-hand instruments. As a result, the surgeon must often work in a crossed hands fashion (Fig. 14-13). Additionally, the axis of the camera view is often in line with the working instruments, making visualization difficult without a deflectable tip laparoscope.

The position of the operating table should permit the surgeon to work with both elbows in at the sides, with arms bent 90° at the elbow. It usually is necessary to alter the operating table position with left or right tilt with the patient in the Trendelenburg or reverse Trendelenburg position, depending on the operative field.
**Imaging Systems**

Two methods of videoendoscopic imaging are widely used. Both methods use a camera with a charge-coupled device (CCD), which is an array of photosensitive sensor elements (pixels) that convert the incoming light intensity to an electric charge. The electric charge is subsequently converted into a color image.

With videoendoscopy, the CCD chip is placed on the internal end of a long, flexible endoscope. With older flexible endoscopes, thin quartz fibers are packed together in a bundle, and the CCD camera is mounted on the external end of the endoscope. Most standard GI endoscopes have the CCD chip at the distal end, but small, delicate choledochoscopes and nephrosopes are equipped with fiber-optic bundles. Distally mounted CCD chips have been developed for laparoscopy but remain very expensive and therefore have not become as widely used.

Video cameras come in two basic designs. Nearly all laparoscopic cameras contain a red, green, and blue input, and are identical to the color cameras used for television production. An additional feature of many video cameras is digital enhancement. Digital enhancement detects edges, areas where there are drastic color or light changes between two adjacent pixels. By enhancing this difference, the image appears sharper and surgical resolution is improved. New laparoscopic cameras contain a high-definition (HD) chip, which increases the lines of resolution from 480 to 1080 lines. To enjoy the benefit of the clarity of HD video imaging, HD monitors also are necessary.

Priorities in a video imaging system for MIS are illumination first, resolution second, and color third. Without the first two attributes, video surgery is unsafe. Illumination and resolution are as dependent on the telescope, light source, and light cable as on the video camera used. Imaging for laparoscopy, thoracoscopy, and subcutaneous surgery uses a rigid metal telescope, usually 30 cm in length. Longer telescopes are available for obese patients and for reaching the mediastinum and deep in the pelvis from a periumbilical entry site. The standard...
telescope contains a series of quartz optical rods and focusing lenses.\textsuperscript{55} Telescopes vary in size from 2 to 12 mm in diameter. Because light transmission is dependent on the cross-sectional area of the quartz rod, when the diameter of a rod/lens system is doubled, the illumination is quadrupled. Little illumination is needed in highly reflective, small spaces such as the knee, and a very small telescope will suffice. When working in the abdominal cavity, especially if blood is present, the full illumination of a 10-mm telescope usually is necessary.

Rigid telescopes may have a flat or angled end. The flat end provides a straight view ($0^\circ$), and the angled end provides an oblique view ($30^\circ$ or $45^\circ$).\textsuperscript{52} Angled telescopes allow greater flexibility in viewing a wider operative field through a single trocar site (Fig. 14-14A); rotating an angled telescope changes the field of view. The use of an angled telescope has distinct advantages for most videoendoscopic procedures, particularly in visualizing the common bile duct during laparoscopic cholecystectomy or visualizing the posterior esophagus or the tip of the spleen during laparoscopic fundoplication. Flexible tip laparoscopes offer even greater optical freedom.

Light is delivered to the endoscope through a fiber-optic light cable. These light cables are highly inefficient, losing $>90\%$ of the light delivered from the light source. Extremely bright light sources (300 watts) are necessary to provide adequate illumination for laparoscopic surgery.

The quality of the videoendoscopic image is only as good as the weakest component in the imaging chain (Fig. 14-15). Therefore, it is important to use a video monitor that has a resolution equal to or greater than the camera being used.\textsuperscript{55} Resolution is the ability of the optical system to distinguish between line pairs. The larger the number of line pairs per millimeter, the sharper and more detailed the image. Most high-resolution monitors have up to 700 horizontal lines. HD television can deliver up to eight times more resolution than standard monitors; when combined with digital enhancement, a very sharp and well-defined image can be achieved.\textsuperscript{52,55} A heads-up display is a high-resolution liquid crystal monitor that is built into eyewear worn by the surgeon.\textsuperscript{56} This technology allows the surgeon to view the endoscopic image and operative field simultaneously. The proposed advantages of heads-up display include a high-resolution monocular image, which affords the surgeon mobility and reduces vertigo and eyestrain. However, this technology has not yet been widely adopted.

Interest in three-dimensional (3-D) laparoscopy has waxed and waned. 3-D laparoscopy provides the additional depth of field that is lost with two-dimensional endosurgery and improves performance of novice laparoscopists performing complex tasks of dexterity, including suturing and knot tying.\textsuperscript{57} The advantages of 3-D systems are less obvious to experienced Brunicardi_Ch14_p0453-p0478.indd   464 01/03/19   4:58 PM
laparoscopists. Additionally, because 3-D systems require the flickering of two similar images, which are resolved with special glasses, the images’ edges become fuzzy and resolution is lost. The optical accommodation necessary to rectify these slightly differing images is tiring and may induce headaches when one uses these systems for a long period of time. The da Vinci robot uses a specialized laparoscope with two optical bundles on opposite sides of the telescope. A specialized binocular eyepiece receives input from two CCD chips, each capturing the image from one of the two quartz rod lens systems, thereby creating true 3-D imaging without needing to employ active or passive technologies that have made 3-D laparoscopy so disappointing.

Single-incision laparoscopy presents new challenges to visualization of the operative field. In the traditional laparoscope, the light source enters the scope at a 90° angle. That position coupled with a bulky scope handle creates crowding in an already limited space. Additionally, because the scope and instruments enter the abdomen at the same point, an adequate perspective is often unobtainable even with a 30° scope. The advent of increased length laparoscopes with lighting coming from the end and a deflectable tip now allows the surgeon to recreate a sense of internal triangulation with little compromise externally. The ability to move the shaft of the scope off line while maintaining the same image provides a greater degree of freedom for the working ports.

Energy Sources for Endoscopic and Endoluminal Surgery

Many MIS procedures use conventional energy sources, but the benefits of bloodless surgery to maintain optimal visualization have spawned new ways of applying energy. The most common energy source is RF electrosurgery using an alternating current with a frequency of 500,000 cycles/s (Hz). Tissue heating progresses through the well-known phases of coagulation (60°C [140°F]), vaporization and desiccation (100°C [212°F]), and carbonization (>200°C [392°F]).68

The two most common methods of delivering RF electrosurgery are with monopolar and bipolar electrodes. With monopolar electrosurgery, a remote ground plate on the patient’s leg or back receives the flow of electrons that originate at a point source, the surgical electrode. A fine-tipped electrode causes a high current density at the site of application and rapid tissue heating. Monopolar electrosurgery is inexpensive and easy to modulate to achieve different tissue effects.59 A short-duration, high-voltage discharge of current (coagulation current) provides extremely rapid tissue heating. Lower-voltage, higher-wattage current (cutting current) is better for tissue desiccation and vaporization. When the surgeon desires tissue division with the least amount of thermal injury and least coagulation necrosis, a cutting current is used.

With bipolar electrosurgery, the electrons flow between two adjacent electrodes. The tissue between the two electrodes is heated and desiccated. There is little opportunity for tissue cutting when bipolar current is used alone, but the ability to coapt the electrodes across a vessel provides the best method of small-vessel coagulation without thermal injury to adjacent tissues.60 Advanced laparoscopic device manufacturers have leveraged the ability to selectively use bipolar energy and combined it with compressive force and a controllable blade to create a number of highly functional dissection and vessel-sealing tools (Fig. 14-16).

To avoid thermal injury to adjacent structures, the laparoscopic field of view must include all uninsulated portions of the electrosurgical electrode. In addition, the integrity of the insulation must be maintained and assured. Capacitive coupling occurs when a plastic trocar insulates the abdominal wall from the current; in turn, the current is bled off of a metal sleeve or laparoscope into the viscera54 (Fig. 14-17A). This may result in thermal necrosis and a delayed fecal fistula. Another potential mechanism for unrecognized visceral injury may occur with the direct coupling of current to the laparoscope and adjacent bowel59 (Fig. 14-17B).

Another method of delivering RF electrosurgery is argon beam coagulation. This is a type of monopolar electrosurgery in which a uniform field of electrons is distributed across a tissue surface by the use of a jet of argon gas. The argon gas jet distributes electrons more evenly across the surface than does spray electrofulguration. This technology has its greatest application for coagulation of diffusely bleeding surfaces such as the cut edge of liver or spleen. It is of less value in laparoscopic procedures because the increased intra-abdominal pressures created by the argon gas jet can increase the chances of a gas embolus. It is paramount to vent the ports and closely monitor insufflation pressure when using this source of energy within the context of laparoscopy.

With endoscopic endoluminal surgery, RF alternating current in the form of a monopolar circuit represents the mainstay for procedures such as snare polypectomy, sphincterotomy, lower esophageal sphincter ablation, and biopsy.61,62 A grounding (return) electrode is necessary for this form of energy. Bipolar electrocoagulation is used primarily for thermal hemostasis. The electrosurgical generator is activated by a foot pedal so the endoscopist may keep both hands free during the endoscopic procedure.

Gas, liquid, and solid-state lasers have been available for medical application since the mid-1960s.63 The CO₂ laser (wavelength 10.6 µm) is most appropriately used for cutting...
and superficial ablation of tissues. It is most helpful in locations unreachable with a scalpel such as excision of vocal cord granulomas. The CO₂ laser beam must be delivered with a series of mirrors and is therefore somewhat cumbersome to use. The next most popular laser is the neodymium yttrium-aluminum garnet (Nd:YAG) laser. Nd:YAG laser light is 1.064 µm (1064 nm) in wavelength. It is in the near-infrared portion of the spectrum and, like CO₂ laser light, is invisible to the naked eye. A unique feature of the Nd:YAG laser is that 1064-nm light is poorly absorbed by most tissue pigments and therefore travels deep into tissue. Deep tissue penetration provides deep tissue heating (Fig. 14-18). For this reason, the Nd:YAG laser is capable of the greatest amount of tissue destruction with a single application.

Such capabilities make it the ideal laser for destruction of large fungating tumors of the rectosigmoid, tracheobronchial tree, or esophagus. A disadvantage is that the deep tissue heating may cause perforation of a hollow viscus.

When it is desirable to coagulate flat lesions in the cecum, a different laser should be chosen. The frequency-doubled Nd:YAG laser, also known as the KTP laser (potassium thionyl phosphate crystal is used to double the Nd:YAG frequency), provides 532-nm light. This is in the green portion of the spectrum, and at this wavelength, selective absorption by red pigments in tissue (such as hemangiomas and arteriovenous malformations) is optimal. The depth of tissue heating is intermediate, between those of the CO₂ and the Nd:YAG lasers. Coagulation (without vaporization) of superficial vascular lesions can be obtained without intestinal perforation.

In flexible GI endoscopy, the CO₂ and Nd:YAG lasers have largely been replaced by heater probes and endoluminal stents. The heater probe is a metal ball that is heated to a temperature (60–100°C [140–212°F]) that allows coagulation of bleeding lesions without perforation.

Photodynamic therapy is a palliative treatment for obstructing cancers of the GI tract. Patients are given an IV dose of porfimer sodium, which is a photosensitizing agent that is taken up by malignant cells. Two days after administration, the drug is endoscopically activated using a laser. The activated porfimer sodium generates oxygen free radicals, which kill the tumor cells. The tumor is later endoscopically debrided. The use of this modality for definitive treatment of early cancers is limited.

A unique application of laser technology provides extremely rapid discharge (<10⁻⁶ s) of large amounts of energy (>10⁷ volts). These high-energy lasers, of which the pulsed dye laser has seen the most clinical use, allow the conversion of light energy to mechanical disruptive energy in the form of a shock wave. Such energy can be delivered through a quartz fiber, and with rapid repetitive discharges, can provide sufficient shock-wave energy to fragment kidney stones and gallstones. Shock waves also may be created with miniature electric spark-plug discharge systems known as electrohydraulic lithotriptors. These devices...
Lasers have the advantage of pigment selectivity, but electrohydraulic lithotriptors are more popular because they are substantially less expensive and are more compact.

Methods of producing shock waves or heat with ultrasonic energy are also of interest. Extracorporeal shockwave lithotripsy creates focused shock waves that intensify as the focal point of the discharge is approached. When the focal point is within the body, large amounts of energy are capable of fragmenting stones.

Slightly different configurations of this energy can be used to provide focused internal heating of tissues. Potential applications of this technology include the ability to noninvasively produce sufficient internal heating to destroy tissue without an incision.

A third means of using ultrasonic energy is to create rapidly oscillating instruments that are capable of heating tissue with friction; this technology represents a major step forward in energy technology. An example of its application is the laparoscopic coagulation shears device (Harmonic Scalpel), which is capable of coagulating and dividing blood vessels by first occluding them and then providing sufficient heat to weld the blood vessel walls together and to divide the vessel (Fig. 14-19). This nonelectric method of coagulating and dividing tissue with a minimal amount of collateral damage has facilitated the performance of numerous endosurgical procedures. It is especially useful in the control of bleeding from medium-sized vessels that are too big to manage with monopolar electrocautery. The ability to clamp tissue between an active blade and passive blade allows annealing of tissues followed by cutting.

**Instrumentation**

Hand instruments for MIS usually are duplications of conventional surgical instruments made longer, thinner, and smaller at the tip. It is important to remember that when grasping tissue with laparoscopic instruments, a greater force is applied over a smaller surface area, which increases the risk for perforation or injury.

Certain conventional instruments such as scissors are easy to reproduce with a diameter of 3 to 5 mm and a length of 20 to 45 cm, but other instruments such as forceps and clamps cannot provide remote access. Different configurations of graspers were developed to replace the various configurations of surgical forceps and clamps. Standard hand instruments are 5 mm in diameter and 30 cm in length, but smaller and shorter hand instruments are now available for pediatric surgery, for microlaparoscopic surgery, and for arthroscopic procedures. A unique laparoscopic hand instrument is the monopolar electrical hook. This device usually is configured with a suction and irrigation apparatus to eliminate smoke and blood from the operative field. The monopolar hook allows tenting of tissue over a bare metal wire with subsequent coagulation and division of the tissue.

Instrumentation for NOTES is still evolving, but many long micrograspers, microscissors, electrocautery adapters, suturing devices, clip applicators, and visceral closure devices are in design and application. These instruments often require an entirely different endoscopic platform requiring manipulation by a surgeon and assistant to accomplish complex maneuvers. Techniques such as mucosotomy, hydrodissection, and clip application require specialized training. The sheer size of the instrumentation often requires an overtube to allow easy exchange throughout the procedure. Instrumentation for SILS seeks to restore the surgeon’s ability to triangulate the left and right hands through variation in length, mechanical articulation, or curved design. Additionally, a lower profile camera head helps reduce the instrument crowding that occurs at the single point of abdominal entry.

**Robotic Surgery**

The term robot defines a device that has been programmed to perform specific tasks in place of those usually performed by people. The devices that have earned the title “surgical robots” would be more aptly termed computer-enhanced surgical devices, as they are controlled entirely by the surgeon for the purpose of improving performance. The first computer-assisted surgical device was the laparoscopic camera holder (Aesop, Computer Motion, Goleta, CA), which enabled the surgeon to maneuver the laparoscope either with a hand control, foot control, or voice activation. Randomized studies with such camera holders demonstrated a reduction in operative time, steadier image, and a reduction in the number of required laparoscope cleanings. This device had the advantage of eliminating the need for a human camera holder, which served to free valuable OR personnel for other duties. This technology has now been eclipsed by simpler systems using passive positioning of the camera with a mechanical arm, but the benefits of a steadier image and fewer members of the OR team remain.

The major revolution in robotic surgery was the development of a master-slave surgical platform that returned the wrist to laparoscopic surgery and improved manual dexterity by developing an ergonomically comfortable work station, with 3-D imaging, tremor elimination, and scaling of movement (e.g., large, gross hand movements can be scaled down to allow suturing with microsurgical precision) (Fig. 14-20). The most recent iteration of the robotic platform features a second surgical console enabling greater assisting and teaching opportunities. The surgeon is physically separated from the operating table, and the working arms of the device are placed over the patient (Fig. 14-21). An assistant remains at the bedside and changes the instruments as needed, providing retraction as needed to facilitate the procedure. The robotic platform (da Vinci, Intuitive Surgical, Sunnyvale, CA) was initially greeted with some skepticism by expert laparoscopists, as it was difficult to prove additional value for operations performed with the da Vinci robot. Not only were the operations longer and the equipment more expensive, but additional quality could not be demonstrated. Two randomized controlled trials compared robotic and conventional laparoscopic approaches to Nissen fundoplication. In both of these trials, the operative time was longer for robotic surgery, and there was no difference in ultimate outcome. Similar results were achieved for laparoscopic cholecystectomy. Nevertheless, the increased dexterity provided by the da

![Figure 14-19. Ultrasonic shear. When closed vibration of black (active blade) against white (passive blade) cuts and cauterizes intervening tissue.](image-url)
The tidal wave of enthusiasm for robotic surgery came when most minimally invasive urologists declared robotic prostatectomy to be preferable to laparoscopic and open prostatectomy. The great advantage—it would appear—of robotic prostatectomy is the ability to visualize and spare the pelvic nerves responsible for erectile function. In addition, the creation of the neocystourethrotomy, following prostatectomy, was greatly facilitated by needle holders and graspers with a wrist in them. Female pelvic surgery with the da Vinci robot is also reaching wide appeal. The magnified imaging provided makes this approach ideal for microsurgical tasks such as reanastomosis of the Fallopian tubes. In general surgery, there is emerging
popularity for the use of the robotic platform for revisional bariatric surgery and complex abdominal wall reconstruction. The ability to close the defect before placement of mesh in ventral hernia repairs or to perform complex transversus abdominus release herniorrhaphy is revolutionizing MIS hernia repair.

The final frontier for computer-enhanced surgery is the promise of telesurgery, in which the surgeon is a great distance from the patient (e.g., combat or space). This application has rarely been used, as the safety provided by having the surgeon at bedside cannot be sacrificed to prove the concept. However, remote laparoscopic cholecystectomy has been performed when a team of surgeons located in New York performed a cholecystectomy on a patient located in France.

Endoluminal and Endovascular Surgery

The fields of vascular surgery, interventional radiology, neuroradiology, gastroenterology, general surgery, pulmonology, and urology all encounter clinical scenarios that require the urgent restoration of luminal patency. Based on this need, fundamental techniques have been pioneered that are applicable to all specialties and virtually every organ system. As a result, all minimally invasive surgical procedures, from coronary artery angioplasty to palliation of pancreatic malignancy, involve the use of access devices, catheters, guidewires, balloon dilators, stents, and other devices (e.g., lasers, atherectomy catheters) that are capable of opening up the occluded biologic cylinder (Table 14-2).

Endoluminal balloon dilators may be inserted through an endoscope, or they may be fluoroscopically guided. Balloon dilators all have low compliance—that is, the balloons do not stretch as the pressure within the balloon is increased. The high pressures achievable in the balloon create radial expansion of the narrowed vessel or orifice, usually disrupting the atherosclerotic plaque, the fibrotic stricture, or the muscular band (e.g., esophageal achalasia).

Once the dilation has been attained, it is frequently beneficial to hold the lumen open with a stent. Stenting is particularly valuable in treating malignant lesions and atherosclerotic occlusions or aneurysmal disease (Fig. 14-22). Stenting is also of value to seal leaky cylinders, including aortic dissections, traumatic vascular injuries, leaking GI anastomoses, and fistulas. Stenting usually is not applicable for long-term management of benign GI strictures except in patients with limited life expectancy (Fig. 14-23).

A variety of stents are available that are divided into six basic categories: plastic stents, metal stents, drug-eluting stents (to decrease fibrovascular hyperplasia), covered metal stents, anchored stent grafts, and removable covered plastic stents (Fig. 14-24). Plastic stents came first and are used widely as endoprosthesis for temporary bypass of obstructions in the biliary or urinary systems. Metal stents generally are delivered over a balloon and expanded with the balloon to the desired size. These metal stents usually are made of titanium or nitinol and are still used in coronary stenting. A chemotherapeutic agent was added to coronary stents several years ago to decrease endothelial proliferation. These drug-eluting stents provide greater long-term patency but require long-term anticoagulation with antiplatelet agents to prevent thrombosis.

Silastic or other materials may prevent tumor ingrowth but also makes stent migration more likely. In an effort to minimize stent migration, stents have been incorporated with hooks and barbs at the proximal end of the stent to anchor it to the wall of the vessel. Endovascular stenting of aortic aneurysms has nearly replaced open surgery for this condition. Lastly, self-expanding plastic stents have been developed as temporary devices to be used in the GI tract to close internal fistulas and bridge leaking anastomoses.

**Natural Orifice Transluminal Endoscopic Surgery**

The use of the flexible endoscope to enter the GI, urinary, or reproductive tracts and then traverse the wall of the structure to enter the peritoneal cavity, the mediastinum, or the chest has strong appeal to patients wishing to avoid scars and pain caused by abdominal wall trauma. In truth, transluminal surgery has been performed in the stomach for a long time, either from the inside out (e.g., percutaneous, PEG, and transgastric pseudocyst drainage) or from the outside in (e.g., laparoscopic-assisted intragastric tumor resection). The catalyzing events for NOTES were the demonstration that a porcine gallbladder could be removed with a flexible endoscope passed through the wall of the stomach and then removed through the mouth and the demonstration in a series of 10 human cases from India of the ability to perform transgastric appendectomy. Since that time, a great deal of money has been invested by endoscopic and MIS companies to help surgeons and gastroenterologists explore this new territory. Systemic inflammatory markers such as C-reactive protein, tumor necrosis factor-α, interleukin (IL)-1β, and IL-6 have been shown to be similar in transgastric and transcolonic NOTES when compared to laparoscopy in porcine models. Concerns about the safety of transluminal access and limitations in equipment remain the greatest barriers to expansion. To date, the most headline-grabbing procedures have been the transvaginal and transgastric removal of the gallbladder (Fig. 14-25). To ensure safety, all human cases thus far have involved laparoscopic assistance to aid in retraction and ensure adequate closure of the stomach or vagina. To date, thousands of transvaginal and transgastric procedures have been performed internationally, with two large registries demonstrating noninferiority to conventional laparoscopy. The fact that the vast majority of these procedures are being done transvaginally creates an obvious limitation in applicability.

The rapid growth of endoscopic technology catalyzed by NOTES has already spun off new technologies capable of performing a wide variety of endoscopic surgical procedures from EMR, to ablation of Barrett’s esophagus, to creation of competent antireflux valves in patients with gastroesophageal reflux disease.

Peroral esophageal myotomy (POEM) has shown promise as a NOTES treatment for esophageal achalasia. In this procedure, a 1.5- to 2-cm mucosotomy is created within the anterior esophagus 10 cm proximal to the gastroesophageal junction. A submucosal tunnel is then created using a combination of electrocautery, hydrodissection, and carbon dioxide insufflation. The scope is advanced beyond the gastroesophageal junction, and a circular myotomy is performed avoiding disruption of the longitudinal fibers. The mucosotomy is then closed using endoscopic clips (Fig. 14-26). Over 1000 clinical POEM cases have been performed worldwide. Data from expert NOTES surgeons suggest that this selective myotomy avoids abdominal trauma.
and minimally disrupts the normal anatomic characteristics of the gastroesophageal junction while providing significant relief of symptoms. Randomized clinical trials and long-term follow-up need to be performed to further evaluate efficacy.

Although this application is still considered experimental, there is little doubt that when equivalent operations can be performed with less pain, fewer scars, and less disability, patients will flock to it. NOTES procedures are associated with an increased mental workload and significant learning curve for even experienced surgical endoscopists. Surgeons should engage only when they can perform these procedures with the safety and efficacy demanded by our profession.

**Single-Incision Laparoscopic Surgery**

As a surgical technique, SILS seems to be a natural progression from conventional laparoscopic surgery. As surgeons sought to reduce the number and size of abdominal wall trocars and NOTES procedures necessitated laparoscopic surveillance, the idea of a hybridization took off. An incision in the umbilicus, a preexisting scar, is thought to be less painful, have fewer wound complications, lead to quicker return to activity, and have a better cosmetic appearance than conventional laparoscopy. Perhaps one of the earliest examples of SILS is the application of laparoscopic instrumentation to resect lesions in the rectum or sigmoid colon. Using the anus as the portal of entry, transanal endoscopic microsurgery (TEMS) employs a specialized multichannel trocar to reach lesions located 8 to 18 cm away from the anal verge (Fig. 14-27).

More deformable versions of these complex trocars have been developed with features to allow insufflation and be amenable to maintaining a seal within the natural orifice of the umbilicus (see Fig. 14-11). Ports typically contain three or four channels. The latter often affords the ability to place a dedicated retractor.

There are many challenges faced by the operating surgeon in SILS procedures. These include crowded trocar placement, lack of triangulation of left- and right-hand instruments, frequent crossing or clashing of instruments, limited visualization, and limited retraction ability. These challenges are mitigated by surgeon’s experience and the development of specialized instruments. Articulating or curved instruments of varying lengths and an extended length can improve working space. Curved instruments are typically reusable and offer less clutter than their more sophisticated counterparts, providing some cost reduction (Fig. 14-28). A low-profile HD scope with or without a deflectable tip can improve visualization greatly. Even with such instrumentation, the learning curve is very steep, particularly when the surgeon is forced to work in a cross-handed technique. The accomplished SILS surgeon will possess a tool bag of innovative...
strategies to retract structures like the gallbladder away from the operative field. These tricks may range from the use of percutaneous needlescopic instruments to the application of transfascial sutures. Expert consensus recommendations for efficient SILS are shown in Tables 14-3 and 14-4. When performing SILS procedures, it is imperative to follow proven tenets of operative conduct such as visualizing the “critical view” of safety in a laparoscopic cholecystectomy. As safety should always be the paramount concern, the addition of extra trocars or conversion to traditional laparoscopy should not be considered a failure.

Contraindications include those true of traditional laparoscopy. Relative contraindications include previous surgery and high body mass index (BMI). Patients with a high BMI or central obesity can pose a challenge because the umbilicus may be located far from operative target. Size and morphology of the target organ should always be considered when doing SILS. Many studies have demonstrated equivalency to standard laparoscopic procedures regarding intraoperative and postoperative complications. However, it is questionable what the full benefit of the dramatic reduction in ergonomics and the increase in complexity provide beyond an improved cosmetic appearance. This is in large part due to the already improved benefits of laparoscopic surgery.

A meta-analysis performed by Ahmed and colleagues in 2010 found the conversion rate from SILS to conventional laparoscopy to be 0% to 24% for cholecystectomies, 0% to 41%

for appendectomies, and 0% to 33% for nephrectomies. The most common complications were intra-abdominal abscesses and wound infections. Existing and emerging robotics platforms may provide the bridge necessary to bypass the significant technical skills learning curve required to operate through a single site (Fig. 14-29).

**SPECIAL CONSIDERATIONS**

**Pediatric Laparoscopy**

The advantages of MIS in children may be more significant than in the adult population. MIS in the adolescent is little different from that in the adult, and standard instrumentation and trocar positions usually can be used. However, laparoscopy in the infant and young child requires specialized instrumentation. The instruments are shorter (15–20 cm), and many are 3 mm in diameter rather than 5 mm. Because the abdomen of the child is much smaller than that of the adult, a 5-mm telescope provides sufficient illumination for most operations. The development of 5-mm clippers and bipolar devices has obviated the need for 10-mm trocars in pediatric laparoscopy. Because the abdominal wall is much thinner in infants, a pneumoperitoneum pressure of 8 mmHg can provide adequate exposure. DVT is rare in children, so prophylaxis against thrombosis probably is unnecessary. A wide variety of pediatric surgical procedures are frequently performed with MIS access, from pull-through procedures for congenital diaphragmatic hernias to repair of congenital diaphragmatic hernias.

**Laparoscopy During Pregnancy**

Concerns about the safety of laparoscopic cholecystectomy or appendectomy in the pregnant patient have been thoroughly investigated and are readily managed. Access to the abdomen in the pregnant patient should take into consideration the height of the uterine fundus, which reaches the umbilicus at 20 weeks. In order not to damage the uterus or its blood supply, most surgeons feel that the open (Hasson) approach should be used in favor of direct puncture laparoscopy. The patient should be positioned slightly on the left side to avoid compression of the vena cava by the uterus. Because pregnancy poses a risk for thromboembolism, sequential compression devices are essential for all procedures. Fetal acidosis induced by maternal hypercarbia also has been raised as a concern. The arterial pH of the fetus follows the pH of the mother linearly; and therefore, fetal acidosis may be prevented by avoiding a respiratory acidosis in the mother. The pneumoperitoneum pressure induced by laparoscopy is not a safety issue either as it has been proved that mid-pregnancy uterine contractions provide a much greater pressure in utero than a pneumoperitoneum of 15 mmHg. More than 100 cases of laparoscopic cholecystectomy in pregnancy have been reported with uniformly good results. The operation should be performed during the second trimester of pregnancy if possible. Protection of the fetus against intraoperative X-rays

is imperative. Some believe it advisable to track fetal pulse rates with a transvaginal ultrasound probe; however, the significance of fetal tachycardia or bradycardia is a bit unclear in the second trimester of pregnancy. To be prudent, however, heart rate decelerations reversibly associated with pneumoperitoneum creation might signal the need to convert to open cholecystectomy or appendectomy.

**Minimally Invasive Surgery and Cancer Treatment**

MIS techniques have been used for many decades to provide palliation for the patient with an obstructive cancer. Laser treatment, intracavitary radiation, stenting, and dilation are outpatient techniques that can be used to reestablish the continuity of an obstructed esophagus, bile duct, ureter, or airway. MIS techniques also have been used in the staging of cancer. Mediastinoscopy is still used occasionally before thoracotomy to assess the status of the mediastinal lymph nodes. Laparoscopy also is used to assess the liver in patients being evaluated for pancreatic, gastric, or hepatic resection. New technology and greater surgical skills allow for accurate minimally invasive staging of cancer. Occasionally, it is appropriate to perform palliative measures (e.g., laparoscopic gastrojejunostomy to bypass a pancreatic cancer) at the time of diagnostic laparoscopy if diagnostic findings preclude attempts at curative resection.

Initially controversial, the role of MIS to provide a safe curative treatment of cancer has proven to be no different from the principles of open surgery. All gross and microscopic tumor should be removed (an R0 resection), and an adequate lymphadenectomy should be performed to allow accurate staging. Generally, this number has been 10 to 15 lymph nodes, although there is still debate as to the value of more extensive lymphadenectomy. All of the major abdominal cancer operations have been performed with laparoscopy. Of the three major cancer resections of GI cancer (liver lobe, pancreatic head, and esophagus), only esophagectomy is routinely performed by a fair number of centers. Laparoscopic hepatectomy has attracted a loyal following, and distal pancreatectomy frequently is performed with laparoscopic access. In Japan, laparoscopic-assisted gastrectomy has become quite popular for early gastric cancer, an epidemic in Japan far exceeding that of colon cancer in North America and Northern Europe. The most common cancer operation performed laparoscopically is segmental colectomy, which has proven itself safe and efficacious in a multicenter, controlled, randomized trial.

**Considerations in the Elderly and Infirm**

Laparoscopic cholecystectomy has made possible the removal of a symptomatic gallbladder in many patients previously thought to be too elderly or too ill to undergo a laparotomy. Older patients are more likely to require conversion to laparotomy because of disease chronicity.

Operations on these patients require close monitoring of anesthesia. The intraoperative management of these patients may be more difficult with laparoscopic access than with open access. The advantage of MIS lies in what happens after the operation. Much of the morbidity of surgery in the elderly is a result of impaired mobility. In addition, pulmonary complications, urinary tract sepsis, DVT, pulmonary embolism, congestive heart failure, and myocardial infarction often are the result of improper fluid management and decreased mobility. By allowing rapid and early mobilization, laparoscopic surgery has made possible the safe performance of procedures in the elderly and infirm.

**Cirrhosis and Portal Hypertension**

Patients with hepatic insufficiency pose a significant challenge for any type of surgical intervention. The ultimate surgical outcome in this population relates directly to the degree of underlying hepatic dysfunction. Often, this group of patients has minimal reserve, and the stress of an operation will trigger complete hepatic failure or hepatorenal syndrome. These patients are at risk for major hemorrhage at all levels, including trocar insertion, operative dissection in a field of dilated veins, and secondary to an underlying coagulopathy. Additionally, ascitic leak from a port site may occur, leading to bacterial peritonitis. Therefore, a watertight port site closure should be carried out in all patients.

It is essential that the surgeon be aware of the severity of hepatic cirrhosis as judged by a Model of End-Stage Liver Disease (MELD) score or Child’s classification. Additionally, the presence of portal hypertension is a relative contraindication to laparoscopic surgery until the portal pressures are reduced with portal decompression. For example, if a patient has an incarcerated umbilical hernia and ascites, a preoperative paracentesis or transjugular intrahepatic portosystemic shunt procedure in conjunction with aggressive diuresis may be considered. Because these patients commonly are intravascularly depleted, insufflation pressures should be reduced to prevent a decrease in cardiac output, and minimal amounts of Na+-sparing IV fluids should be given.

**Economics of Minimally Invasive Surgery**

Minimally invasive surgical procedures reduce the costs of surgery most when length of hospital stay can be shortened and return to work is quickened. For example, shorter hospital stays can be demonstrated in laparoscopic cholecystectomy, Nissen fundoplication, splenectomy, and adrenalectomy. Procedures such as inguinal herniorrhaphy that are already performed as outpatient procedures are less likely to provide cost savings. Procedures that still require a 4- to 7-day hospitalization, such as laparoscopic-assisted colectomy, are less likely to deliver a lower bottom line than their open surgery counterparts. Nonetheless, with responsible use of disposable instrumentation and a commitment to the most effective use of the inpatient setting, most laparoscopic procedures can be made less expensive than their conventional equivalents.

**Education and Skill Acquisition**

Historically, surgeons in training (residents, registrars, and fellows) acquired their skills in minimally invasive techniques through a series of operative experiences of graded complexity. This training occurred on patients. Although such a paradigm did not compromise patient safety, learning in the OR is costly. In addition, the recent worldwide constraint placed on resident work hours makes it attractive to teach laparoscopic skills outside of the OR.

Skills labs started at nearly every surgical training center in the 1990s with low fidelity box-type trainers. These were rudimentary simulated abdominal cavities with a video camera, monitor, trocars, laparoscopic instruments, and target models. These targets were often as simple as a pegboard and rubber rings, or a latex drain to practice suturing and knot tying. Virtual reality training devices present a unique opportunity to improve and enhance experiential learning in endoscopy and laparoscopy.
for all surgeons. This technology has the advantage of enabling objective measurement of psychomotor skills, which can be used to
determine progress in skill acquisition and, ultimately, technical competency. Several of these devices have been validated as a means of measuring proficiency in skill performance. More
importantly, training on virtual reality platforms has proven to translate to improved operative performance in randomized trials. Currently, surgical skills labs are mandatory for Residency Review Committee credentialing. Successful completion of the Fundamentals of Laparoscopic Surgery (FLS) technical and cognitive examination became a mandatory prerequisite for the American Board of Surgery (ABS) qualification examination in general surgery in 2010. The Fundamentals of Endoscopic Surgery (FES) became a prerequisite to ABS qualification in 2015. In the future, institutions may require simulator training to document specific entrustable professional activities (EPA) related to laparoscopic procedures before privileging in the OR. A Fundamentals of Robotic Surgery (FRS) high stakes exam is on the horizon for future surgical trainees. The American College of Surgeons has taken a leadership position in accrediting skills labs across the world as American College of Surgeons–accredited educational institutes.

**Telementoring**

In response to the Institute of Medicine’s call for the development of unique technologic solutions to deliver health care to rural and underserved areas, surgeons are beginning to explore the feasibility of telementoring. Teleconsultation or telementoring is two-way audio and visual communication between two geographically separated providers. This communication can take place in the office setting or directly in the OR when complex scenarios are encountered. Although local communication channels may limit its performance in rural areas, the technology is available and currently is being used, especially in states and provinces with large geographically remote populations.

**Innovation and Introduction of New Procedures**

The revolution in minimally invasive general surgery, which occurred in 1990, created ethical challenges for the profession. The problem was this: If competence is gained from experience, how was the surgeon to climb the competence curve (otherwise known as the learning curve) without injuring patients? If it was indeed impossible to achieve competence without making mistakes along the way, how should one effectively communicate this to patients such that they understand the weight of their decisions? Even more fundamentally important is determining the path that should be followed before one recruits the first patient for a new procedure.

Although procedure development is fundamentally different than drug development (i.e., there is great individual variation in the performance of procedures, but no difference between one tablet and the next), adherence to a process similar to that used to develop a new drug is a reasonable path for a surgical innovator. At the outset, the surgeon must identify the problem that is not solved with current surgical procedures. For example, although the removal of a gallbladder through a Kocher incision is certainly effective, it creates a great deal of disability, pain, and scarification. As a result of those issues, many patients with very symptomatic biliary colic delayed operation until life-threatening complications occurred. Clearly, there was a need for developing a less invasive approach (Fig. 14-30).

Once the opportunity has been established, the next step involves a search through other disciplines for technologies and techniques that might be applied. Again, this is analogous to the drug industry, where secondary drug indications have often turned out to be more therapeutically important than the primary indication for drug development. The third step is in vivo studies in the most appropriate animal model. These types of studies are controversial because of the resistance to animal experimentation, and yet without such studies, many humans would be injured or killed during the developmental phase of medical drugs, devices, and techniques. These steps often are called the preclinical phase of procedure development.

The decision as to when such procedures are ready to come out of the lab is a difficult one. Put simply, the procedure should be reproducible, provide the desired effect, and not have serious side effects. Once these three criteria are reached, the time for human application has arrived. Before the surgeon discusses the new procedure with patients, it is important to achieve full institutional support. Involvement of the medical board, the chief of the medical staff, and the institutional review board is essential before commencing on a new procedure. These bodies are responsible for the use of safe, high-quality medical practices within their institution, and they will demand that great caution and all possible safeguards are in place before proceeding.

The dialogue with the patient who is to be first must be thorough, brutally honest, and well documented. The psychology

![Figure 14-30](image-url) The progress of general surgery can be reflected by a series of performance curves. General anesthesia and sterile technique allowed the development of maximally invasive open surgery over the last 125 years. Video optics allowed the development of minimally invasive surgery over the last 25 years. Noninvasive (seamless) surgery will result when a yet undiscovered transformational event allows surgery to occur without an incision, and perhaps without anesthesia.
that allows a patient to decide to be first is quite interesting, and may, under certain circumstances, require psychiatric evaluation. Certainly, if a dying cancer patient has a chance with a new drug, this makes sense. Similarly, if the standard surgical procedure has a high attendant morbidity and the new procedure offers a substantially better outcome, the decision to be first is understandable. On the other hand, when the benefits of the new approach are small and the risks are largely unknown, a more complete psychological profile may be necessary before proceeding.

For new surgical procedures, it generally is wise to assemble the best possible operative team, including a surgeon experienced with the old technique, and assistants who have participated in the earlier animal work. This initial team of experienced physicians and nurses should remain together until full competence with the procedure is attained. This may take 10 procedures, or it may take 50 procedures. The team will know that it has achieved competence when the majority of procedures take the same length of time and the team is relaxed and sure of the flow of the operation. This will complete phase I of the procedure development.

In phase II, the efficacy of the procedure is tested in a nonrandomized fashion. Ideally, the outcome of new techniques must be as good as or better than the procedure that is being replaced. This phase should occur at several medical centers to prove that good outcomes are achievable outside of the pioneering institution. These same requirements may be applied to the introduction of new technology into the OR. The value equation requires that the additional measurable procedure quality exceeds the additional measurable cost to the patient or healthcare system. In phase III, a randomized trial pits the new procedure against the old.

Once the competence curve has been climbed, it is appropriate for the team to engage in the education of others. During the ascension of the competence curve, other learners in the institution (i.e., surgical residents) may not have the opportunity to participate in the first case series. Although this may be difficult for them, the best interest of the patient must be put before the education of the resident.

The second stage of learning occurs when the new procedure has proven its value and a handful of experts exist, but the majority of surgeons have not been trained to perform the new procedure. In this setting, it is relatively unethical for surgeons to forge ahead with a new procedure in humans as if they had spent the same amount of time in intensive study that the first team did. The fact that one or several surgical teams were able to perform an operation does not ensure that all others with the same medical degrees can perform the operation with equal skill. It behooves the learners to contact the experts and request their assistance to ensure an optimal outcome at the new center. Although it is important that the learners contact the experts, it is equally important that the experts be willing to share their experience with their fellow professionals. As well, the experts should provide feedback to the learners as to whether they feel the learners are equipped to forge ahead on their own. If not, further observation and assistance from the experts are required. Although this approach may sound obvious, it is fraught with difficulties. In many situations, ego, competitiveness, and monetary concerns have short-circuited this process and led to poor patient outcomes. To a large extent, MIS has recovered from the black eye it received early in development, when inadequately trained surgeons caused an excessive number of significant complications.

If innovative procedures and technologies are to be developed and applied without the mistakes of the past, surgeons must be honest when they answer these questions: Is this procedure safe? Would I consider undergoing this procedure if I developed a surgical indication? Is the procedure as good as or better than the procedure it is replacing? Do I have the skills to apply this procedure safely and with equivalent results to the more experienced surgeon? Answering these questions in the affirmative should be a professional obligation. A negative response should motivate the surgeon to seek an alternative procedure or outside assistance before subjecting a patient to the new procedure.

OVERVIEW OF MOLECULAR CELL BIOLOGY

The beginning of modern medicine can be traced back to centuries ago when physicians and scientists began studying human anatomy from cadavers in morgues and animal physiology following hunting expeditions. Gradually, from the study of animals and plants in greater detail and the discovery of microbes, scientific principles governing life led to the emergence of the biologic sciences. As biologic science developed and expanded, scientists and physicians began to utilize its principles to solve challenges of human diseases while continuing to explore the fundamentals of life in greater detail. With ever-evolving state-of-the-art scientific tools, our understanding of how cells, tissues, organs, and entire organisms function, down to the level of molecular and subatomic structure, has resulted in modern biology with an enormous impact on modern healthcare and the discovery of amazing treatments for disease at an exponential pace. Significant progress has been made in molecular studies of organ development, cell signaling, and gene regulation. The advent of recombinant DNA technology, polymerase chain reaction (PCR) techniques, and next-generation genomic sequencing, which resulted in the sequencing of the human genome, holds the potential to have a transformational influence on healthcare and society this century by not only broadening our understanding of the pathophysiology of disease, but also by bringing about necessary changes in personalized medicine.

Today’s practicing surgeons are becoming increasingly aware that many modern surgical procedures rely on the information gained through molecular research (i.e., precision surgery). Genomic information, such as deleterious *BRCA* and *RET* proto-oncogene mutations, is being used to help direct prophylactic procedures to remove potentially harmful tissues before they do damage to patients. Molecular engineering has led to cancer-specific gene therapy that could serve in the near future as a more effective adjunct to surgical debulking of tumors than radiation or chemotherapy, so surgeons will benefit from a clear introduction to how basic biochemical and biologic principles relate to the developing area of molecular biology. This chapter reviews the current information on modern molecular biology for the surgical community.

Basic Concepts of Molecular Research

The modern era of molecular biology, which has been mainly concerned with how genes govern cell activity, began in 1953 when James D. Watson and Francis H. C. Crick made one of the greatest scientific discoveries by deducing the double-helical structure of deoxyribonucleic acid (DNA).1,2 The year 2003 marked the 50th anniversary of this great discovery. In the same year, the Human Genome Project completed with sequencing approximately 20,000 to 25,000 genes and 3 billion base pairs in human DNA.3 Before 1953, one of the most mysterious aspects of biology was how genetic material was precisely duplicated from one generation to the next. Although DNA had been implicated as genetic material, it was given rise to the notion that a template was involved in the transfer of information between generations, and thus confirmed the suspicion that DNA carried an organism’s hereditary information.

Within cells, DNA is packed tightly into chromosomes. One important feature of DNA as genetic material is its ability to encode important information for all of a cell’s functions (Fig. 15-1). Based on the principles of base complementarity, scientists also discovered how information in DNA is accurately transferred into the protein structure. DNA serves as a template for RNA synthesis, termed *transcription*, including messenger RNA (mRNA, or the protein-encoding RNA), ribosomal RNA (rRNA), and transfer RNA (tRNA). mRNA carries the information from DNA to make proteins, termed *translation*, with the assistance of rRNA and tRNA. Each of these steps is precisely
controlled in such a way that genes are properly expressed in each cell at a specific time and location. In recent years, new classes of noncoding RNAs (ncRNA), for example, microRNA (or miRNA), piwi-interacting RNA (or piRNA), and long intergenic noncoding RNA (or lincRNA), have been identified. Although the number of ncRNAs encoded in the human genome is unknown and a lot of ncRNAs have not been validated for their functions, ncRNAs have been associated to regulate gene expression through posttranscriptional gene regulation such as mRNA degradation or epigenetic regulation such as chromatin structure modification and DNA methylation induction. Consequently, the differential gene activity in a cell determines its actions, properties, and functions.

**Molecular Approaches to Surgical Research**

Rapid advances in molecular and cellular biology over the past half century have revolutionized the understanding of disease and will radically transform the practice of surgery. In the future, molecular techniques will be increasingly applied to surgical disease and will lead to new strategies for the selection and implementation of operative therapy. Surgeons should be familiar with the fundamental principles of molecular and cellular biology so that emerging scientific breakthroughs can be translated into improved care of the surgical patient.

The greatest advances in the field of molecular biology have been in the areas of analysis and manipulation of DNA. Since Watson and Crick’s discovery of DNA structure, an intensive effort has been made to unlock the deepest biologic secrets of DNA. Among the avalanche of technical advances, one discovery in particular has drastically changed the world of molecular biology: the uncovering of the enzymatic and microbiologic techniques that produce recombinant DNA. Recombinant DNA technology involves the enzymatic manipulation of DNA and, subsequently, the cloning of DNA. DNA molecules are cloned for a variety of purposes including safeguarding DNA samples, facilitating sequencing, generating probes, and expressing recombinant proteins in one or more host organisms. DNA can be produced by a number of means, including restricted digestion of an existing vector, PCR, and cDNA synthesis. As DNA cloning techniques have developed over the last quarter century, researchers have moved from studying DNA to studying the functions of proteins, and from cell and animal models to molecular therapies in humans. Expression of recombinant proteins provides a method for analyzing gene regulation, structure, and function. In recent years, the uses for recombinant proteins have expanded to include a variety of new applications, including gene therapy and biopharmaceuticals. The basic molecular approaches for modern surgical research include DNA cloning, cell manipulation, disease modeling in animals, and clinical trials in human patients.

**FUNDAMENTALS OF MOLECULAR AND CELL BIOLOGY**

**DNA and Heredity**

DNA forms a right-handed, double-helical structure that is composed of two antiparallel strands of unbranched polymeric deoxyribonucleotides linked by phosphodiester bonds between the 5′ carbon of one deoxyribose moiety to the 3′ carbon of the next (Fig. 15-2). DNA is composed of four types of deoxyribonucleotides: adenine (A), cytosine (C), guanine (G), and thymine (T). The nucleotides are joined together by phosphodiester bonds. In the double-helical structure deduced by Watson and Crick, the two strands of DNA are complementary to each other.

**Figure 15-1.** The flow of genetic information from DNA to protein to cell functions. The process of transmission of genetic information from DNA to RNA is called transcription, and the process of transmission from RNA to protein is called translation. Proteins are the essential controlling components for cell structure, cell signaling, and metabolism. Genomics and proteomics are the study of the genetic composition of a living organism at the DNA and protein level, respectively. The study of the relationship between genes and their cellular functions is called functional genomics.

Figure 15-2. Schematic representation of a DNA molecule forming a double helix. DNA is made up of four types of nucleotides, which are linked covalently into a DNA strand. A DNA molecule is composed of two DNA strands held together by hydrogen bonds between the pair bases. The arrowheads at the ends of the DNA strands indicate the polarities of the two strands, which run antiparallel to each other in the DNA molecule. The diagram at the bottom left of the figure shows the DNA molecule straightened out. In reality, the DNA molecule is twisted into a double helix, of which each turn of DNA is made up of 10.4 nucleotide pairs, as shown on the right.

Because of size, shape, and chemical composition, A always pairs with T, and C with G, through the formation of hydrogen bonds between complementary bases that stabilize the double helix.

Recognition of the hereditary transmission of genetic information is attributed to the Austrian monk, Gregor Mendel. His seminal work, ignored upon publication until its rediscovery in 1900, established the laws of segregation and of independent assortment. These two principles established the existence of paired elementary units of heredity and defined the statistical laws that govern them. DNA was isolated in 1869, and a number of important observations of the inherited basis of certain diseases were made in the early part of the 20th century. Although today it appears easy to understand how DNA replicates, before the 1950s the idea of DNA as the primary genetic material was not appreciated. The modern era of molecular biology began in 1944 with the demonstration that DNA was the substance that carried genetic information. The first experimental evidence that DNA was genetic material came from simple transformation experiments conducted in the 1940s using Streptococcus pneumoniae. One strain of the bacteria could be converted into another by incubating it with DNA from the other, just as the treatment of the DNA with deoxyribonuclease would inactivate the transforming activity of the DNA. Similarly, in the early 1950s, before the discovery of the double-helical structure of DNA, the entry of viral DNA and not the protein into the host bacterium was believed to be necessary to initiate infection by the bacterial virus or bacteriophage. Key historical events concerning genetics are outlined in Table 15-1.

For cells to pass on the genetic material (DNA) to each progeny, the amount of DNA must be doubled. Watson and Crick recognized that the complementary base-pair structure of DNA implied the existence of a template-like mechanism for the copying of genetic material. The transfer of DNA material from the mother cell to daughter cells takes place during somatic cell division (also called mitosis). Before a cell divides, DNA must be precisely duplicated. During replication, the two strands of DNA separate, and each strand creates a new complementary strand by precise base-pair matching (Fig. 15-3). The two, new, double-stranded DNAs carry the same genetic information, which can then be passed on to two daughter cells. Proofreading mechanisms ensure that the replication process occurs in a highly accurate manner. The fidelity of DNA replication is absolutely crucial to maintaining the integrity of the genome from generation to generation. However, mistakes can still occur during this process, resulting in mutations, which may lead to a change of the DNA’s encoded protein and, consequently, a change of the cell’s behavior. The reliable dependence of many features of modern organisms on subtle changes in genome is linked to Mendelian inheritance and also contributes to the processes of Darwinian evolution. In addition, massive changes, so-called genetic instability, can occur in the genome of somatic cells such as cancer cells.

Gene Regulation

Living cells have the necessary machinery to enzymatically transcribe DNA into RNA and translate the mRNA into protein. This machinery accomplishes the two major steps required for gene expression in all organisms: transcription and translation (Fig. 15-4). However, gene regulation is far more complex, particularly in eukaryotic organisms. For example, many gene transcripts must be spliced to remove the intervening sequences. The sequences that are spliced off are called introns, which appear to be useless, but in fact may carry some regulatory information. The sequences that are joined together, and are eventually translated into protein, are called exons. Additional regulation of gene expression includes modification of mRNA, control of mRNA stability, and its nuclear export into cytoplasm (where it is assembled into ribosomes for translation). After mRNA is translated into protein, the levels and functions of the proteins can be further regulated posttranslationally. However, the following sections will mainly focus on gene regulation at transcriptional and translational levels.

Transcription. Transcription is the enzymatic process of RNA synthesis from DNA. In bacteria, a single RNA polymerase carries out all RNA synthesis, including that of mRNA, rRNA,
Figure 15-3. DNA replication. As the nucleotide A only pairs with T, and G with C, each strand of DNA can determine the nucleotide sequence in its complementary strand. In this way, double-helical DNA can be copied precisely.

CHAPTER 15

Nucleus Protein

DNA

Nuclear envelope

Figure 15-4. Four major steps in the control of eukaryotic gene expression. Transcriptional and posttranscriptional control determine the level of messenger RNA (mRNA) that is available to make a protein, while translational and posttranslational control determine the final outcome of functional proteins. Note that posttranscriptional and posttranslational controls consist of several steps.

and tRNA. Transcription often is coupled with translation in such a way that an mRNA molecule is completely accessible to ribosomes, and bacterial protein synthesis begins on an mRNA molecule even while it is still being synthesized. Therefore, a discussion of gene regulation with a look at the simpler prokaryotic system precedes that of the more complex transcription and posttranscriptional regulation of eukaryotic genes.

Transcription in Bacteria Initiation of transcription in prokaryotes begins with the recognition of DNA sequences by RNA polymerase. First, the bacterial RNA polymerase catalyzes RNA synthesis through loose binding to any region in the double-stranded DNA and then through specific binding to the promoter region with the assistance of accessory proteins called σ factors (sigma factors). A promoter region is the DNA region upstream of the transcription initiation site. RNA polymerase binds tightly at the promoter sites and causes the double-stranded DNA structure to unwind. Consequently, few nucleotides can be base-paired with the DNA template to begin transcription. Once transcription begins, the σ factor is released. The growing RNA chain may begin to peel off as the chain elongates. This occurs in such a way that there are always about 10 to 12 nucleotides of the growing RNA chains that are base-paired with the DNA template.

The bacterial promoter contains a region of about 40 bases that include two conserved elements called −35 region and −10 region. The numbering system begins at the initiation site, which is designated +1 position, and counts backward (in negative numbers) on the promoter and forward on the transcribed region. Although both regions on different promoters are not the same sequences, they are fairly conserved and very similar. This conservation provides the accurate and rapid initiation of transcription for most bacterial genes. It is also common in bacteria that one promoter serves to transcribe a series of clustered genes, called an operon. A single transcribed mRNA contains a series of coding regions, each of which is later independently translated. In this way, the protein products are synthesized in a coordinated manner. Most of the time, these proteins are involved in the same metabolic pathway, thus demonstrating that the control by one operon is an efficient system. After initiation of transcription, the polymerase moves along the DNA to elongate the chain of RNA, although at a certain point, it will stop. Each step of RNA synthesis, including initiation, elongation, and termination, will require the integral functions of RNA polymerase as well as the interactions of the polymerase with regulatory proteins.

Transcription in Eukaryotes Transcription mechanisms in eukaryotes differ from those in prokaryotes. The unique features of eukaryotic transcription are as follows: (a) Three separate RNA polymerases are involved in eukaryotes: RNA polymerase I transcribes the precursor of 5.8S, 18S, and 28S rRNAs; RNA polymerase II synthesizes the precursors of mRNA as well as microRNA; and RNA polymerase III makes tRNAs and 5S rRNAs. (b) In eukaryotes, the initial transcript is often the precursor to final mRNAs, tRNAs, and rRNAs. The precursor is then modified and/or processed into its final functional form. RNA splicing is one type of processing to remove the noncoding introns (the region between coding exons) on an mRNA. (c) In contrast to bacterial DNA, eukaryotic DNA often is packaged with histone and nonhistone proteins into chromatin. Transcription will only occur when the chromatin structure changes in such a way that DNA is accessible to the polymerase. (d) RNA is made in the nucleus and transported into cytoplasm, where translation occurs. Therefore, unlike bacteria, eukaryotes undergo uncoupled transcription and translation.

Eukaryotic gene transcription also involves the recognition and binding of RNA polymerase to the promoter DNA. However, the interaction between the polymerase and DNA is far more complex in eukaryotes than in prokaryotes. Because the majority of studies have been focused on the regulation and functions of proteins, this chapter primarily focuses on how protein-encoding mRNA is made by RNA polymerase II.

Translation. DNA directs the synthesis of RNA; RNA in turn directs the synthesis of proteins. Proteins are variable-length polypeptide polymers composed of various combinations of 20 different amino acids and are the working molecules of the cell. The process of decoding information on mRNA to synthesize proteins is called translation (see Fig. 15-1). Translation takes place in ribosomes composed of rRNA and ribosomal proteins. The numerous discoveries made during the 1950s made it easy to understand how DNA replication and transcription involve base-pairing between DNA and DNA or DNA and RNA. However, at that time, it was still impossible to comprehend how mRNA transfers the information to the protein-synthesizing machinery. The genetic information on mRNA is composed of
arranged sequences of four bases that are transferred to the linear arrangement of 20 amino acids on a protein. Amino acids are characterized by a central carbon unit linked to four side chains: an amino group (–NH₂), a carboxy group (–COOH), a hydrogen, and a variable (–R) group. The amino acid chain is assembled via peptide bonds between the amino group of one amino acid and the carboxy group of the next. Because of this decoding, the information carried on mRNA relies on tRNA. Translation involves all three RNAs. The precise transfer of information from mRNA to protein is governed by \textit{genetic code}, the set of rules by which codons are translated into an amino acid (Table 15-2). A \textit{codon}, a triplet of three bases, codes for one amino acid. In this case, random combinations of the four bases form \(4 \times 4 \times 4\), or 64, because 64 codes are more than enough for 20 amino acids, most amino acids are coded by more than one codon. The start codon is AUG, which also corresponds to methionine; therefore, almost all proteins begin with this amino acid. The sequence of nucleotide triplets that follows the start codon signal is termed the \textit{reading frame}. The codons on mRNA are sequentially recognized by tRNA adaptor proteins. Specific enzymes termed \textit{aminoacyl-tRNA synthetases} link a specific amino acid to a specific tRNA. The translation of mRNA to protein requires the ribosomal complex to move stepwise along the mRNA until the initiator methionine sequence is identified. In concert with various protein initiator factors, the methionyl-tRNA is positioned on the mRNA and protein synthesis begins. Each new amino acid is added sequentially by the appropriate tRNA in conjunction with proteins called \textit{elongation factors}. Protein synthesis proceeds in the amino-to-carboxy-terminus direction.

The biologic versatility of proteins is astounding. Among many other functions, proteins serve as enzymes that catalyze critical biochemical reactions, carry signals to and from the extracellular environment, and mediate diverse signaling and regulatory functions in the intracellular environment. They also transport ions and various small molecules across plasma membranes. Proteins make up the key structural components of cells and the extracellular matrix and are responsible for cell motility. The unique functional properties of proteins are largely determined by their structure (Fig. 15-5).

\textbf{Regulation of Gene Expression.} The human organism is made up of a myriad of different cell types that, despite their vastly different characteristics, contain the same genetic material. This cellular diversity is controlled by the \textit{genome} and is accomplished by tight regulation of gene expression. This leads to the synthesis and accumulation of different complements of RNA and, ultimately, to the proteins found in different cell types. For example, muscle and bone express different genes or the same genes at different times. Moreover, the choice of which genes are expressed in a given cell at a given time depends on signals received from its environment. There are multiple levels at which gene expression can be controlled along the pathway from DNA to RNA to protein (see Fig. 15-4). \textit{Transcriptional control} refers to the mechanism for regulating when and how often a gene is transcribed. Splicing of the primary RNA transcript (\textit{RNA processing control}) and selection of completed

mRNAs for nuclear export (RNA transport control) represent additional potential regulatory steps. The mRNAs in the cytoplasm can be selectively translated by ribosomes (translational control) or selectively stabilized or degraded (mRNA degradation control). Finally, the resulting proteins can undergo selective activation, inactivation, or compartmentalization (protein activity control).

Because a large number of genes are regulated at the transcriptional level, regulation of gene transcripts (i.e., mRNA) often is referred to as gene regulation in a narrow definition. Each of the steps during transcription is properly regulated in eukaryotic cells. Because genes are differentially regulated from one another, one gene can be differentially regulated in different cell types or at different developmental stages. Therefore, gene regulation at the level of transcription is largely context dependent. However, there is a common scheme that applies to transcription at the molecular level (Fig. 15-6). Each gene promoter possesses unique sequences called TATA boxes that can be recognized and bound by a large complex containing RNA polymerase II, forming the basal transcription machinery. Usually located upstream of the TATA box (but sometimes longer distances) are a number of regulatory sequences referred to as enhancers that are recognized by regulatory proteins called transcription factors. These transcription factors specifically bind to the enhancers, often in response to environmental or developmental cues, and cooperate with each other and with basal transcription factors to initiate transcription. Regulatory sequences that negatively regulate the initiation of transcription also are present on the promoter DNA. The transcription factors that bind to these sites are called repressors, in contrast to the activators that activate transcription. The molecular interactions between transcription factors and promoter DNA, as well as between the cooperative transcription factors, are highly regulated and context-dependent. Specifically, the recruitment of transcription factors to the promoter DNA occurs in response to physiologic signals. A number of structural motifs in these DNA-binding transcription factors facilitate this recognition and interaction. These include the helix-turn-helix, the homeodomain motif, the zinc finger, the leucine zipper, and the helix-loop-helix motifs.

Human Genome

Genome is a collective term for all genes present in one organism. The human genome contains DNA sequences of 3 billion base pairs, carried by 23 pairs of chromosomes. The human genome has an estimated 25,000 to 30,000 genes, and overall it is 99.9% identical in all people. Approximately 3 million locations where single-base DNA differences exist have been identified and termed single nucleotide polymorphisms. Single nucleotide polymorphisms may be critical determinants of human variation in disease susceptibility and responses to environmental factors.

The completion of the human genome sequence in 2003 represented another great milestone in modern science. The Human Genome Project created the field of genomics, which is the study of genetic material in detail (see Fig. 15-1). The medical field is building on the knowledge, resources, and technologies emanating from the human genome to further the understanding of the relationship of the genes and their mutations to human health and disease. This expansion of genomics into human health applications resulted in the field of genomic medicine.

The emergence of genomics as a science will transform the practice of medicine and surgery in this century. This breakthrough has allowed scientists the opportunity to gain remarkable insights into the lives of humans. Ultimately, the goal is to use this information to develop new ways to treat, cure, or even prevent the thousands of diseases that afflict humankind. In the 21st century, work will begin to incorporate the information embedded in the human genome sequence into surgical practices. By doing so, the genomic information can be used for diagnosing and predicting disease and disease susceptibility. Diagnostic tests can be designed to detect errant genes in patients suspected of having particular diseases or of being at risk for developing them. Furthermore, exploration into the function of each human gene is now possible, which will shed
light on how faulty genes play a role in disease causation. This knowledge also makes possible the development of a new generation of therapeutics based on genes. Drug design is being revolutionized as researchers create new classes of medicines based on a reasoned approach to the use of information on gene sequence and protein structure function rather than the traditional trial-and-error method. Drugs targeted to specific sites in the body promise to have fewer side effects than many of today’s medicines. Finally, other applications of genomics will involve the transfer of genes to replace defective versions or the use of gene therapy to enhance normal functions such as immunity.

Proteomics refers to the study of the structure and expression of proteins as well as the interactions among proteins encoded by a human genome (see Fig. 15-1). A number of Internet-based repositories for protein sequences exist, including Swiss-Prot (www.expasy.ch). These databases allow comparisons of newly identified proteins with previously characterized sequences to allow prediction of similarities, identification of splice variants, and prediction of membrane topology and posttranslational modifications. Tools for proteomic profiling include two-dimensional gel electrophoresis, time-of-flight mass spectrometry, matrix-assisted laser desorption/ionization, and protein microarrays. Structural proteomics aims to describe the three-dimensional structure of proteins that is critical to understanding function. Functional genomics seeks to assign a biochemical, physiologic, cell biologic, and/or developmental function to each predicted gene. An ever-increasing arsenal of approaches, including transgenic animals, RNA interference (RNAi), and various systematic mutational strategies, will allow dissection of functions associated with newly discovered genes. Although the potential of this field of study is vast, it is in its early stages.

It is anticipated that a genomic and proteomic approach to human disease will lead to a new understanding of pathogenesis that will aid in the development of effective strategies for early diagnosis and treatment. For example, identification of altered protein expression in organs, cells, subcellular structures, or protein complexes may lead to development of new biomarkers for disease detection. Moreover, improved understanding of how protein structure determines function will allow rational design of drugs for therapeutic efficacy and potential toxicity. A genomic and proteomic approach to human disease will lead to a new understanding of pathogenesis that will aid in the development of effective strategies for early diagnosis and treatment. For example, identification of altered protein expression in organs, cells, subcellular structures, or protein complexes may lead to development of new biomarkers for disease detection. Moreover, improved understanding of how protein structure determines function will allow rational design of drugs for therapeutic efficacy and potential toxicity.

Cell Cycle and Apoptosis

Every organism is composed of many different cell types at different developmental stages. Some cell types continue to grow, while some cells stop growing after a developmental stage or resume growth after a break. For example, embryonic stem cells grow continuously, while nerve cells and striated muscle cells stop dividing after maturation. Cell cycle is the process for every cell including DNA replication and protein synthesis, DNA segregation in half, and package DNA and protein in two newly formed cells to enable passage of identical genetic information from one parental cell to two daughter cells. Thus, the cell cycle is the fundamental mechanism to maintain tissue homeostasis. A cell cycle comprises four periods: G1 (first gap phase before DNA synthesis), S (synthesis phase when DNA replication occurs), G2 (the gap phase before mitosis), and M (mitosis, the phase when two daughter cells with identical DNA are generated) (Fig. 15-7). After a full cycle, the daughter cells enter G1 again, and when they receive appropriate signals, undergo another cycle, and so on. The machinery that drives cell cycle progression is made up of a group of enzymes called cyclin-dependent kinases (CDKs). Cyclin expression fluctuates during the cell cycle, and cyclins are essential for CDK activities and form complexes with CDK. The cyclin A/CDK1 and cyclin B/CDK1 drive the progression for the M phase, while cyclin A/CDK2 is the primary S phase complex. Early G1, cyclin D/CDK4/6 or late G1, cyclin E/CDK2 controls the G1-S transition. There also are negative regulators for CDK termed CDK inhibitors, which inhibit the assembly or activity of the cyclin-CDK complex. Expression of cyclins and CDK inhibitors often is regulated by developmental and environmental factors.

The cell cycle is connected with signal transduction pathways as well as gene expression. Although the S and M phases rarely are subjected to changes imposed by extracellular signals, the G1 and G2 phases are the primary periods when cells decide whether or not to move on to the next phase. During the G1 phase, cells receive green- or red-light signals, S phase entry or G1 arrest, respectively. Growing cells proliferate only when supplied with appropriate mitogenic growth factors. Cells become committed to entry of the cell cycle only toward the end of G1. Mitogenic signals stimulate the activity of early G1 CDKs (e.g., cyclin D/CDK4) that inhibit the activity of pRb protein and activate the transcription factor called E2F to induce the expression of batteries of genes essential for G1-S progression. Meanwhile, cells also receive antiproliferative signals such as those from tumor suppressors. These antiproliferative signals also act in the G1 phase to stop cells’ progress into the S phase by inducing CKI production. For example, when DNA is damaged, cells will repair the damage before entering the S phase. Therefore, G1 contains one of the most important checkpoints for cell cycle progression. If the analogy is made that CDK is to a cell as an engine is to a car, then cyclins and CKI are the gas pedal and brake, respectively. Accelerated proliferation or
improper cell cycle progression with damaged DNA would be disastrous. Genetic gain-of-function mutations in oncogenes (that often promote expression or activity of the cyclin/CDK complex) or loss-of-function mutations in tumor suppressor (that stimulate production of CKI) are causal factors for malignant transformation.

In addition to cell cycle control, cells use genetically programmed mechanisms to kill cells. This cellular process, called apoptosis or programmed cell death, is essential for the maintenance of tissue homeostasis (Fig. 15-8).

Normal tissues undergo proper apoptosis to remove unwanted cells, those that have completed their jobs or have been damaged or improperly proliferated. Apoptosis can be activated by many physiologic stimuli such as death receptor signals (e.g., Fas or cytokine tumor necrosis factor), growth factor deprivation, DNA damage, and stress signals. Two major pathways control the biochemical mechanisms governing apoptosis: the death receptor and mitochondrial. However, recent advances in apoptosis research suggest an interconnection of the two pathways. What is central to the apoptotic machinery is the activation of a cascade of proteinases called caspases. Similar to CDK in the cell cycle, activities and expression of caspases are well controlled by positive and negative regulators. The complex machinery of apoptosis must be tightly controlled. Perturbations of this process can cause neoplastic transformation or other diseases.

**Signal Transduction Pathways**

Gene expression in a genome is controlled in a temporal and spatial manner, at least in part by signaling pathways. A signaling pathway generally begins at the cell surface and, after a signaling relay by a cascade of intracellular effectors, ends up in the nucleus (Fig. 15-9). All cells have the ability to sense changes in their external environment. The bioactive substances to which cells can respond are many and include proteins, short peptides, amino acids, nucleotides/nucleosides, steroids, retinoids, fatty acids, and dissolved gases. Some of these substances are lipophilic and thereby can cross the plasma membrane by
Control and specificity through simple protein-protein interactions—referred to as adhesions—is a common feature of signal transduction pathways in cells. Signaling also involves catalytic activities of signaling molecules, such as protein kinases/phosphatases, that modify the structures of key signaling proteins. Upon binding and/or modification by upstream signaling molecules, downstream effectors undergo a conformational (allosteric) change and, consequently, a change in function. The signal that originates at the cell surface and is relayed by the cytoplasmic proteins often ultimately reaches the transcriptional apparatus in the nucleus. It alters the DNA binding and activities of transcription factors that directly turn genes on or off in response to the stimuli. Abnormal alterations in signaling activities and capacities in otherwise normal cells can lead to diseases such as cancer.

Advances in biology in the last two decades have dramatically expanded the view on how cells are wired with signaling pathways. In a given cell, many signaling pathways operate simultaneously and crosstalk with one another. A cell generally may react to a hormonal signal in a variety of ways: (a) by changing its metabolite or protein, (b) by generating an electrical current, or (c) by contracting. Cells continually are subject to multiple input signals that simultaneously and sequentially activate multiple receptor- and non–receptor-mediated signal transduction pathways, which form a signaling network. Although the regulators responsible for cell behavior are rapidly identified as a result of genomic and proteomic techniques, the specific functions of the individual proteins, how they assemble, and the networks that control cellular behavior remain to be defined. An increased understanding of cell regulatory pathways—and how they are disrupted in disease—will likely reveal common themes based on protein interaction domains that direct associations of proteins with other polypeptides, phospholipids, nucleic acids, and other regulatory molecules. Advances in the understanding of signaling networks will require methods of investigation that move beyond traditional “linear” approaches into medical informatics and computational biology. The bewildering biocomplexity of such networks mandates multidisciplinary and transdisciplinary research collaboration. The vast amount of information that is rapidly emerging from genomic and proteomic data mining will require the development of new modeling methodologies within the emerging disciplines of medical mathematics and physics.

Signaling pathways often are grouped according to the properties of signaling receptors. Many hydrophobic signaling molecules are able to diffuse across plasma membranes and directly reach specific cytoplasmic targets. Steroid hormones, thyroid hormones, retinoids, and vitamin D are examples that exert their activity upon binding to structurally related receptor proteins that are members of the nuclear hormone receptor superfamily. Ligand binding induces a conformational change that enhances transcriptional activity of these receptors. Most extracellular signaling molecules interact with transmembrane protein receptors that couple ligand binding to intracellular signals, leading to biologic actions.

There are three major classes of cell-surface receptors: transmitter-gated ion channels, seven-transmembrane G-protein–coupled receptors (GPCRs), and enzyme-linked receptors. The superfamily of GPCRs is one of the largest families of proteins, representing over 800 genes of the human genome. Members of this superfamily share a characteristic seven-transmembrane configuration. The ligands for these receptors are diverse and include hormones, chemokines, neurotransmitters, proteinases, inflammatory mediators, and even sensory signals such as odorants and photons. Most GPCRs signal through heterotrimeric G proteins, which are guanine-nucleotide regulatory complexes. Thus, the receptor serves as the receiver, the G protein serves as the transducer, and the enzyme serves as the effector arm. Enzyme-linked receptors possess an extracellular ligand-recognition domain and a cytosolic domain that either has intrinsic enzymatic activity or directly links with an enzyme. Structurally, these receptors usually have only one transmembrane-spanning domain. Of at least five forms of enzyme-linked receptors classified by the nature of the enzyme activity to which they are coupled, the growth factor receptors such as tyrosine kinase receptor or serine/threonine kinase receptors mediate diverse cellular events including cell growth, differentiation, metabolism, and survival/apoptosis. Dysregulation (particularly mutations) of these receptors is thought to underlie conditions of abnormal cellular proliferation in the context of cancer. The following sections will further review two examples of growth factor signaling pathways and their connection with human diseases.

Insulin Pathway and Diabetes. The discovery of insulin in the early 1920s is one of the most dramatic events in the treatment of human disease. Insulin is a peptide hormone that is secreted by the β-cell of the pancreas. Insulin is required for the growth and metabolism of most mammalian cells, which contain cell-surface insulin receptors (InsR). Insulin binding to InsR activates the kinase activity of InsR. InsR then adds phosphoryl groups, a process referred to as phosphorylation, and subsequently activates its immediate intracellular effector, called insulin receptor substrate (IRS). IRS plays a central role in coordinating the signaling of insulin by activating distinct signaling pathways, the PI3K-Akt pathway and MAPK pathway, both of which possess multiple protein kinases that can control transcription, protein synthesis, and glycolysis (Fig. 15-10).

The primary physiologic role of insulin in glucose homeostasis, which is accomplished through the stimulation of glucose uptake into insulin-sensitive tissues such as fat and skeletal muscle. Defects in insulin synthesis/secretion and/or responsiveness are major causal factors in diabetes, one of the leading causes of death and disability in the United States, affecting an estimated 16 million Americans. Type 2 diabetes accounts for about 90% of all cases of diabetes. Clustering of type 2 diabetes in certain families and ethnic populations points to a strong genetic background for the disease. More than 90% of affected individuals have insulin resistance, which develops when the body is no longer able to respond correctly to insulin circulating in the blood. Although relatively little is known about the biochemical basis of this metabolic disorder, it is clear that the insulin-signaling pathways malfunction in this disease. It is also known that genetic mutations in the InsR or IRS cause type 2 diabetes, although which one is not certain. The majority of type 2 diabetes cases may result from defects in downstream-signaling components in the insulin-signaling pathway.
Figure 15-10. Insulin-signaling pathway. Insulin is a peptide growth factor that binds to and activates the heterotetrameric receptor complex (InsR). InsR possesses protein tyrosine kinase activity and is able to phosphorylate the downstream insulin receptor substrate (IRS). Phosphorylated IRS serves as a scaffold and controls the activation of multiple downstream pathways for gene expression, cell survival, and glucose metabolism. Inactivation of the insulin pathway can lead to type 2 diabetes.

Type 2 diabetes also is associated with declining β-cell function, resulting in reduced insulin secretion; these pathways are under intense study. A full understanding of the basis of insulin resistance is crucial for the development of new therapies for type 2 diabetes. Furthermore, apart from type 2 diabetes, insulin resistance is a central feature of several other common human disorders, including atherosclerosis and coronary artery disease, hypertension, and obesity.

**Transforming Growth Factor-β (TGF-β) Pathway and Cancers.** Growth factor signaling controls cell growth, differentiation, and apoptosis. Although insulin and many mitogenic growth factors promote cell proliferation, some growth factors and hormones inhibit cell proliferation. TGF-β is one of them. The balance between mitogens and TGF-β plays an important role in controlling the proper pace of cell cycle progression. The growth inhibition function of TGF-β signaling in epithelial cells plays a major role in maintaining tissue homeostasis.

The TGF-β superfamily comprises a large number of structurally related growth and differentiation factors that act through a receptor complex at the cell surface (Fig. 15-11). The complex consists of transmembrane serine/threonine kinases. The receptor signals through activation of heterotrimeric complexes of intracellular effectors called SMADs (which are contracted from homologous Caenorhabditis elegans Sma and Drosophila Mad, two evolutionarily conserved genes for TGF-β signaling). Upon phosphorylation by the receptors, SMAD complexes translocate into the nucleus, where they bind to gene promoters and cooperate with specific transcription factors to regulate the expression of genes that control cell proliferation and differentiation. For example, TGF-β strongly induces the transcription of a gene called p15INK4B (a type of CKI) and, at the same time, reduces the expression of many oncogenes such as c-Myc. The outcome of the altered gene expression leads to the inhibition of cell cycle progression. Meanwhile, the strength and duration of TGF-β signaling is fine-tuned by a variety of positive or negative modulators, including protein phosphatases. Therefore, controlled activation of TGF-β signaling is an intrinsic mechanism for cells to ensure controlled proliferation.

Resistance to TGF-β’s anticancer action is one hallmark of human cancer cells. TGF-β receptors and SMADs are identified as tumor suppressors. The TGF-β signaling circuit can be disrupted in a variety of ways and in different types of human tumors. Some lose TGF-β responsiveness through downregulation or mutations of their TGF-β receptors. The cytoplasmic SMAD4 protein, which transduces signals from ligand-activated TGF-β receptors to downstream targets, may be eliminated through mutation of its encoding gene. The locus encoding cell cycle inhibitor p15INK4B may be deleted. Alternatively, the immediate downstream target of its actions, cyclin-dependent kinase 4 (CDK4), may become unresponsive to the inhibitory actions of p15INK4B because of mutations that block p15INK4B binding. The resulting cyclin D/CDK4 complexes constitutively inactivate tumor suppressor pRb by hyperphosphorylation. Finally, functional pRb, the end target of this pathway, may be lost through mutation of its gene. For example, in pancreatic and colorectal cancers, 100% of cells derived from these cancers carry genetic defects in the TGF-β signaling pathway. Therefore, the antiproliferative pathway converging onto pRb...
and the cell division cycle is, in one way or another, disrupted in a majority of human cancer cells. Besides cancer, dysregulation of TGF-β signaling also has been associated with other human diseases such as Marfan’s syndrome and thoracic aortic aneurysm.

**Gene Therapy and Molecular Drugs in Cancer**

Modern advances in the use of molecular biology to manipulate genomes have greatly contributed to the understanding of the molecular basis for how cells live, die, or differentiate. Given the fact that human diseases arise from improper changes in the genome, the continuous understanding of how the genome functions will make it possible to tailor medicine on an individual basis. Although significant hurdles remain, the course toward therapeutic application of molecular biology already has been mapped out by many proof-of-principle studies in the literature. In this section, cancer is used as an example to elaborate some therapeutic applications of molecular biology. Modern molecular medicine includes gene therapy and molecular drugs that target genes or gene products within human cells.

Cancer is a complex disease, involving uncontrolled growth and spread of tumor cells (Fig. 15-12). Cancer development depends on the acquisition and selection of specific characteristics that set the tumor cell apart from normal somatic cells. Cancer cells have defects in regulatory circuits that govern normal cell proliferation and homeostasis. Many lines of evidence indicate that tumorigenesis in humans is a multistep process and that these steps reflect genetic alterations that drive the progressive transformation of normal human cells into highly malignant derivatives. The genomes of tumor cells are invariably altered at multiple sites, having suffered disruption through lesions as subtle as point mutations and as obvious as changes in chromosome complement. A succession of genetic changes, each conferring one or another type of growth advantage, leads to the progressive conversion of normal human cells into cancer cells.

Cancer research in the past 20 years has generated a rich and complex body of knowledge, revealing cancer to be a disease involving dynamic changes in the genome. The causes of cancer include genetic predisposition, environmental influences, infectious agents, and aging. These transform normal cells into cancerous ones by derailing a wide spectrum of regulatory pathways including signal transduction pathways, cell cycle machinery, or apoptotic pathways.15,16 The early notion that cancer was caused by mutations in genes critical for the control of cell growth implied that genome stability is important for preventing oncogenesis. There are two classes of cancer genes in which alteration has been identified in human and animal cancer cells: oncogenes, with dominant gain-of-function mutations, and tumor suppressor genes, with recessive loss-of-function mutations. In normal cells, oncogenes promote cell growth by activating cell cycle progression, whereas tumor suppressors counteract oncogenes’ functions. Therefore, the balance between oncogenes and tumor suppressors maintains a well-controlled state of cell growth.

During the development of most types of human cancer, cancer cells can break away from primary tumor masses, invade adjacent tissues, and hence travel to distant sites where they form new colonies. This spreading process of tumor cells, called metastasis, is the cause of 90% of human cancer deaths. Metastatic cancer cells that enter the bloodstream can reach virtually all tissues of the body. Bones are one of the most common places for these cells to settle and start growing again. Bone metastasis is one of the most frequent causes of pain in people with cancer. It also can cause bones to break and create other symptoms and problems for patients.

The progression in the knowledge of cancer biology has been accelerating in recent years. All of the scientific knowledge...
acquired through hard work and discovery has made it possible for cancer treatment and prevention. As a result of explosive new discoveries, some modern treatments were developed. The success of these therapies, together with traditional treatments such as surgical procedures, is further underscored by the fact that in 2002 the cancer rate was reduced in the United States. Current approaches to the treatment of cancer involve killing cancer cells with toxic chemicals, radiation, or surgery. Alternatively, several new biologic- and gene-based therapies are aimed at enhancing the body’s natural defenses against invading cancers. Understanding the biology of cancer cells has led to the development of designer therapies for cancer prevention and treatment. Gene therapy, immune system modulation, genetically engineered antibodies, and molecularly designed chemical drugs are all promising fronts in the war against cancer.

Immunotherapy. The growth of the body is controlled by many natural signals through complex signaling pathways. Some of these natural agents have been used in cancer treatment and have been proven effective for fighting several cancers through the clinical trial process. These naturally occurring biologic agents, such as interferons, interleukins, and other cytokines, can now be produced in the laboratory. These agents, as well as the synthetic agents that mimic the natural signals, are given to patients to influence the natural immune response agents either by directly altering the cancer cell growth or by acting indirectly to help healthy cells control the cancer. One of the most exciting applications of immunotherapy has come from the identification of certain tumor targets called antigens and the aiming of an antibody at these targets. This was first used as a means of localizing tumors in the body for diagnosis and was more recently used to attack cancer cells. Trastuzumab (Herceptin) is an example of such a drug. Trastuzumab is a monoclonal antibody that neutralizes the mitogenic activity of cell-surface growth factor receptor HER-2, which is overexpressed in approximately 25% of breast cancers. HER-2—overexpressing tumors tend to grow faster and generally are more likely to recur than tumors that do not overproduce HER-2. Trastuzumab is designed to attack cancer cells that overexpress HER-2 by slowing or preventing the growth of these cells, resulting in increased survival of HER-2—positive breast cancer patients. Another significant example is the administration of interleukin-2 (IL-2) to patients with metastatic melanoma or kidney cancer, which has been shown to mediate the durable regression of metastatic cancer. IL-2, a cytokine produced by human helper T lymphocytes, has a wide range of immune regulatory effects, including the expansion of lymphocytes following activation by a specific antigen. Although IL-2 has no direct impact on cancer cells, the impact of IL-2 on cancers in vivo derives from its ability to expand lymphocytes with antitumor activity. The expanded lymphocyte pool enables recognition of the antigen on cancer cells. Thus, the molecular identification of cancer antigens has opened new possibilities for the development of effective immunotherapies for patients with cancer. Clinical studies using immunization with peptides derived from cancer antigens have shown that high levels of lymphocytes with antitumor activity can be produced in cancer-bearing patients. Highly avid antitumor lymphocytes can be isolated from immunized patients and grown in vitro for use in cell-transfer therapies.

Chemotherapy. The primary function of anticancer chemicals is to block different steps involved in cell growth and replication. These chemicals often block a critical chemical reaction in a signal transduction pathway or during DNA replication or gene expression. For example, STI571, also known as Gleevec, is one of the first molecularly targeted drugs based on the changes that cancer causes in cells. STI571 offers promise for the treatment of chronic myeloid leukemia (CML) and may soon surpass interferon-γ as the standard treatment for the disease. In CML, STI571 is targeted at the Bcr-Abl kinase, an activated oncogene product in CML (Fig. 15-13). Bcr-Abl is an over activated protein kinase resulting from a specific genetic abnormality generated by chromosomal translocation that is found in the cells of patients with CML. STI571-mediated inhibition of Bcr-Abl kinase activity not only prevents cell growth of Bcr-Abl–transformed leukemic cells, but also induces apoptosis. Clinically, the drug quickly corrects the blood cell abnormalities caused by the leukemia in a majority of patients, achieving a complete disappearance of the leukemic blood cells and the return of normal blood cells. Additionally, the drug appears to have some effect on other cancers including certain breast tumors and gastrointestinal (GI) stromal tumors, a very rare type of stomach cancer.

Gene Therapy. Gene therapy is an experimental treatment that involves genetically altering a patient’s own tumor cells or lymphocytes (cells of the immune system, some of which can attack cancer cells). For years, the concept of gene therapy has held promise as a new, potentially potent weapon to attack cancer. Although a rapid progression in the understanding of the molecular and clinical aspects of gene therapy has been witnessed in the past decade, gene therapy treatment has not yet been shown to be superior to standard treatments in humans.

Figure 15-13. Mechanism of STI571 as a molecular drug. Bcr-Abl is an over activated oncogene product resulting from a specific genetic abnormality generated by chromosomal translocation that is found in cells of patients with chronic myeloid leukemia. Bcr-Abl is an activated protein kinase and thus requires adenosine triphosphate (ATP) to phosphorylate substrates, which in turn promote cell proliferation. STI571 is a small molecule that competes with the ATP-binding site and thus blocks the transfer of phosphoryl group to substrate. PO₄ = phosphate; Tyr = tyrosine.
Several problems must be resolved to transform it into a clinically relevant form of therapy. The major issues that limit its translation to the clinic are improving the selectivity of tumor targeting, improving the delivery to the tumor, and the enhancement of the transduction rate of the cells of interest. In most gene therapy trials for malignant diseases, tumors can be accessed and directly injected (in situ gene therapy). In situ gene therapy also offers a better distribution of the vector virus throughout the tumor. Finally, a combination of gene therapy strategies will be more effective than the use of a single gene therapy system. An important aspect of effective gene therapy involves the choice of appropriate genes for manipulation. Genes that promote the production of messenger chemicals or other immune-active substances can be transferred into the patient’s cells. These include genes that inhibit cell cycle progression, induce apoptosis, enhance host immunity against cancer cells, block the ability of cancer cells to metastasize, and cause tumor cells to undergo suicide. Recent development of RNAi technology, which uses a loss-of-function approach to block gene functions, ensures a new wave of hopes for gene therapy. Nonetheless, gene therapy is still experimental and is being studied in clinical trials for many different types of cancer. The mapping of genes responsible for human cancer is likely to provide new targets for gene therapy in the future. The preliminary results of gene therapy for cancer are encouraging, and as advancements are made in the understanding of the molecular biology of human cancer, the future of this rapidly developing field holds great potential for treating cancer.

It is noteworthy that the use of multiple therapeutic methods has proven more powerful than a single method. The use of chemotherapy after surgery to destroy the few remaining cancerous cells in the body is called adjuvant therapy. Adjuvant therapy was first tested and found to be effective in breast cancer. It was later adopted for use in other cancers. A major discovery in chemotherapy is the advantage of multiple chemotherapeutic agents (known as combination or cocktail chemotherapy) over single agents. Some types of fast-growing leukemias and lymphomas (tumors involving the cells of the bone marrow and lymph nodes) responded extremely well to combination chemotherapy, and clinical trials led to gradual improvement of the drug combinations used. Many of these tumors can be cured today by combination chemotherapy. As cancer cells carry multiple genetic defects, the use of combination chemotherapy, immunotherapy, and gene therapies may be more effective in treating cancers.

**Stem Cell Research**

Stem cell biology represents a cutting-edge scientific research field with potential clinical applications. It may have an enormous impact on human health by offering hope for curing human diseases such as diabetes mellitus, Parkinson’s disease, neurologic degeneration, and congenital heart disease. Stem cells are endowed with two remarkable properties (Fig. 15-14). First, stem cells can proliferate in an undifferentiated but pluripotent state and, as a result, can self-renew. Second, they have the ability to differentiate into many specialized cell types. There are two groups of stem cells: embryonic stem (ES) cells and adult stem cells.

Human ES cells (hESCs) are derived from early preimplantation embryos called blastocysts (5 days postfertilization) and are capable of generating all differentiated germ layers in the body by chimera assays or 2-D/3-D differentiation in a dish—ectoderm, mesoderm, and endoderm—and therefore are considered pluripotent. There are two pluripotent states associated with hESCs, one of which is the classic culture with bFGF (basic fibroblast growth factor) and knock out replacer (KSR), termed as “primed” pluripotent state. More recently, “naïve” hESC culture methods have been introduced based on mouse studies, by supplementing 2i inhibitors (MEK1 and GSK3β inhibitors) into the medium in addition to bFGF.

Adult stem cells are present in and can be isolated from adult tissues. They often are tissue specific and only can generate the cell types comprising a particular tissue in the body; therefore, they are considered multipotent. However, in some cases, they can transdifferentiate into cell types found in other tissues, called transdifferentiation. For example, hematopoietic stem cells are adult stem cells. They reside in bone marrow and are capable of generating all cell types of the blood and immune system. Another example is mesenchymal stem cells (MSCs), which is initially identified in the bone marrow (BM) to support hematopoietic stem cell homeostasis. In addition to BM, MSCs are also present in adipose tissue, umbilical cord, placenta, amniotic fluid, dental pulp, skeletal muscle, tendons, and synovial, etc., and are reported to obtain the ability to differentiate into osteogenic, chondrogenic, and adipogenic lineages in vitro. Due to their characteristics of easy acquisition (from adipose tissue, for example), strong ex vivo proliferation, immune-modulatory function, and ability to migrate to damaged tissue, MSCs have been utilized in regenerative medicine.

Stem cells can be grown in culture and be induced to differentiate into a particular cell type, either in vitro or in vivo. With the recent and continually increasing improvement in culturing stem cells, scientists are beginning to understand the molecular mechanisms of stem cell self-renewal and differentiation in response to environmental cues. It is believed that discovery of the signals that control self-renewal vs differentiation will be extremely important for the therapeutic use of stem cells in treating disease. It is possible that success in the study of the changes in signal transduction pathways in stem cells will lead to the development of therapies to replace diseased or damaged cells in the body using stem cell derivatives. Recently, stem cell research has been transformed by the discovery from the Shinya Yamanaka group and the James Thomsen group, who have found that a simple genetic manipulation can reprogram adult differentiated cells back into pluripotent stem cells. This exciting discovery not only bypasses the ethical issues of using early embryos to generate ES cells, but also ensures a...
potentially limitless source of patient-specific stem cells for tissue engineering and regenerative medicine.

**The Atomic Theory of Disease**

As early as the 5th century B.C., the ancient Greek Democritus first proposed that matter is composed of indivisible particles called “atoms.” In the 17th and 18th centuries, Isaac Newton described the expansion of gases as rushed atoms into empty space. The existence of atoms was doubted until the discovery of subatomic particles in the 20th century, which demonstrated that the atom was actually divisible into protons, neutrons, and electrons.

Over 100 years after this discovery, direct impacts from utilizing subatomic particles were revealed. This began with the discovery of the X-ray. The most advanced and well-applied atomic technologies include accurate imaging such as X-ray computed tomography (CT) scan, magnetic resonance imaging (MRI), single photon emission computed tomography (SPECT), and positron emission tomography (PET). Additional applications include radiation oncology, which utilizes ionizing particles to treat malignant diseases by inducing double-strand DNA breaks resulting in programmed cell death.

The staggering advances in anatomy, physiology, and molecular biology over the past centuries have led us to our current state in which the atom is now the anatomy of the 21st century. As 99% of the body is composed of six elements (oxygen, carbon, hydrogen, nitrogen, calcium, and phosphorus), the next great advance in medicine will be bridging the subatomic, molecular, and genomic levels by forming an atomic theory of disease, which states that alterations in the composition of subatomic particles are the root cause of disease. The atomic theory of disease would include genetic alterations at the atomic/subatomic level that are akin to single nucleotide polymorphisms (SNPs), in which alleles for a gene differ on the exact nucleotide in a single location, which can change the ultimate protein structure. This can lead to subtle changes in function or dramatic results that cause pathology. We hypothesize that on a subatomic level, there could potentially be polymorphisms as well, in which there are subtle changes in the sea of subatomic particles. Isotopes, discovered 100 years ago, would fall into this category of subatomic polymorphism, as they differ in the number of neutrons present in the atom. Differences in other particles may not change the mass of the atom, but may alter some of the characteristics of the atom. This is where the basic human variations originate because an atomic polymerism would result in particular genetic change. Remarkably, somatic point mutations of *KRAS* and *P53* are caused by a single proton shift in cytosine, which is known as tautomerization of cytosine. In turn, the tautomerized cytosine binds with adenine, and not guanine, thus leading to point mutations in *KRAS* and *P53*, which are well known driver mutations for many cancers. This is another example of alterations in subatomic particles that directly cause disease.

A known example of a change in the subatomic milieu of an element leading to a disease process is that of methemoglobinemia, a disorder characterized by an overabundance of methemoglobin. Methemoglobin contains an oxidized form of iron (carrying an extra electron), as opposed to the reduced form in normal hemoglobin. This results in a shift in the oxygen-hemoglobin dissociation curve to the left, causing hypoxia. Methemoglobinemia can be congenital, due to a defect in an enzyme that normally reduces methemoglobin back to hemoglobin, or acquired, caused by breakdown products of drugs that can oxidize hemoglobin. Although there is less than 1% of methemoglobin normally present in human tissues, affecting local blood flow and inflammation through its effects on nitric oxide and heme, large quantities can lead to respiratory failure and death.

Another example would be exposure to external energy such as radiation that leads to instability of nuclear genome. In Chernobyl and Fukushima, radiolabeled food was metabolized and incorporated into body cells and decay to emit gamma radiation, causing DNA damage. This radiation damage occurs primarily at a subatomic level from a radiobiologic point of view with a direct or indirect ionization of atoms. The clinical results depend on the tissue characteristics and the equilibrium between the damage applied to normal and diseased tissues.

**TECHNOLOGIES OF MOLECULAR AND CELL BIOLOGY**

**DNA Cloning**

Since the advent of recombinant DNA technology three decades ago, hundreds of thousands of genes have been identified. Recombinant DNA technology is the technology that uses advanced enzymatic and microbiologic techniques to manipulate DNA. Pure pieces of any DNA can be inserted into bacterial DNA or other carrier DNA such as plasmids to produce recombinant DNA in bacteria. In this way, DNA can be reconstructed, amplified, and used to manipulate the functions of individual cells or even organisms. This technology, often referred to as DNA cloning, is the basis of all other DNA analysis methods. It is only with the awesome power of recombinant DNA technology that the completion of the Human Genome Project was possible. It also has led to the identification of the entire gene complements of organisms such as viruses, bacteria, worms, flies, and plants.

*Molecular cloning* refers to the process of cloning a DNA fragment of interest into a DNA vector that ultimately is delivered into bacterial or mammalian cells or tissues (Fig. 15-15). This represents a very basic technique that is widely used in almost all areas of biomedical research. DNA vectors often are called *plasmids*, which are extrachromosomal molecules of DNA that vary in size and can replicate and be transmitted from bacterial cell to cell. Plasmids can be propagated either in the cytoplasm or after insertion, as part of the bacterial chromosome in *Escherichia coli*. The process of molecular cloning involves several steps of manipulation of DNA. First, the vector plasmid DNA is cleaved with a restriction enzyme to create compatible ends with the foreign DNA fragment to be cloned. The vector and the DNA fragment are then joined in vitro by a DNA ligase. Alternatively, DNA cloning can be simply done through the so-called *Gateway Technology* that allows for the rapid and efficient transfer of DNA fragments between different cloning vectors while maintaining reading frame and orientation, without the use of restriction endonucleases and DNA ligase. The technology, which is based on the site-specific recombination system of bacteriophage λ, is simple, fast, robust, and automatic and thus compatible for high-throughput DNA cloning.

Finally, the ligation product or the Gateway reaction product is introduced into competent host bacteria; this procedure is called *transformation*, which can be done by either calcium/heat shock or electroporation. Precautions must be taken in every step of cloning to generate the desired DNA construct.
Figure 15-15. Generation of recombinant DNA. The vector is a circular DNA molecule that is capable of replicating in *Escherichia coli* cells. Insert DNA (often your favorite gene) is ligated to the vector after ends of both DNA are properly treated with restriction enzymes. Ligated DNA (i.e., the recombinant plasmid DNA) is then transformed into *E. coli* cells, where it replicates to produce recombinant progenies. *E. coli* cells carrying the recombinant plasmid can be propagated to yield large quantities of plasmid DNA.

The vector must be correctly prepared to maximize the creation of recombinants; for example, it must be enzymatically treated to prevent self-ligation. Host bacteria must be made sufficiently competent to permit the entry of recombinant plasmids into cells. The selection of desired recombinant plasmid-bearing *E. coli* normally is achieved by the property of drug resistance conferred by the plasmid vectors. The plasmids encoding markers provide specific resistance to (i.e., the ability to grow in the presence of) antibiotics such as ampicillin, kanamycin, and tetracycline. The foreign component in the plasmid vector can be a mammalian expression cassette, which can direct expression of foreign genes in mammalian cells. The resulting plasmid vector can be amplified in *E. coli* to prepare large quantities of DNA for its subsequent applications such as transfection, gene therapy, transgenics, and knockout mice.

**Detection of Nucleic Acids and Proteins**

**Southern Blot Hybridization.** Southern blotting refers to the technique of transferring DNA fragments from an electrophoresis gel to a membrane support and the subsequent analysis of the fragments by hybridization with a radioactively or chemiluminescently labeled probe (Fig. 15-16). Southern blotting is named after E. M. Southern, who in 1975 first described the technique of DNA analysis. It enables reliable and efficient analysis of size-fractionated DNA fragments in an immobilized membrane support. Southern blotting is composed of several steps. It normally begins with the digestion of the DNA samples with appropriate restriction enzymes, which will discriminate wild-type and mutant DNA by size and the separation of DNA samples in an agarose gel by electrophoresis with appropriate DNA size markers, called the DNA ladder. The DNA gel is stained with a dye, usually ethidium bromide, and photographed with a ruler laid alongside the gel so that band positions can later be identified on the membrane. The DNA gel then is treated so the DNA fragments are denatured (i.e., strand separation). The DNA then is transferred onto a nitrocellulose membrane by capillary diffusion or under electricity. After immobilization, the DNA can be subjected to hybridization analysis, enabling bands with sequence similarity to a radioactively or chemiluminescently labeled probe to be identified.

The development of Southern transfer and the associated hybridization techniques made it possible for the first time to obtain information about the physical organization of single and multicopy sequences in complex genomes. The later application of Southern blotting hybridization to the study of restriction fragment length polymorphisms opened up new possibilities such as genetic fingerprinting and prenatal diagnosis of genetic diseases.

**Northern Blot Hybridization.** Northern blotting refers to the technique of size fractionation of RNA in a gel and the transferring of an RNA sample to a solid support (membrane) in such a manner that the relative positions of the RNA molecules are maintained. The resulting membrane then is hybridized with a labeled probe complementary to the mRNA of interest. Signals generated from detection of the membrane can be used to determine the size and abundance of the target RNA. In principle,
Northern blot hybridization is similar to Southern blot hybridization (and hence its name), with the exception that RNA, not DNA, is on the membrane. Although reverse-transcriptase PCR has been used in many applications (described in the next section, “Polymerase Chain Reaction”), Northern analysis is the only method that provides information regarding mRNA size and has remained a standard method for detection and quantitation of mRNA. The process of Northern hybridization involves several steps, as does Southern hybridization, including electrophoresis of RNA samples in an agarose-formaldehyde gel, transfer to a membrane support, and hybridization to a radioactively labeled DNA probe. Data from hybridization allow quantification of steady-state mRNA levels and, at the same time, provide information related to the presence, size, and integrity of discrete mRNA species. Thus, Northern blot analysis, also termed RNA gel blot analysis, commonly is used in molecular biology studies relating to gene expression.

**Polymerase Chain Reaction.** PCR is an in vitro method for the polymerase-directed amplification of specific DNA sequences using two oligonucleotide primers that hybridize to opposite strands and flank the region of interest in the target DNA (Fig. 15-17).27 One cycle of PCR reaction involves template denaturation, primer annealing, and the extension of

---

**Figure 15-17.** Amplification of DNA using the polymerase chain reaction (PCR) technique. Knowledge of the DNA sequence to be amplified is used to design two synthetic DNA oligonucleotides, each complementary to the sequence on one strand of the DNA double helix at opposite ends of the region to be amplified. These oligonucleotides serve as primers for in vitro DNA synthesis, which is performed by a DNA polymerase, and they determine the segment of the DNA that is amplified. A. PCR starts with a double-stranded DNA, and each cycle of the reaction begins with a brief heat treatment to separate the two strands (Step 1). After strand separation, cooling of the DNA in the presence of a large excess of the two primer DNA oligonucleotides allows these primers to hybridize to complementary sequences in the two DNA strands (Step 2). This mixture is then incubated with DNA polymerase and the four deoxyribonucleoside triphosphates so that DNA is synthesized, starting from the two primers (Step 3). The entire cycle is then begun again by a heat treatment to separate the newly synthesized DNA strands. B. As the procedure is performed over and over again, the newly synthesized fragments serve as templates in their turn, and, within a few cycles, the predominant DNA is identical to the sequence bracketed by and including the two primers in the original template. Of the DNA put into the original reaction, only the sequence bracketed by the two primers is amplified because there are no primers attached anywhere else. In the example illustrated in B, three cycles of reaction produce 16 DNA chains, eight of which (boxed in brown) are the same length as and correspond exactly to one or the other strand of the original bracketed sequence shown at the far left; the other strands contain extra DNA downstream of the original sequence, which is replicated in the first few cycles. After three more cycles, 240 of the 256 DNA chains correspond exactly to the original bracketed sequence, and after several more cycles, essentially all of the DNA strands have this unique length.
the annealed primers by DNA polymerase. Because the primer extension products synthesized in one cycle can serve as a template in the next, the number of target DNA copies nearly doubles at each cycle. Thus, a repeated series of cycles results in the exponential accumulation of a specific fragment in which the termini are sharply defined by the 5' ends of the primers. The introduction of the thermostable DNA polymerase (e.g., Taq polymerase) transforms the PCR into a simple and robust reaction. The reaction components (e.g., template, primers, Taq polymerase, 2'-deoxynucleoside 5'-triphosphates, and buffer) could all be assembled and the amplification reaction carried out by simply cycling the temperatures within the reaction tube. The specificity and yield in amplifying a particular DNA fragment by PCR reaction are affected by the proper setting of the reaction parameters (e.g., enzyme, primer, and Mg²⁺ concentration, as well as the temperature cycling profile). Modifying various PCR parameters to optimize the specificity of amplification yields more homogenous products, even in rare template reactions.

The emergence of the PCR technique has dramatically altered the approach to both fundamental and applied biological problems. The capability of amplifying a specific DNA fragment from a gene or the whole genome greatly advances the study of the gene and its function. It is simple, yet robust, speedy, and most of all, flexible. As a recombinant DNA tool, it underlies almost all of molecular biology. This revolutionary technique enabled the modern methods for the isolation of genes, construction of a DNA vector, introduction of alterations into DNA, and quantitation of gene expression, making it a fundamental cornerstone of genetic and molecular analysis.

**Immunoblotting and Immunoprecipitation.** Analyses of proteins are primarily carried out by antibody-directed immunologic techniques. For example, Western blotting, also called immunoblotting, is performed to detect protein levels in a population of cells or tissues, whereas immunoprecipitation is used to concentrate proteins from a larger pool. Using specific antibodies, microscopic analysis called immunofluorescence and immunohistochemistry is possible for the subcellular localization and expression of proteins in cells or tissues, respectively.

Immunoblotting refers to the process of identifying a protein from a mixture of proteins (Fig. 15-18). It consists of five steps: (a) sample preparation; (b) electrophoresis (separation of a protein mixture by sodium dodecyl sulfate-polyacrylamide gel electrophoresis); (c) transfer (the electrophoretic transfer of proteins from gel onto membrane support [e.g., nitrocellulose, nylon, or polyvinylidene difluoride]); (d) staining (the subsequent immunodetection of target proteins with specific antibody); and (e) development (colorimetric, chemiluminescent, and recently fluorescent visualization of the antibody-recognized protein). Thus, immunoblotting combines the resolution of gel electrophoresis with the specificity of immunochromic detection. Immunoblotting is a powerful tool used to determine a number of important characteristics of proteins. For example, immunoblotting analysis will determine the presence and the quantity of a protein in a given cellular condition and its relative molecular weight. Immunoblotting also can be used to determine whether posttranslational modification such as phosphorylation has occurred on a protein. Importantly, through immunoblotting analysis, a comparison of the protein levels and modification states in normal vs diseased tissues is possible.

Immunoprecipitation, another widely used immunochromic technique, is a method that uses antibody to enrich a protein of interest and any other proteins that are associated with it (Fig. 15-19). The principle of the technique lies in the property of a strong and specific affinity between antibodies and their antigens to locate and pull down target proteins in solution. Once the antibody-antigen (target protein) complexes are formed in the solution, they are collected and purified using small agarose beads with covalently attached protein A or protein G. Both protein A and protein G specifically interact with the antibodies,
thus forming a large immobilized complex of antibody-antigen bound to beads. The purified protein can then be analyzed by a number of biochemical methods. When immunoprecipitation is combined with immunoblotting, it can be used for the sensitive detection of proteins in low concentrations, which would otherwise be difficult to detect. Moreover, combined immunoprecipitation and immunoblotting analysis is very efficient in analyzing the protein-protein interactions or determining the posttranslational modifications of proteins. In addition, immunoprecipitated proteins can be used as preparative steps for assays such as intrinsic or associated enzymatic activities. The success of immunoprecipitation is influenced by two major factors: (a) the abundance of the protein in the original preparation and (b) the specificity and affinity of the antibody for this protein.

Recently, immunoprecipitation is even used to enrich modified DNA (for example, 5-methylcytosine) for bisulfite sequencing. Besides proteins of interest, specific antibodies can also be raised against specially modified DNA. Like the protein immunoprecipitation, modified DNA can be pulled down, taking advantage of the specificity and affinity of antibody to antigen.

**DNA Microarray.** Now that the human genome sequence is completed, the primary focus of biologists is rapidly shifting toward gaining an understanding of how genes function. One of the interesting findings about the human genome is that there are only approximately 25,000 to 30,000 protein-encoding genes. However, it is known that genes and their products function in a complicated and yet orchestrated fashion and that the surprisingly small number of genes from the genome sequence is sufficient to make a human being. Nonetheless, with the tens of thousands of genes present in the genome, traditional methods in molecular biology, which generally work on a one-gene-in-one-experiment basis, cannot generate the whole picture of genome function. In the past several years, a new technology called DNA microarray has attracted tremendous interest among biologists as well as clinicians. This technology promises to monitor the whole genome on a single chip so researchers can have a better picture of the interactions among thousands of genes simultaneously.

DNA microarray, also called gene chip, DNA chip, and gene array, refers to large sets of probes of known sequences orderly arranged on a small chip, enabling many hybridization reactions to be carried out in parallel in a small device (Fig. 15-20).28 Like Southern and Northern hybridization, the underlying principle of this technology is the remarkable ability of nucleic acids to form a duplex between two strands with complementary base sequences. DNA microarray provides a medium for matching known and unknown DNA samples based on base-pairing rules and automating the process of identifying the unknowns. Microarrays require specialized robotics and imaging equipment that spot the samples on a glass or nylon substrate, carry out the hybridization, and analyze the data generated. DNA microarrays containing different sets of genes from a variety of organisms are now commercially available, allowing biologists to simply purchase the chips and perform hybridization and data collection. The massive scale of microarray experiments requires the aid of computers. They are used during the capturing of the image of the hybridized target, the conversion of the image into usable measures of the extent of hybridization, and the interpretation of the extent of hybridization into a meaningful measure of the amount of the complementary sequence in the target. Some data-analysis packages are available commercially or can be found in the core facility of certain institutions.

DNA microarray technology has produced many significant results in quite different areas of application. There are two major application forms for the technology: identification of sequence (gene/gene mutation) in multiple regions of a genome and determination of expression level (abundance) of large numbers of genes simultaneously. For example, analysis of genomic DNA detects amplifications and deletions found in human tumors. Differential gene expression analysis also has uncovered networks of genes differentially present in cancers that cannot be distinguished by conventional means. Significantly, recent advancements in next-generation sequencing (e.g., Solexa and 454 technology) have demonstrated the precision and speed to analyze gene expression in any genome.

**Next-Generation Sequencing.**29,30 First-generation sequencing, also termed Sanger's sequencing, requires a single-stranded DNA template, a specific DNA primer, a DNA polymerase, normal deoxynucleoside triphosphates (dTTPs), and modified di-deoxynucleotidetriphosphates (ddNTPs). In the process of DNA sequencing, DNA polymerase adds random dNTP or ddNTP
Figure 15-20. DNA microarrays. DNA microarrays, also referred to as gene chips, have arrayed oligonucleotides or complementary DNAs (cDNAs) corresponding to tens or hundreds of distinct genes. DNA microarray is used to comparatively analyze gene expression in different cells or tissues. Messenger RNAs (mRNAs) extracted from different sources are converted into cDNAs, which are then labeled with different fluorescent dyes. The two fluorescent cDNA probes are mixed and hybridized to the same DNA microarrays. The ratio of red to green fluorescence at each spot on the chip represents the relative expression of levels of that gene between two different cells. In the example shown in the figure, cDNA from cell #1 is labeled with red fluorescence and that from cell #2 is labeled with green fluorescence. On the microarray, red spots demonstrate that the gene in the cell sample #1 is expressed at a higher level than the corresponding gene in cell sample #2. The green spots indicate that the gene in the cell sample #2 is expressed at a higher level than the corresponding gene in the cell sample #1. Yellow spots represent equal expression of the gene in both cell samples.

after the primer. If ddNTP is incorporated at the end of the chain, it terminates the reaction and results in DNA fragments of different sizes. The ddNTPs could be radioactively or fluorescently labeled for auto-machine detection. Usually, Sanger’s sequencing is able to read sequence below 1 kb with the quality deteriorating after 700 bp. The accuracy and success rate largely depends on the DNA polymerase used.

Recombinant DNA technology greatly impacts the completion of the Human Genome Project due to the invention of shotgun sequencing, which includes breaking the genome DNA into small pieces and randomly cloning those pieces into DNA vectors that are easily sequenced. Based on the overlapping sequence of each clone, computer analysis can be programmed to map and align the DNA sequence that will ultimately cover the whole human genome.

Based on shotgun sequencing, as the sequencing technologies advance, next-generation sequencing (NGS), also called second-generation sequencing, has become one of the most powerful tools to analyze DNA mutation, identify epigenetic modification, and profile gene expression or ncRNA expression. The next-generation sequencing process usually includes library construction, sequencing, and data analysis. There are three major NGS platforms: Roche 454, Life Technologies Ion Torrent, and Illumina Solexa. Take the Illumina next-generation sequencing as an example: DNA are shared or digested into small pieces and then used to generate a DNA library with adapters on both ends of each DNA piece. Then, the DNA library is diluted and loaded on a chamber of a slide, called a lane, for cluster amplification. Cycled fluorescent deoxyribonucleotide triphosphates (dNTPs) are then added to the chamber to enable DNA polymerization, resulting in different fluorescent emission representing different dNTP reading on different clusters, into a microscope. The fluorescent signal is transformed into sequencing data that will be aligned and mapped to a standard genome database. The advantages of next-generation sequencing include the following: no necessity of DNA cloning; fast and cost-effective; and a huge amount of data to give good depth and accuracy of the sequence.

Based on the applications, the most common next-generation sequencing technologies for whole-genome sequencing are whole-genome DNA sequencing, whole-genome bisulfite sequencing (BS-seq), RNA sequencing (RNA-seq), and chromatin immunoprecipitation (ChIP) sequencing (ChIP-seq). Whole-genome DNA sequencing is purely to sequence the DNA sequence of a genome without any preprocessing of the DNA, reflecting any deletions, replications, and mutations within the genomic DNA. Given that the genomic information for human is enormous, to achieve great depth and accuracy the genome needs to be sequenced multiple times to reach statistic significance and pass quality control. Therefore, whole-genome DNA sequencing is still considered to be costly for diagnosis as well as for research purposes. Under clinical settings, one of the most applied DNA sequencing technologies is whole-exome sequencing, i.e., using techniques to capture and analyze exons in all coding genes, given that most known diseases are due to mutations in spliced-in regions of coding genes. Whole-exome sequencing is mostly used for detecting single nucleotide variants and is less reliable in detecting insertion-deletion variants or small copy number variants.

BS-seq is commonly used to identify DNA methylation on the genome (5-methylcytosine [5mC]). The process always involves a bisulfite treatment of DNA before library
construction, during which the unmethylated cytosine will be transformed to a uracil, resulting in reading as a thymine in data output, whereas 5mC is protected and remains as cytosine in data output. Thus, 5mC and cytosine are distinguished this way. To perform whole-genome BS-seq, the library construction starts with a decent amount of DNA followed by a complete conversion of unmethylated cytosine. Because it is also counted as whole-genome sequencing, a certain depth of data needs to be achieved for accurate and convincing results. To develop an affordable genome-wide DNA methylation analysis, the reduced representation bisulfite sequencing (RRBS) approach has been applied to enrich CpG-dense regions of the genome by digesting genomic DNA using a methylation-insensitive restriction enzyme, usually MspI. This method covers a majority of promoters as well as some repetitive regions in the genome. RNA-seq is usually performed to analyze transcription for the same purpose as performing a microarray. However, RNA-seq is more accurate and provides more information such as splicing variants than traditional microarray. Usually, cDNA that is reversely transcribed from extracted RNA is used to generate libraries. Depending on the needs, mRNA and ncRNA can be enriched in different protocols for RNA extraction. Currently, techniques have been improved to perform RNA profiling on a single cell level. Single-cell RNA sequencing (scRNA-seq) allows expression analysis of individual cells in a population. One use is to examine heterogeneity in tumor cells. Although low copy number genes are usually poorly detected, scRNA-seq on a large number of cells can reveal rare cell subpopulations and uncommon RNA expression patterns among different subpopulations.

ChIP-seq is always used to map the location of a DNA-binding protein in the genome. Prior to library construction, ChIP is performed to enrich DNA bound by the protein of interest (POI). First, POI and DNA are cross-linked before sonication. Then, a specific antibody is used to pull down POI and attached DNA fragments. After the protein and DNA are reverse cross-linked, DNA is purified to make the ChIP-seq library. If using an antibody against particular transcription factor (TF), DNA sequences bound by this TF are pulled down and examined. The TF binding consensus sequences is then predicted, and if the TF binds to a promoter region, it is likely that the gene using this promoter is regulated by this TF. If using an antibody against an epigenetic modification, the modified regions are marked up into the genome to facilitate identification of potential epigenetic regulating mechanisms.

By using next-generation sequencing technology, any potential mutations in a patient can be scrutinized as well as any defects in epigenetic modification. By combining data from different kinds of sequencing (DNA-seq, RNA-seq, ChIP-seq), better understanding of mutation or transcription-caused diseases aligning with epigenetic regulation can be achieved, which will greatly facilitate the diagnosis of patients and personalization of medicine in a fast and economic way by preventing unnecessary medical costs and procedures.

Third-generation sequencing has emerged rapidly at the research level to involve single molecule real-time sequencing (SMRT). Although first developed and marketed by Pacific Biosciences (Paci Bio), Roche is now leading this technology. Third-generation sequencing allows amplification-free single-molecule sequencing with read length extension up to megabases and reduced sequencing coverage bias. It can be used to build the gap in the human genome (for example, low complexity regions), provide access to structural genomic variants, and simultaneously analyze genome-wide single-nucleotide methylation. So far, clinical application and research is heavily dependent on NGS, especially standardizing and reducing the cost of post-NGS analysis. Third-generation sequencing is under fast development and has been adapted to aid and append NGS.

**Cell Manipulations**

**Cell Culture.** Cell culture has become one of the most powerful tools in biomedical laboratories, as cultured cells are being used in a diversity of biologic fields ranging from biochemistry to molecular and cellular biology. Through their ability to be maintained in vitro, cells can be manipulated by the introduction of genes of interest (cell transfection) and be transferred into in vivo biologic receivers (cell transplantation) to study the biologic effect of the interested genes (Fig. 15-21). In common

---

**Figure 15-21.** Cell culture and transfection. A. Primary cells can be isolated from tissues and cultured in medium for a limited period of time. After genetic manipulations to overcome the cell aging process, primary cells can be immortalized into cell lines for long-term culture. B. DNA can be introduced into cells to produce recombinant gene products or to analyze the biologic functions of the gene.
laboratory settings, cells are cultured either as a monolayer (in which cells grow as one layer on culture dishes), considered 2-D, or in suspension or biomedical material skeleton such as hydrogel, considered 3-D.

It is important to know the wealth of information concerning cell culturing before attempting the procedure. For example, conditions of culture will depend on the cell types to be cultured (e.g., origins of the cells such as epithelial or fibroblasts, or primary vs immortalized/transformed cells). It is also necessary to use a cell type-specific culture medium that varies in combination of growth factors and serum concentrations. If primary cells are derived from human patients or animals, some commercial resources have a variety of culture media available for testing. Generally, cells are manipulated in a sterile hood, and the working surfaces are wiped with 70% to 80% ethyl alcohol solution. Cultured cells are usually maintained in a humidified 5% carbon dioxide incubator at 37°C (98.6°F) to maintain a pH value raging from 7.2 – 7.4 and need to be examined daily under an inverted microscope to check for possible contamination and confluency (the area cells occupy on the dish). In some cases, cells need to be maintained in hypoxia, and the oxygen input could be reduced to as low as 1%. As a general rule, cells should be fed with fresh medium every 2 to 3 days and split when they reach confluency. Depending on the growth rate of cells, the actual time and number of plates required to split cells in two varies from cell line to cell line. Splitting a monolayer requires the detachment of cells from plates by using a trypsin or collagenase treatment, of which concentration and time period vary depending on cell lines. If cultured cells grow continuously in suspension, they are split or subcultured by dilution.

Because cell lines may change their properties when cultured, it is not possible to maintain cell lines in culture indefinitely. Therefore, it is essential to store cells at various time passages for future use. The common procedure to use is cryopreservation. The solution for cryopreservation is usually fetal calf serum containing 10% dimethyl sulfoxide or glycerol, stored in liquid nitrogen (−196°C [−320.8°F]) for years of preservation. However, the viability and health of cells when thawed will decrease over time even in liquid nitrogen.

**Cell Transfection.** Cells are cultured for two reasons: to maintain and to manipulate them (see Fig. 15–21). The transfer of foreign macromolecules, such as nucleic acid, into living cells provides an efficient method for studying a variety of cellular processes and functions at the molecular level. DNA transfection has become an important tool for studying the regulation and function of genes. The cDNA to be expressed should be in a plasmid vector, behind an appropriate promoter working in mammalian cells (e.g., the constitutively active cytomegalovirus promoter or inducible promoter). Depending on the cell type, many ways of introducing DNA into mammalian cells have been developed. Commonly used approaches include calcium phosphate, electroporation, liposome-mediated transfection, the nonliposomal formulation, and the use of viral vectors. These methods have shown variable success when attempting to transfected a wide variety of cells. Transfection can be performed in the presence or absence of serum. It is suggested to test the transfection efficiency of cell lines of interest by comparing transfection with several different approaches. For a detailed transfection protocol, it is best to follow the manufacturer’s instructions for the particular reagent. General considerations for a successful transfection depend on several parameters, such as the quality and quantity of DNA and cell culture (type of cell and growth phase). To minimize variations in both of these in transfection experiments, it is best to use cells that are healthy, proliferate well, and are plated at a constant density.

Depending on the transfection method, DNA expression can be transient or stable. Using calcium phosphate and liposome-mediated transfection, after DNA is introduced into the cells it is normally maintained epitopically in cells and will be diluted while host cells undergo cell division. Therefore, functional assays should be performed 24 to 72 hours after transfection, also termed transient transfection. In many applications, it is important to study the long-term effects of DNA in cells by stable transfection. Thus, electroporation and viral vector are often used in these situations to enable integration of ectopic DNA into the host genome. Stable cell clones can be selected when plasmids carry an antibiotic-resistant marker. In the presence of antibiotics, only those cells that continuously carry the antibiotic-resistant marker (after generations of cell division) can survive. One application of stable transfection is the generation of transgenic or knockout mouse models, in which the transgene has to be integrated in the mouse genome in the ES cells, followed by microinjection of those transgenic ES cells into blastocysts to generate chimera mice. Stable cells also can be transplanted into host organs to test the effect of transgenic cells in vivo.

**Genetic Manipulations**

Understanding how genes control the growth and differentiation of the mammalian organism has been the most challenging topic of modern research. It is essential for us to understand how genetic mutations and chemicals lead to the pathologic condition of human bodies. The knowledge and ability to change the genetic program will inevitably make a great impact on society and have far-reaching effects on how we think of ourselves.

The mouse has become firmly established as the primary experimental model for studying how genes control mammalian development. Genetically altered mice are powerful tools to study the function and regulation of genes as well as modeling human diseases. The gene function can be studied by creating mutant mice through homologous recombination (gene knockout). A gene of interest (GOI) also can be introduced into the mouse (transgenic mouse) to study its effect on development or diseases. Because mouse models do not precisely represent human biology, genetic manipulations of human somatic or ES cells provide a great means for the understanding of the molecular networks in human cells in addition to mouse models. In all cases, the gene to be manipulated must first be cloned. Gene cloning has been made easy by recombinant DNA technology and the availability of human and mouse genomes (see “Human Genome”). The following section briefly describes the technologies and the principles behind combining both mouse genetics and human cell culture to explore gene function and disease mechanisms.

**Transgenic Mice.** During the past 20 years, DNA cloning and other techniques have allowed the introduction of new genetic material into the mouse germline. As early as 1980, the first genetic material was successfully introduced into the mouse germline by using pronuclear microinjection of DNA (Fig. 15–22). These animals, called transgenic, contain foreign DNA within their genomes. In simple terms, a transgenic mouse is created by the microinjection of ectopic DNA into the one-celled mouse embryo to induce integration, allowing the
efficient introduction of cloned genes into the following developing mouse somatic tissues, as well as into the germline.

**Designs of a Transgene** The transgenic technique has proven to be extremely important for basic investigations of gene regulation, creation of animal models of human disease, and genetic engineering of livestock. The design of a transgene construct is a simple task. Like constructs used in cell transfection, a simple transgene construct consists of a protein-encoding gene and a promoter that precedes it. The most common applications for the use of transgenic mice are similar to those in the cell culture system: (a) to study the functions of proteins encoded by the transgene, (b) to analyze the tissue-specific and developmental-stage–specific activity of a gene promoter, and (c) to generate reporter lines to facilitate biomedical studies. Examples of the first application include overexpression of oncogenes, growth factors, hormones, and other key regulatory genes, as well as genes of viral origins. Overexpression of the transgene normally represents gain-of-function mutations. The tissue distribution or expression of a transgene is determined primarily by cis-acting promoter enhancer elements within or in the immediate vicinity of the genes themselves. Thus, controlled expression of the transgene can be made possible by using an inducible or tissue-specific promoter. Furthermore, transgenic mice carrying dominant negative mutations of a regulatory gene have also been generated. For example, a truncated growth factor receptor that can bind to the ligand, but loses its catalytic activity when expressed in mice, can block the growth factor binding to the endogenous protein. In this way, the transgenic mice exhibit a loss of function of phenotype, possibly resembling the knockout of the endogenous gene. The second application of the transgenic expression is to analyze the gene promoter of interest. The gene promoter of interest normally is fused to a reporter gene that encodes β-galactosidase (also called LacZ), luciferase, or green fluorescence protein. Chemical staining of LacZ activity or detection of chemiluminescence/fluorescence can easily visualize the expression of the reporter gene. The third application originates from the second: when the activity of the promoter is known, a fluorescent reporter gene (such as GFP) will be driven by the tissue-specific promoter, therefore labeling a particular type of cells at a particular stage. This application is generally used to isolate a special cell type expressing the GFP reporter by fluorescence-activated cell sorting (FACS), as well as lineage-tracing experiments.

**Production of Transgenic Mice** The success of generating transgenic mice is largely dependent on the proper quality and concentration of the DNA supplied for microinjection. For DNA to be microinjected into mouse embryos, it should be linearized by restriction digestion to increase the chance of proper transgene integration. Concentration of DNA should be accurately determined. Mice that develop from injected eggs often are termed *founder* mice.

**Genotyping of Transgenic Mice** The screening of founder mice and the transgenic lines derived from the founders is accomplished by determining the integration of the injected gene into the genome. This normally is achieved by performing PCR or Southern blot analysis with a small amount of DNA extracted from the mouse tail. Once a given founder mouse is identified to be transgenic, it will be mated to begin establishing a transgenic line. Usually, for a given gene, more than one transgenic line is generated to assure that the phenotype is due to transgene but not to the interruption of the gene where the transgene integrates into.

**Analysis of Phenotype of Transgenic Mice** Phenotypes of transgenic mice are dictated by both the expression pattern and biologic functions of the transgene. Depending on the promoter and the transgene, phenotypes can be predictable or unpredictable. Elucidation of the functions of the transgene-encoded protein in vitro often offers some clue to what the protein might function to do in vivo. When a constitutively active promoter is used to drive the expression of transgenes, mice should express the gene in every tissue; however, this mouse model may not allow the identification and study of the earliest events in disease pathogenesis. Ideally, the use of tissue-specific or inducible promoter allows one to determine if the pathogenic protein leads to a reversible or irreversible disease process in a cell-autonomous manner. For example, rat insulin promoter can target transgene expression exclusively in the β-cells of pancreatic islets. The phenotype of insulin promoter-mediated transgenic mice is projected to affect the function of human β-cells.

**Gene Knockout in Mice.** The first recorded knockout mouse was created by Mario R. Capecchi, Sir Martin J. Evans, and Oliver Smithies in 1989. They were awarded the 2007 Nobel Prize in Physiology or Medicine. The isolation and genetic manipulation of mouse ES cells represents one of the most important milestones for modern genetic technologies. Several unique properties of ES cells, such as the pluripotency to differentiate into all germ layers in an embryo, including the germline, make them an efficient vehicle to introduce genetic alterations in mice. An important breakthrough from this idea is to generate gene-targeted mutation in mice, first by introducing the targeting vector into the ES cells, allowing selection...

Figure 15-23. Knockout mouse technology. Summary of the procedures used for making gene replacements in mice. In the first step (A), an altered version of the gene is introduced into cultured embryonic stem (ES) cells. Only a few rare ES cells will have their corresponding normal genes replaced by the altered gene through a homologous recombination event. Although the procedure is often laborious, these rare cells can be identified and cultured to produce many descendants, each of which carries an altered gene in place of one of its two normal corresponding genes. In the next step of the procedure (B), these altered ES cells are injected into a very early mouse embryo; the cells are incorporated into the growing embryo, and a mouse produced by such an embryo will contain some somatic cells that carry the altered gene. Some of these mice also will contain germline cells that contain the altered gene. When bred with a normal mouse, some of the progeny of these mice will contain the altered gene in all of their cells. If two such mice are in turn bred (not shown), some of the progeny will contain two altered genes (one on each chromosome) in all of their cells. If the original gene alteration completely inactivates the function of the gene, these mice are known as knockout mice. When such mice are missing genes that function during development, they often die with specific defects long before they reach adulthood. These defects are carefully analyzed to help decipher the normal function of the missing gene.

for successful homologous recombination in a dish, then introducing the selected ES clone into the blastocysts, and finally recovering animals bearing the mutant allele from the germline (Fig. 15-23). This not only makes mouse genetics a powerful approach to address important gene functions, but also identifies the mouse as a great system to model human disease.

Targeting Vector The basic concept in building a target vector to knock out a gene is to use two segments of homologous sequence to a GOI that flank a part of the gene essential for functions (e.g., the coding region). In the targeting vector, a positive selectable marker (e.g., the neo gene) is placed between the homology arms. Upon the homologous recombination between the arms of the vector and the corresponding genomic regions of the GOI in ES cells, the positive selectable marker will replace the essential segment of the target gene, thus creating a null allele. In addition, a negative selectable marker also can...
be used alone or in combination with the positive selectable marker, but must be placed outside of the homologous arms to enrich for homologous recombination. To create a conditional knockout (i.e., gene knockout in a spatiotemporal fashion), site-specific recombinases such as the popular cre-loxP system are used. If the consensus loxP sequences that are recognized by cre recombinases are properly designed into targeting loci, controlled expression of the recombinase as a transgene can result in the site-specific recombination at the right time and in the right place (i.e., cell type or tissue). This method, often referred to as conditional knockout, is markedly useful to prevent developmental complications and to introduce null mutations in the adult mouse that would otherwise be lethal. To bring in additional control to tissue-specific cre, an inducible cre could be adopted on top of the tissue-specific promoter. The most popular inducible cre includes CreER: CreER encodes a cre fused with estrogen receptor located to cytosol. With the signaling of tamoxifen, CreER is released and then translocates into the nucleus to induce the recombination of loxP. Therefore, the timing of recombination could be precisely determined by controlling the time of administering tamoxifen. Overall, this cre-loxP system allows for spatial and temporal control over transgene expression and takes advantage of inducers with minimal pleiotropic effects.

**Introduction of the Targeting Vector into ES Cells** ES cell lines can be obtained from other investigators or commercial sources or established from blastocyst-stage embryos. To maintain ES cells at their full developmental potential, optimal growth conditions should be provided in culture. If culture conditions are inappropriate or inadequate, ES cells may acquire genetic lesions or alter their gene expression patterns and consequently decrease their pluripotency. Excellent protocols are available in public domains or in mouse facilities in most institutions.

To alter the genome of ES cells, the targeting vector DNA then is transfected into ES cells. Electroporation is the most widely used and the most efficient transfection method for ES cells. Similar procedures for stable cell transfection are used for selecting ES cells that carry the targeting vector. High-quality, targeting-vector DNA free of contaminating chemicals is first linearized and then electroporated into ES cells. Stable ES cells are selected in the presence of a positive selectable antibiotic drug. After a certain period of time and depending on the type of antibiotics, all sensitive cells die, and the resistant cells grow into individual colonies of the appropriate size for subcloning by picking. It is extremely important to minimize the time during which ES cells are in culture between selection and injection into blastocysts. Before injecting the ES cells, DNA is prepared from ES colonies to screen for positive ES cells that exhibit the correct integration or homologous recombination of the targeting vector. Positive ES colonies are then expanded and used for creation of chimeras.

**Creation of the Chimera** A chimeric organism is one in which cells originate from more than one embryo source. Here, chimeric mice are denoted as those that contain some tissues from the ES cells with an altered genome. When these ES cells give rise to the lineage of the germ layer, the germ cells carrying the altered genome can be passed on to the offspring, thus creating the germline transmission from ES cells. There are two methods for introducing ES cells into preimplantation-stage embryos: injection and aggregation. The injection of embryonic cells directly into the cavity of blastocysts is one of the fundamental methods for generating chimeras, but aggregation chimeras also have become an important alternative for transmitting the ES cell genome into mice. Since every tissue type of a chimera should contain cells from different origins, the mixture of recognizable markers (e.g., coat color) that are specific to the donor mouse and the ES cells can be used to identify chimeric mice. However, most experimenters probably use existing mouse core facilities already established in some institutions or contract a commercial vendor for the creation of a chimera.

**Genotyping and Phenotyping of Knockout Animals** The next step is to analyze whether germline transmission of targeted mutation occurs in mice. DNA from a small amount of tissue from offspring of the chimera is extracted and subjected to genomic PCR or Southern blot DNA hybridization. Positive mice (i.e., those with properly integrated targeting vector into the genome) will be used for the propagation of more knockout mice for phenotype analysis. When the knockout genes are crucial for early embryogenesis, mice often die in utero, an occurrence called embryonic lethality. When this happens, only the phenotype of the homozygous (both alleles ablated) knockout mouse embryos and the phenotype of the heterozygous (only one allele ablated) adult mice can be studied. Because most researchers are interested in the phenotype of adult mice, in particular when using mice as disease models, it is recommended to create the conditional knockout using the cre-loxP system so that the GOI can be knocked out at will.

To date, more than 5000 genes have been disrupted by homologous recombination and transmitted through the germline. The phenotypic studies of these mice provide ample information about the functions of these genes in growth and differentiation of organisms and during development of human diseases.

**RNA Interference.** Although gene ablation in animal models provides an important means to understand the in vivo functions of GOI, animal models may not adequately represent human biology. Alternatively, gene targeting can be used to knock out genes in human cells, including human ES cells. Gene targeting in human ES cells by homologous recombination has extremely low efficiency, although there are more new techniques emerging at increasing the targeting efficiency. A number of recent advances have made gene targeting in somatic cells as easy as in murine ES cells. However, gene targeting (knocking out both alleles) in somatic cells is a time-consuming process.

Development of RNAi technology in the past few years has provided a more promising approach to understanding the biologic functions of human genes in human cells. RNAi is an ancient natural mechanism by which small, double-stranded RNA (dsRNA) acts as a guide for an enzyme complex that destroys complementary RNA and downregulates gene expression in a sequence-specific manner. Although the mechanism by which dsRNA suppresses gene expression is not entirely understood, experimental data provide important insights. In nonmammalian systems such as Drosophila, it appears that longer dsRNA is processed into 21–23 nt dsRNA (called small interfering RNA or siRNA) by an enzyme called Dicer containing RNase III motifs. The siRNA apparently then acts as a guide sequence within a multicompartment nuclease complex to target complementary mRNA for degradation. Because long dsRNA induces a potent antiviral response pathway in mammalian cells, short siRNAs are used to perform gene silencing experiments in mammalian cells (Fig. 15-24).
For siRNA studies in mammalian cells, researchers have used two 21-mer RNAs with 19 complementary nucleotides and 3′ terminal noncomplementary dimers of thymidine or uridine. The antisense siRNA strand is fully complementary to the mRNA target sequence. Target sequences for an siRNA are identified visually or by software.

The target 19 nucleotides should be compared to an appropriate genome database to eliminate any sequences with significant homology to other genes. Those sequences that appear to be specific to the GOI are the potential siRNA target sites. A few of these target sites are selected for siRNA design. The antisense siRNA strand is the reverse complement of the target sequence. The sense strand of the siRNA is the same sequence as the target mRNA sequence. A deoxythymidine dimer is routinely incorporated at the 3′ end of the sense strand siRNA, although it is unknown whether this noncomplementary dinucleotide is important for the activity of siRNAs.

There are two ways to introduce siRNA to knock down gene expression in human cells:

1. RNA transfection: siRNA can be made chemically or using an in vitro transcription method. Like DNA oligos, chemically synthesized siRNA oligos can be commercially ordered. However, synthetic siRNA is expensive, and several siRNAs may have to be tried before a particular gene is successfully silenced. In vitro transcription provides a more economic approach. Both short and long RNA can be synthesized using bacteriophage RNA polymerase T7, T3, or SP6. In the case of long dsRNAs, RNase such as recombinant Dicers will be used to process the long dsRNA into a mixture of 21–23 nt siRNA. siRNA oligos or mixtures can be transfected into a few characterized cell lines such as HeLa (human cervical carcinoma) and 293T cells (human kidney carcinoma). Transfection of siRNA directly into primary cells may be difficult.

2. DNA transfection: Expression vectors for expressing siRNA have been made using RNA polymerase III promoters such as U6 and H1. These promoters precisely transcribe a hairpin structure of dsRNA, which will be processed into siRNA in the cell (see Fig. 15-24). Therefore, properly designed DNA oligos corresponding to the desired siRNA will be inserted downstream of the U6 or H1 promoter. There are two advantages of the siRNA expression vectors over siRNA oligos. First, it is easier to transfect DNA into cells. Second, stable populations of cells can be generated that maintain the long-term silencing of target genes. Furthermore, the siRNA expression cassette can be incorporated into a retroviral or adenoviral vector to provide a wide spectrum of applications in gene therapy.

There has been a fast and fruitful development of RNAi tools for in vitro and in vivo use in mammals. These novel approaches, together with future developments, will be crucial to put RNAi technology to use for effective disease therapy or to exert the awesome power of mammalian genetics. Therefore, the applications of RNAi to human health are enormous. siRNA can be applied as a new tool for sequence-specific regulation of gene expression in functional genomics and biomedical studies. With the availability of the human genome sequences, RNAi approaches hold tremendous promise for unleashing the dormant potential of sequenced genomes.

There is the potential of sequenced genomes. RNAi approaches hold tremendous promise for unleashing the dormant potential of sequenced genomes.

Figure 15-24. RNA interference in mammalian cells. Small interfering RNA (siRNA) can be produced from a polymerase III–driven expression vector. Such a vector first synthesizes a 19–29 nt double-stranded (ds)RNA stem and a loop (labeled as shRNA in the figure), and then the RNase complex called Dicer processes the hairpin RNA into a small dsRNA (labeled as siRNA in the figure). siRNA can be chemically synthesized and directly introduced into the target cell. In the cell, through RNA-induced silencing complex (RISC), siRNA recognizes and degrades target messenger RNAs (mRNAs).
the human genome blueprint, the promise of gene therapy and molecular therapies, and the existence of stem cells have captured the imagination of the public and the biomedical community. Aside from their potential in curing human diseases, these emerging technologies also have provoked many political, economic, religious, and ethical discussions. As more is discerned about the technologic scientific advances, more attention must also be paid to concerns for their inherent risks and social implications. It is important for surgeons to play a leadership role in the emergence of personalized medicine and surgery, as surgeons have access to the diseased tissues. Surgeons should be establishing collaborations with the genomic and molecular scientists to develop genomic biobanks in order to study the genome and molecular signaling of the disease tissues that will help with an understanding of the underlying cause of an individual’s disease and ultimately lead to effective, targeted therapies. Surgeons must take this enormous opportunity to collaborate with basic and clinical scientists to develop the field of precision medicine and surgery this century.

Bifunctional RNAi Technology. Over the last 20 years, the field has worked to define oncogene and nononcogene addiction, discriminate between driver and passenger genes, and appreciate the complexity of complex, robust, network interactions. These insights have led to a preliminary understanding of therapeutically relevant sensitivity and resistance pathway signal patterns requiring multiple target modulation. However, this knowledge has not been effectively or reproducibly clinically translated. Clinical response is usually far greater when a combination of single-target molecular therapy is administered. However, it must also be realized that targeting two or more pathways may also increase the toxicity profile, particularly if target specificity is limited. When attempted, off-target toxicity has been demonstrated with combination small-molecule therapy. In contrast, multitargeting bifunctional short hairpin (bi-shRNA) DNA vectors are designed to limit off-target effect given the high specificity for the genes they are designed to target.

Exogenously applied hairpin constructs can be designed to be incorporated into cleavage-dependent RISC or cleavage-independent RISC complexes, or both. The concept of a bifunctional shRNA is to increase knockdown efficiency without loss of sequence specificity by engaging both siRNA and miRNA-like (i.e., common biogenic pathway but complementary to target sequence) RISCs, thereby concurrently activating nucleolytic (Ago2-RISC) and nonnucleolytic (Ago1, 3, 4 ± Ago2-RISC) processes. Each bi-shRNA contains both a matched stem sequence to promote Ago2-mediated passenger strand cleavage and a second partial mismatched stem sequence for cleavage-independent passenger strand departure. Thus, functionality of the effectors is set by programmed passenger strand guided RISC loading rather than Ago subset distribution in the cancer cell. Both component Ago2 and Ago (1, 2, 4 ± 3) RNAi moieties are fully complementary to the mRNA target sequence. Preliminary data indicate reduced “off-target effects” by shRNA compared with target-identical siRNAs. More than two mismatches in sequences within the target region drastically reduce knockdown effect to undetectable levels (unpublished results). The design process involves in silico scanning of the entire human mRNA RefSeq database to avoid any potential sequence-related “off-target effects.” Published data also indicate persistent susceptibility to shRNA-mediated gene knockdown despite recent evidence of reduced Dicer expression in human cancer cells.

The first clinical experience with the bi-shRNA platform involved the ex vivo knockdown of furin, a Ca2+-dependent, nonredundant proprotein convertase that is essential for proteolytic maturational processing of immunosuppressive TGF-β isoforms (β1 and β2). An autologous whole-cell cancer vaccine, FANG™ (furin-knockdown and GMCSF-augmented), was produced based on a dual function immunosensitization principle of augmenting tumor antigen expression, presentation, and processing via granulocyte-macrophage colony-stimulating factor (GMCSF) cytokine transgene expression and attenuating secretory immunosuppressive TGF-β. Harvested, autologous cancer cells are transfected with the GMCSF/bi-shRNAfurin (FANG) expression plasmid via electroporation. A phase I clinical trial (BB-IND 14205) involving 52 cancer patients was recently completed. Results demonstrated better than 90% knockdown of the bi-shRNA target, furin, and better than 90% knockdown of furin-regulated proteins TGF-β1 and TGF-β2, thereby confirming the mechanistic expectation of this novel RNAi platform. Moreover, predicted extensive GMCSF expression verified our ability to successfully construct multi-cassette vectors with good manufacturing practice techniques fulfilling Food and Drug Administration requirements for clinical testing.

Twenty-seven patients received one or more vaccine dose, and 23 patients achieved stable disease as their best response. No toxic effect was identified. Median survival of the FANG™-treated patients from time of procurement was 554 days and has not been reached from time of treatment. Expected survival of similar patients is historically less than 1 year. Sequential enzyme-linked immunosorbent spot (ELISPOT) analysis revealed a dramatic and significant increase in immune response from baseline to month 4 in half of the FANG™-treated patients. Comparison of survival between ELISPOT-positive and ELISPOT-negative patients demonstrated a statistically significant increase in survival from time of procurement (P = .045) and time of treatment (P = .025).

These phase 1 study results demonstrated mechanism, safety, and effectiveness of the bi-shRNA technology and clinical functionality of a multitargeting (dual) DNA expression vector. Further utilization of bi-shRNAi technology is under way clinically (targeting STMN1, a microtubule modulation critical to cancer program) and preclinically targeting PDX1 (an oncogene-like transcription factor for pancreatic embryogenesis using nonviral nanoparticle delivery mechanisms).

Precision Medicine and Surgery

Genes determine our susceptibility to diseases and direct our body’s response to medicine. Because an individual’s genes differ from those of another, the determination of each individual’s genome has the potential to improve the predication, prevention, and treatment of disease. Sequencing of individual genomes holds the key to realize this revolution called precision medicine and surgery. Next-generation sequencing, such as Illumina sequencing and 454 pyrosequencing technology, is promising to reduce the time and cost so that genome sequencing can be affordable within healthcare systems. The goal of precision medicine and surgery is to identify the gene variations in each individual and to target the specific gene variations causing the disease by choosing personalized treatments that effectively work in association with the individual’s genomic profile. The importance of surgeons in this transformational field of
biomedical science is that surgeons have access to the diseased tissues on a daily basis. Surgeons should partner with the genomic scientists to develop genomic biobanks in order to study the genome of the disease tissues and determine how this information can improve the outcomes of surgery, i.e., precision surgery. These discovery studies are rapidly leading to the uncovering of mutations and SNPs that are the underlying cause of an individual’s disease and ultimately lead to targeted therapies. Although precision medicine and surgery holds the potential to revolutionize the practice of modern medicine, there currently exists a gap between our ability to sequence any given individual’s genome and how clinicians can apply this information to guide care. There is a rapidly growing list of single genes that are currently guiding care, and these genes are listed as type 1 precision genes. Examples of these genes are *BRCA1*, *RET* proto-oncogene, and *CHD1* mutation, which guide potential use of mastectomy, thyroidectomy, and gastrectomy, respectively; however, the great challenge before the scientific and medical community this century is to learn to use the entire genome to guide precision care.

**Targeted Genome Editing Using the CRISPR-Cas9 System**

Conventional genetic manipulations have proven their value in biomedical research. Researchers today depend on the manipulation of genetic materials in cells or in animal models in almost every project they work on. These genetic manipulation techniques (see “Genetic Manipulations”), though sufficient for general research purposes, suffer from disadvantages. Transfection of target genes into cells is quick and specific, but nonnative. RNA interference (RNAi) is easy to perform and targets native genes, but RNAi never fully eliminates the target gene, and off-target effects are commonly seen using RNAi. Gene knockout mice provide an ideal platform to study native genes with clean background, but conventional knockout methods are time-consuming and costly.

An entirely new gene-editing method now known as the CRISPR-Cas9 system has emerged since 2013 and has quickly gained popularity among biologists for gene editing. This new method is easy to perform, can work specifically on the desired gene or DNA sequence, and can generate gene knockout, knock-in, point mutation, or the insertion of an epitope tag in almost any cell line or animal models with high efficiencies.

CRISPR stands for Clustered Regularly Interspaced Short Palindromic Repeats. It is a region on the genomic DNA first discovered in the microbes as an adapted immune system against exogenous DNA. A typical CRISPR region contains a cluster of short (21–48 bp) DNA repeats (ranging from 2 to hundreds) interspaced by nonrepetitive sequences called spacers. Within a CRISPR region, while each spacer has its unique sequence, the sequence of the repeats is highly conserved. Several genes, called the CRISPR-associated (Cas) genes, are almost always found directly flanking the CRISPR region.

Extensive studies in the past decade revealed the function of the CRISPR-cas system in DNA-interfering. When bacteria or archaea carrying the CRISPR-cas system are invaded by phage or plasmid DNA, a new spacer can be added to the CRISPR region with its sequence identical to the “proto-spacer,” a fragment of the invading DNA. It was found that the proto-spacer must be followed by a recognition sequence (NGG in the case of Cas9) called proto-spacer associated motif (PAM). With constitutive transcription, the CRISPR region is transcribed as mRNA, and cut by Cas proteins to generate RNA fragments minimally containing one spacer and parts of the repetitive sequence. This fragment associates with target DNA through Watson-Crick base-pairing and directs the cutting of target DNA by Cas proteins with nuclease activity.

Several CRISPR-Cas systems have been characterized, with a variety of Cas proteins found in these systems. Cas9 in the type II system from *Streptococcus pyogenes* is the most commonly used Cas for gene editing. Cas9 contains one RuvC-like nuclease domain near its N-terminal and one HNH-like nuclease domain in the middle of the protein. The RuvC-like domain cuts the proto-spacer strand (the strand with PAM), and the HNH-like domain cuts the strand pairing with the spacer, resulting in a double-strand break (DSB) on the target DNA. It is known that Cas9 cuts a blunt end 3 bp 5’ to the PAM sequence. The specificity provided by the spacer, or so-called “guide RNA,” and the ability of Cas9 to cut double-stranded DNA means that this system can specifically target anywhere in a genome with a known sequence.

**CRISPR-Cas9–Guided Gene Editing.** The CRISPR-Cas9 system was made suitable for gene editing in mammalian cell lines and in animal models through several years of optimization. The key concept for CRISPR-Cas9–mediated gene editing is to introduce DNA strand break and let the cell repair the break. Through the repair process, sequence deletions, insertions, and mutations can be applied to the target gene.

Two DNA repair pathways are utilized in CRISPR-Cas9–mediated gene editing: the nonhomologous end-joining (NHEJ) pathway and the homology-directed repair (HDR). When a homologous repair template is unavailable, the NHEJ pathway joins the ends of the DSB together, usually with random insertion/deletion (indel) mutations. Such mutations within an open reading frame can cause frameshift and/or premature stop codons. When a repair template is available, however, the cell may choose HDR and repair the DSB through pairing with the template. The HDR pathway can introduce longer insertion/deletion mutations than NHEJ and can specify the mutated sequence (by contrast, NHEJ creates random mutations). However, HDR is usually only active in dividing cells and is of a lower efficiency than NHEJ. Its efficiency also depends on gene location, cell type, and the repair template. Therefore, the choice of the pathway depends on the need of the outcome: to simply create a gene knockout, NHEJ is much simpler and highly efficient; to achieve precise gene editing (introduce a specific mutation, add or delete a specific sequence), HDR must be used. The two pathways have similar protocols, but they differ in certain details in experimental designs.

**Gene Editing Through NHEJ** Tools for NHEJ-mediated gene editing can be incorporated onto one simple plasmid, including a single-guide RNA (sgRNA) sequence containing the guide RNA, a U6 promoter driving the expression of the sgRNA, and an expression cassette including codon-optimized Cas9 fused with nuclear localization sequences (NLS) and an optional selection marker (puromycin resistance or a GFP). NHEJ is usually used to knock out a target gene (Fig. 15-24). Generally, a 20 bp sequence preceding a PAM sequence (NGG for Cas9) is selected as the guide RNA sequence. This sequence can be chosen within the first couple of exons through running online search engines against the target genome to minimize off-target probabilities. The guide RNA sequence is then inserted into the
Figure 15-25. CRISPR-Cas9–mediated gene editing through NHEJ or HDR. The Cas9 protein cleaves target DNA through its RuvC-like and HNH-like domains, guided by the sgRNA. The cell repairs the double-strand break through either NHEJ or HDR. In NHEJ, the broken ends are recognized, bound, and tethered by end-binding protein complexes. The ends are then processed and ligated but may result in random insertion/deletion (experimentally, deletions are more commonly seen) mutations at the break site. The repair process in HDR, however, generates no random error due to the presence of a homologous repair template. During the repair, the broken strands find the homologous template and proceed with DNA synthesis using the template. This results in a repaired DNA that has the same sequence as the repair template. Therefore, point mutations, insertions, or deletions carried on the template will be inherited by the repaired DNA and thus achieve precise gene editing.

Designed site within the sgRNA, and the constructed plasmid is transfeeted into target cells. Expressed Cas9 proteins would associate with expressed sgRNAs to mediate DSB directed by the guide RNA sequence. For cell lines, pure mutant clones can be generated by separating single colonies. Knockout mutations can be confirmed through PCR amplification of the target region be generated by separating single colonies. Knockout mutations can be confirmed through PCR amplification of the target region and sequencing. If antibodies against the target protein are available, western blotting can be used as a supplemental method to DNA sequencing results to confirm the knockout of the gene.

Gene Editing Through HDR HDR requires a homologous template to repair the DSB. Therefore, apart from the guide RNA, another sequence homologous to the flanking regions of the DSB needs to be present (Fig. 15-25). The homologous sequence can carry insertions, deletions, and mutations to replace the sequence at the DSB, thus achieving precise gene editing on the target. The homologous sequence can be introduced into the cell either as a template on a plasmid or as a single-stranded oligonucleotide. After the induction of the DSB, the homologous template pairs with the flanking regions of the DSB and serves as the template for the repair of the break site. HDR happens at lower efficiency than NHEJ and therefore is of lower success rate than NHEJ-mediated gene editing. Therefore, HDR is only recommended when precise mutations are desired. Fast screen of positive mutant clones can be achieved by incorporating restriction enzyme cutting sites within the homologous template.

Reducing Off-Target Effects Using Cas9 Nickase The CRISPR-Cas9 system uses a 20 bp guide RNA for sequence recognition. Due to the similar length of recognition sequence to RNAi techniques, CRISPR-Cas9 system also suffers from off-target effects. Because CRISPR-Cas9 requires a PAM site directly following the guide RNA sequence, one way to reduce off-targets is to run through online databases against the genome of the target cell to select a target sequence with the least number of possible off-targets (CRISPR-Cas9 system tolerates no more than three mismatches). On the other hand, a mutant version of the Cas9 called Cas9 nickase can be used to minimize the risk of off-targets.

As mentioned, Cas9 contains one RuvC-like and one HNH-like nuclease domain, each responsible for cutting one strand. The D10A mutant Cas9 (Cas9 nickase) lacks the activity of the RuvC-like domain, leaving the proto-spacer strand intact and a nick on the antisense strand. Using two properly spaced (0–20 bp apart), oppositely oriented guide RNA, the Cas9 nickase will leave two single-strand nicks on both strands in close proximity, creating a double-strand break with 5’ overhangs on both strands. This leads to NHEJ or HDR at this breaking site, while other off-target single-strand nicks will be repaired without impact. This strategy doubles the number of base pairs required for site recognition, reducing off-target possibilities almost to zero (from about 1 off-target in 30 million bp to 1 in 1000 trillion bp).

Application of the CRISPR-Cas9 System in Biomedical Sciences The biggest advantage of the CRISPR-Cas9 system is its ability to edit genes in almost any cell type and any animal model with high efficiency and accuracy. Plus, it is easy to design and easy to use. Within a couple of years, successful gene editing in C. elegans, zebrafish, fruit fly, mouse, dogs, and even nonhuman primates was achieved. CRISPR-Cas9 was also reported to be successful in a variety of cell types including stem cells.

Currently, CRISPR-Cas9 is most used for editing single genes, through gene knockout, gene mutation, or the addition of an epitope tag to a native gene, for functional characterization of the gene of interest. For example, oncogenes or tumor suppressor genes can be knocked out to identify the causative gene for a particular cancer type; point mutations in functional domains
may illustrate the mechanism of action of a protein; for proteins without available antibodies, epitope tags can be inserted onto the native gene for the detection of the native protein.

Apart from single gene editing, CRISPR-Cas9 can be used for large scale loss-of-function gene screen. Multiple lentiviral guide RNA libraries have been established covering the whole human/mouse genome or particular subsets.

Owing to its ability to bind to specific nucleotide sequences, CRISPR-Cas9 has also been used for non–gene-editing purposes. To achieve this, both the RuvC-like and the HNH-like domains are mutated to give a catalytically inactive Cas9 (dCas9). Directed by guide RNA, this dCas9 can bind to particular genes to reversibly suppress or activate gene transcription by the fusion of transcription activators or suppressors with dCas9. Epigenetic modulators (e.g., DNA methylase) can also be fused with dCas9 to achieve controlled epigenetic modulations. Moreover, dCas9 can also be fused with fluorescent markers such as GFP to track a particular DNA region in live cells.

The most exciting potential application of the CRISPR-Cas9 system is perhaps the correction or modification of disease-causing genes in human embryos or in human patients to eradicate disease-causing genes. However, extension of this application may lead to the creation of the so called “perfect human,” hence raising huge ethical concerns and controversies.57 Because of such ethical considerations, gene editing in human embryos should be cautiously conducted. Nonetheless, reports have shown the great potential of this powerful gene-editing technique in correcting gene mutations.58-60

In conclusion, the CRISPR-Cas9 system is the most powerful gene-editing system characterized so far, showing its strong ability to edit genes efficiently and precisely. Its applications greatly benefit biomedical researches and, with a solution to ethical issues, can greatly benefit clinical medicine as well.

INTRODUCTION

The skin is a complex organ encompassing the body's surface and is continuous with the mucous membranes. Accounting for approximately 15% of total body weight, it is the largest organ in the human body. Enabled by an array of tissue and cell types, intact skin protects the body from external insults. However, the skin is also the source of a myriad of pathologies that include inflammatory disorders, mechanical and thermal injuries, infectious diseases, and benign and malignant tumors. The intricacies and complexities of this organ and associated pathologies are reasons the skin and subcutaneous tissue remain of great interest and require the attention of various surgical disciplines that include plastic surgery, dermatology, general surgery, and surgical oncology.

ANATOMY AND HISTOLOGY

Background

It is important that surgeons understand completely the cutaneous anatomy and its variability as they play an enormous role in patient health and satisfaction. The skin is made up of tissues derived from both the ectodermal and mesodermal germ cell layers. Three distinct tissue layers comprise the organ, and differ in composition based on location, age, sex, and ethnicity, among other variables. The outermost layer is the epidermis, which is predominantly characterized by a protective, highly keratinized layer of cells. The next layer is the dermis, which is made up of an organized collagen network to support the numerous epidermal appendages, neurovascular structures, and supportive cells within the skin. The fatty layer below the dermis is collectively known as the hypodermis and functions in body processes of thermoregulation and energy storage, among others. These three distinct layers function together harmoniously and participate in numerous activities essential to life.

Epidermis

The epidermis is the outermost layer of the cutaneous tissue, and consists primarily of continually regenerating keratinocytes. The tissue is also stratified, forming four to five histologically distinct layers, depending on the location in the body. These layers are, from deep to superficial, the stratum basale, stratum spinosum, stratum granulosum, stratum lucidum and stratum corneum (Fig. 16-1). The different layers of the epidermis represent layers of keratinocytes at differing stages of their approximately thirty-day life cycle. A minority of other cell types are found in different layers of the epidermis as well. Some of these cells are permanent residents, while others are visitors from other parts of the body. All the epidermal appendages, such as sweat glands and pilosebaceous follicles, are derived from this tissue. The thickness of the epidermis is quite variable with regard to location and age, ranging from 75 to 150 µm in thin skin (eyelids) to 0.4 to 1.5 mm in thick skin (palms and soles). The epidermis lacks any vascular
Key Points

1. The epidermis consists of continually regenerating stratified epithelium, and 90% of cells are ectodermally derived keratinocytes.

2. Pilosebaceous units are lined by the germinal epithelium of the epidermis and thus serve as an important source of epidermal regeneration after partial-thickness injury or split-thickness skin graft.

3. Dermal fibers are predominantly made of type I and III collagen in a 4:1 ratio. They are responsible for the mechanical resistance of skin.

4. The drugs most commonly associated with epidermal necrolysis include aromatic anticonvulsants, sulfonamides, allopurinol, oxicams (nonsteroidal anti-inflammatory drugs), and nevirapine.

5. In wounds being allowed to heal secondarily, negative pressure wound therapy can increase the rate of granulation tissue formation.

6. Staphylococcus aureus is the most common isolate of all skin infections. Impetigo, cellulitis, erysipelas, folliculitis, furuncles, and simple abscesses are examples of uncomplicated infections, whereas deep-tissue infections, extensive beginning of the life cycle of the keratinocytes of the epidermis. This layer is bound to its basement membrane by complexes made of keratin filaments and anchoring structures called hemidesmosomes. They are bound to other keratinocytes by structures called desmosomes. High mitotic activity and thus large nuclei and basophilic staining characterize the stratum basale on light microscopy. This layer also lines the epidermal appendages that reside largely within the substance of the dermis and later serves as a regenerative source of epithelium in the event of partial thickness wounds.

7. Hemangiomas arise from benign proliferation of endothelial cells surrounding blood-filled cavities. They most commonly present after birth, rapidly grow during the first year of life, and gradually involute in most cases.

8. Basal cell carcinoma represents the most common tumor diagnosed in the United States, and the nodular variant is the most common subtype. The natural progression of basal cell carcinoma is one of local invasion rather than distant metastasis.

9. Squamous cell carcinoma is the second most common skin cancer, and typically arises from an actinic keratosis precursor. Primary treatment modalities are surgical excision and Mohs microsurgery. Cautery and ablation, cryotherapy, drug therapy, and radiation therapy are alternative treatments.

10. Tumor thickness, ulceration, and mitotic rate are the most important prognostic indicators of survival in melanoma. Sentinel lymph node biopsy is often used to stage individuals with biopsy-proven high risk melanoma and clinically node-negative disease.

Figure 16-1. Schematic representation of the skin and its appendages. Note that the root of the hair follicle may extend beneath the dermis into the subcutis.
The next layer is the stratum spinosum, or “spiny” layer. This layer is from five to fifteen cells in thickness and is so named due to the spinous appearance of the intercellular desmosomal attachments under light microscopy. The production of keratin in this cell layer is responsible for their eosinophilic appearance on hematoxylin and eosin (H&E) staining.

As the keratinocytes continue to migrate superficially, they begin to flatten and develop basophilic keratohyalin granules. There are also structures called lamellar granules within these cells that contain the lipids and glycolipids that will ultimately undergo exocytosis to produce the lipid layer around the cells. It is in this layer that the keratinocytes manufacture many of the structures that will eventually serve to protect the skin and underlying tissues from environmental insult. At the superficial aspect of this layer, the keratinocytes begin to undergo programmed cell death, losing all cellular structures except for the keratin filaments and their associated proteins. In thick skin, such as that found on the palms and soles, there is a layer of flat, translucent keratinocytes called the stratum lucidum.

The final stage of the keratinocyte life cycle results in the layer of the epidermis known as the stratum corneum, or cornified layer. The protein-rich, flattened keratinocytes are now anucleate and surrounded by a lipid-rich matrix. Together the cells and surrounding matrix of this layer serve to protect the tissue from mechanical, chemical, and bacterial disruption while preventing insensible water losses through the skin.

Langerhans Cells. Of the cells in the epidermis, 3% to 6% are immune cells known as Langerhans cells. Typically found within the stratum spinosum, these mobile, dendritic cells interdigitate between keratinocytes of the epidermis to create a dense network, sampling any antigens that attempt to pass through the cutaneous tissue. Through use of their characteristic rod- or racket-shaped Birbeck granules, they take up antigens for presentation to T-cells. These monocyte-derived cells represent a large part of the skin’s adaptive immunity. Because of the effectiveness of their antigen presentation, Langerhans cells could be utilized as vaccine vehicles in the future. The Langerhans cells are functionally impaired by UV radiation, specifically UVB radiation, and may play a role in the development of cutaneous malignancies after UV radiation exposure.

Melanocytes. Within the stratum basale are melanocytes, the cells responsible for production of the pigment melanin in the skin. These neural crest-derived cells are present in a density of four to ten melanocytes per melanocyte, and about 500 to 2000 melanocytes per mm² of cutaneous tissue. This density varies based on location in the body, but differences in skin pigmentation are based on the activity of individual melanocytes and the number of melanocytes. In darker-skinned ethnicities, melanocytes create and store melanosomes in keratinocytes at a higher rate, but still have a pale-staining cytoplasm on light microscopy. Hemidesmosomes also attach these cells to the basement membrane, but the intercellular desmosomal connections are not present. The melanocytes interact with keratinocytes of the stratum basale and spinosum via long cytoplasmic extensions leading to invaginations in several keratinocytes. Tyrosinase is created and distributed into melanosomes, and these organelles travel along the dendritic processes to eventually become phagocytized by keratinocytes and distributed in a supranuclear orientation. This umbrella-like cap then serves to protect the nuclear material from damage by radiation; this could explain why light-skinned ethnicities are more prone to the development of cutaneous malignancies. Melanocytes express the bcl-2 protein, S100 protein, and vimentin, which are important in the pathology and histologic diagnosis of disorders of melanocytes.

Merkel Cells. Merkel cells are slow-adapting mechanoreceptors of unclear origin essential for light touch sensation. Thus, they typically aggregate among basal keratinocytes of the skin in areas where light tactile sensation is warranted, such as the digits, lips, and bases of some hair follicles. They are joined to keratinocytes in the basal layer by desmosomes and have dense neurosecretory granules containing peptides. These neurosecretory granules allow communication with the CNS via afferent, unmyelinated nerve fibers that contact the basolateral portion of the cell via expanded terminal discs. The clinical significance of Merkel cells arises in the setting of Merkel cell carcinoma, a rare, but difficult-to-treat malignancy.

Lymphocytes. Less than 1% of the cells in the epidermis are lymphocytes, and these are found primarily within the basal layer of keratinocytes. They typically express an effector memory T-cell phenotype.

Toker Cells. Toker cells are found in the epidermis of the nipple in 10% of both males and females and were first described in 1970. While distinct from Paget’s cells, immunohistochemical studies have implicated them as a possible source of Paget’s disease of the nipple.

Epidermal Appendages

Sweat Glands. Sweat glands, like other epidermal appendages, are derived from the embryologic ectoderm, but the bulk of their substance resides within the dermis. Their structure consists of a tubular-shaped exocrine gland and excretory duct. Eccrine sweat glands make up a majority of the sweat glands in the body and are extremely important to the process of thermoregulation. Solutes are released into the gland via exocytosis. They are present in greatest numbers on the palms, soles, axillae, and forehead. Collectively they produce approximately 10 L/d in an adult. These glands are the most effective means of temperature regulation in humans via evaporative heat loss.

A second type of sweat gland, known as the apocrine sweat gland, is found around the axilla, anus, areola, eyelid, and external auditory canal. The cells in this gland undergo an excretion process that involves decapitation of part of the cell. These apocrine glands are typically activated by sex hormones and thus activate around the time of puberty. The secretion from apocrine glands is initially odorless, but bacteria in the region may cause an odor to develop. Pheromone production may have been a function of the apocrine glands, but this may now be vestigial. While eccrine sweat glands are activated by the cholinergic system, apocrine glands are activated by the adrenergic system.

There is also a third type of sweat gland called apocrine. This is similar to an apocrine gland but opens directly to the skin surface and does not present until puberty. Both types of glands are surrounded by a layer of myoepithelial cells that can contract and assist in the excretion of glandular contents to the skin surface.

Pilosebaceous Units. A pilosebaceous unit is a multicomponent unit made up of a hair follicle, sebaceous gland, an erector pili muscle, and a sensory organ. These units are responsible for the production of hair and sebum and are present almost entirely
Throughout the body, sparing the palms, soles, and mucosa. They are lined by the germinal epithelium of the epidermis and thus serve as an important source of epidermal regeneration after partial-thickness injury or split-thickness skin graft. The sebaceous glands secrete sebum into the follicle and skin via a duct. The lipid-secreting glands are largely influenced by androgens and become functionally active during puberty. They are present in greatest numbers on the face and scalp.

**Nails.** The nails are keratinaceous structures overlying the distal phalanges of the fingers and toes. The nail is made of three main parts. The proximal portion of the nail, continuous with the germinal nail matrix, is the nail root. The root is an adherence point for the nail. The nail plate is the portion of the nail that lies on top of the nail bed, the shape of which is determined by the underlying phalanx. The third part of the nail is the free edge, which overlies a thickened portion of epidermis known as the hyponychium. The nail functions to protect the distal digits and augment the function of the pulp of the digits as a source of counter-pressure.

**Dermal Components**

**Architecture.** The dermis is a mesoderm-derived tissue that protects and supports the epidermis while anchoring it to the underlying subcutaneous tissue. It consists primarily of three unique components: a fibrous structure, the ground substance that surrounds those fibers, and the cell population that is supported by the dermis. In addition, the dermis houses the neurovasculature that supports the epidermis and facilitates interaction with the outward environment, as well as the epidermal appendages previously described. The dermis varies in thickness based upon body region, thinnest in the eyelids and reaching a thickness of up to 4 mm on the back, and is composed of two distinct layers, the papillary layer and the reticular layer. The papillary layer is made up of papillae that interdigitate with the rete ridges of the deep portion of the epidermis. This structure increases the surface area between the dermis and epidermis, increasing the resistance to shear forces as well as facilitating greater diffusion of nutrients across the dermal-epidermal junction. The papillary layer is characterized by a greater density of cells, and the reticular layer is almost entirely made up of a coarse network of fibers and the ground substance within which those fibers reside. They are typically spindle- or stellate-shaped and have a well-developed rough endoplasmic reticulum, typical of cells engaged in active protein production. The fibroblasts can also differentiate into myofibroblasts, cell types that harbor myofilaments of smooth muscle, actin, and desmin, which help to decrease the surface area of the wound by contraction. Because of these fundamental functions of fibroblasts, they are the workhorses of wound healing, while macrophages are the orchestrators.

**Fibers and Ground Substance.** Ninety-eight percent of the dry weight of the dermis is made up of collagen, typically 80% to 90% type I collagen and 8% to 12% type III collagen. Collagen types IV and VII are also found in much smaller quantities in the dermo-epidermal junction. The structure of the fibers varies along the depth of the dermis. At the superficial part of the dermis, in the papillary layer, the collagen bundles are arranged more loosely and are primarily made up of type III collagen. Deeper in the reticular layer of the dermis, the collagen fibrils are larger in diameter and organized into interwoven bundles surrounded by elastic fibers all within the hydrated ground substance. In a healthy adult, these dermal fibers are in a constant state of breakdown and production, dictated by the activity of matrix metalloproteases and fibroblasts, respectively. The activity of the MMPs is induced by UV radiation, thus leading to increased degradation and disorganization of the collagen fibers, resulting in wrinkling and weakening of the dermis in sun-exposed areas.

The retractile properties of skin are due in part to elastic fibers found throughout the dermis. These fibers, like the collagen fibers, are thinner and more perpendicularly oriented in the papillary dermis and become thicker and parallel in the reticular dermis. These elastic fibers are also produced by fibroblasts, but they are unique in that they can stretch to twice their original length, and return to their original configuration. The elastic fibers are also in a constant state of turnover that can be negatively impacted by the effects of UV radiation.

The fibrous network of the dermis lies within a hydrated amorphous ground substance made of a variety of proteoglycans and glycosaminoglycans, molecules that can contain up to 1000 times their weight in water. This ground substance facilitates the development of the structure of the dermis and cell migration within the dermis. It also assists in redistributing forces placed on the cutaneous tissues.

**Cells**

**Fibroblasts.** Fibroblasts, like most cells in the dermis, are found in the loose, papillary layer, and are the fundamental cells of the dermis. They are responsible for producing all dermal fibers and the ground substance within which those fibers reside. They are typically spindle- or stellate-shaped and have a well-developed rough endoplasmic reticulum, typical of cells engaging in active protein production. The fibroblasts can also differentiate into myofibroblasts, cell types that harbor myofilaments of smooth muscle, actin, and desmin, which help to decrease the surface area of the wound by contraction. Because of these fundamental functions of fibroblasts, they are the workhorses of wound healing, while macrophages are the orchestrators.

**Dermal Dendrocytes.** Dermal dendrocytes are comprised of a variety of mesenchymal dendritic cells recognizable mainly by immunohistochemistry. They are responsible for antigen uptake and processing for presentation to the immune system, as well as the orchestration of processes involved in wound healing and tissue remodeling. They are typically found in the papillary dermis around vascular structures as well as sweat glands and pilosebaceous units.

**Mast Cells.** Mast cells are effector secretory cells of the immune system that are responsible for immediate type 1 hypersensitivity reactions. When primed with IgE antibodies, encounter with a provoking antigen causes the release of histamine and cytokines, leading to vasodilation and dermatitis commonly seen in allergic reactions.

**Cutaneous Vasculature**

While the epidermis is void of any vasculature structures, the dermis has a rich supply of blood and nutrients supported by paired plexuses connected by a system of arteriovenous shunts. The superficial, subpapillary plexus is located between the papillary and reticular dermis and provides a vascular loop to every papilla of the papillary dermis. The deep dermal plexus is located at the junction of the reticular dermis and hypodermis, and it derives its blood supply from perforating arteries of larger vessels below the cutaneous tissues. The arteriovenous shunts connecting the two horizontal plexuses can divert blood flow to or away from the skin when necessary to conserve or release body heat, or to divert blood flow to vital organs when needed. Associated with the vascular loops of the dermal papillae are the blind-ended beginnings of lymphatic vessels, which serve to transport extravasated fluid and proteins from the soft tissues back into the venous circulatory system.
The skin is a highly specialized tool for interacting with our environment and, as such, carries a rich network of nervous tissue to facilitate this purpose. An afferent component made up of free nerve endings and specialized corpuscular receptors is responsible for conveying to our brain information about the environment, while numerous functions of the cutaneous tissues, such as AV-shunting, piloerection, and sweat secretion are controlled by the myelinated and unmyelinated fibers of an efferent component of the CNS.25

The hypodermis, or subcutaneous tissue, is a richly vascularized loose connective tissue that separates and attaches the dermis to the underlying muscle and fascia. It is made up primarily of pockets of lipid-laden adipocytes separated by septae that contain cellular components similar to the dermis, neurovascular structures supplying the cutaneous tissue, and the deepest parts of sweat glands.26 The hypodermis serves multiple functions—namely insulation, storage of energy, and protection from mechanical forces, allowing the skin to glide over the underlying tissues.

INFLAMMATORY CONDITIONS

Hidradenitis Suppurativa
Hidradenitis suppurativa, also known as acne inversa, is a painful skin condition typically affecting areas of the body bearing apocrine glands—typically the axillae, perineum, and the inframammary and inguinal folds. It is characterized by tender, deep nodules that can expand, coalesce, spontaneously drain, and form persistent sinus tracts in some cases leading to significant scarring and hyperkeratosis. There can be superimposed bacterial infection during episodic flares of the disease as well. In women, flares often occur premenstrually.

Hidradenitis suppurativa typically affects females (female to male ratio of 3:1), most commonly during the third decade of life and has demonstrated associations with smoking and obesity.27 While the etiology of hidradenitis is incompletely understood, it is thought to be the consequence of a genetic predisposition exacerbated by environmental factors. About one-third of affected patients endorse a family history of the disease. A specific gene locus has not been identified, but mutations in the γ-secretase gene have been linked to the disease in some familial cases.28 The histologic progression of the disease is characterized by atrophy of the sebaceous gland, followed by inflammation of the pilosebaceous unit from both the innate and adaptive immune systems, causing hyperkeratosis and eventual granuloma formation.29 Some studies have shown involvement of the IL12-IL23 pathway and TNF-α, supporting the theory that the disease is at least in part caused by an inflammatory disorder.30,31

The diagnosis of hidradenitis is clinical, and the presentation is most commonly categorized by the Hurley classification system, divided into three stages. Single or multiple nodules or abscesses without any sinus tracts or scarring would be classified as stage I disease. As abscesses recur and sinus tracts and scarring form, the disease is classified as Hurley stage 2. Stage 3 is the most advanced stage, with diffuse disease and interconnected sinus tracts and abscesses.

Treatment is typically based on Hurley staging, with topical and systemic antibiotics (typically clindamycin) being used for stage I and II disease,32 while radical excision, laser treatment, and biologic agents are reserved for more advanced stage II and III disease.33-36 Even with complete surgical resection, recurrence rates are still high, reaching up to 50% in the infra mammary and inguino-perineal regions. Because of increased risks of recurrence with primary closure, it is preferable to pursue other methods of wound closure, like split-thickness skin grafting, local or regional flaps, and healing by secondary intention. Topical antimicrobial creams should be used during the healing process.

Pyoderma Gangrenosum
Pyoderma gangrenosum is an uncommon inflammatory condition of the skin characterized by the development of sterile pustules which progress to painful, ulcerating lesions with purple borders. This disease is typically diagnosed between the ages of 40 and 60 years and has a slightly higher prevalence in females. Although the exact etiology is currently unknown, it typically arises in individuals with a hematologic malignancy or inflammatory disorder, such as inflammatory bowel disease or rheumatoid arthritis. The most commonly affected sites are the legs, but lesions can occur anywhere. Extracutaneous manifestations are also possible, and it can affect mucosal tissue and solid organs. While the initial pathology is sterile, it can easily become secondarily infected. The diagnosis of this condition is based upon history and clinical presentation after the exclusion of infectious etiologies. There are five distinct types of pyoderma gangrenosum described: vegetative, pustular, peritoma, ulcerative, and bullous. The pathogenesis of this disease is incompletely understood, but it is thought to be a genetic predisposition that is triggered by an environmental influence. An inciting cutaneous injury can often be identified preceding the ulceration. Histopathologic studies have demonstrated significantly elevated levels of inflammatory cytokines, as well as neutrophils exhibiting aberrant chemotactic signaling.37-39 Treatment of pyoderma gangrenosum generally involves treatment of the underlying disorder (i.e., management of Crohn’s disease) as well as systemic anti-inflammatory medications such as steroids or immunosuppressants like calcineurin inhibitors. Patients with Crohn’s disease and PG treated with infliximab (tumor necrosis factor [TNF]-α inhibitor) and etanercept (TNF-α antagonist) had a marked improvement in their PG.40,41 In cases of peristomal pyoderma gangrenosum, topical calcineurin inhibitors have been shown to be useful.42 Concurrent treatment with systemic and topical antimicrobials, as well as local wound care, including the debridement of purulent exudate and devitalized tissue, is also beneficial. Surgical therapy without proper systemic treatment will generally result in recurrent disease. Final wound closure can be achieved with primary closure or grafts.

Epidermal Necrolysis
Epidermal necrolysis (EN) is a rare mucocutaneous disorder characterized by cutaneous destruction at the dermoepidermal junction. EN is commonly referred to as either Stevens-Johnson syndrome (SJS) or toxic epidermal necrolysis (TEN) depending on the extent of skin involvement present. SJS refers to cases in which <10% of total body surface area is involved, while cases with >30% involvement are considered TEN, with an SJS-TEN overlap syndrome referring to all cases in between. These two disorders are now considered to be the same clinical entity that vary simply on the extent of cutaneous involvement. Erythema multiforme was once considered as part of the clinical subgroup...
encompassing SJS and TEN, but it is now thought to be a separate entity related to herpetic or *Mycoplasma* infections.

The clinical presentation usually occurs within 8 weeks of initiation of a new drug treatment and is characterized by a macular rash beginning in the face and trunk and progressing to the extremities within hours to days. A positive Nikolsky sign is often present, in which lateral pressure on the skin causes separation of the epidermis from the dermis. The macular rashes then begin to blister and coalesce, forming bullae that eventually burst, leaving partial thickness wounds with exposed dermis. Mucous membrane involvement is seen in 90% of cases and can involve the oral, genital, and ocular mucosa, as well as the respiratory and gastrointestinal tracts. The cutaneous manifestations can also be associated with high fever and pain. It is important to distinguish EN from infectious etiologies like staphylococcal scalded skin syndrome due to their similar clinical presentation.

While the etiology is not entirely clear, it is well documented to be a reaction to various drugs. While over 100 drugs have been implicated as the inciting agent of EN, there are a handful of high-risk drugs that account for a majority of the cases. The drugs most commonly associated with EN include aromatic anticonvulsants, sulfonamides, allopurinol, oxycams (nonsteroidal anti-inflammatory drugs), and nevirapine. The pathophysiology is also incompletely understood, but it has generally been accepted that it involves cell-mediated cytotoxicity targeted at keratinocytes and the cytokine-induced expression of “death-receptors” like Fas-L. Recently, studies have demonstrated greatly increased concentrations of granulysin, an apoptotic protein secreted by cytotoxic T cells, within EN lesions, and thus this protein may be implicated in the pathogenesis of EN. A genetic component may also exist, and genetic testing before carbamazepine treatment is recommended in people of Han Chinese ancestry to exclude carriers of HLA-B1502.

The prognosis of EN is generally related to the surface area affected and secondary complications of extensive cutaneous damage, like secondary infections and loss of hemodynamic stability due to increased insensible losses and third spacing of fluid. Modern burn- and ICU-care has decreased mortality significantly. The first principle of management of EN is discontinuation of the offending agent, and in drugs with short half-lives, this can significantly increase chances of survival. Other management principles include maintenance of euvoolemia, early enteral feeding, and measures to reduce risk of infection. This includes surgical debridement of devitalized tissue, the use of topical antibiotics or antimicrobial dressings, nonadherent dressings, or temporary biologic or synthetic grafts until the underlying dermis can reepithelialize. The cornea should regularly be inspected with a Wood’s lamp to evaluate for corneal sloughing.

The use of systemic corticosteroids in the acute setting is controversial as there have been mixed results. Some studies have shown a slowed disease progression when corticosteroid therapy was administered early, while others showed increased rates of sepsis and overall mortality with no effect on disease progression. IVIG has also been used in an effort to inhibit the Fas-L cytotoxic pathway, with some mixed results. A 2007 meta-analysis of nine IVIG trials concluded that high-dose IVIG improves survival, while a large retrospective analysis in 2013 concluded that there was no mortality benefit. Other agents, like cyclosporine A, plasmapheresis and anti-TNF-α have been studied with mixed results. Recent guidelines out of the United Kingdom confirm that there is still no treatment with clearly demonstrated benefit in the management of EN. The cutaneous manifestations of EN generally progress for 7 to 10 days, while reepithelialization generally occurs over 3 weeks.

**INJURIES**

**Radiation-Induced Injuries**

Radiation injuries can result from exposure to electromagnetic radiation from industrial/occupation applications or, more commonly, from environmental exposure and medical treatments. This is especially true in the continually evolving role of radiation therapy in the multidisciplinary approach to oncologic disease and other skin conditions. In addition to treatment for lymphomas, head and neck squamous cell carcinomas, and prostate adenocarcinoma, it is often an adjuvant or neoadjuvant component of the surgical treatment of rectal, breast, esophageal, and cervical cancers. Although the new modalities and principles of radiation therapy have allowed for more precise administration of this therapy, there is still collateral damage in the cutaneous and visceral tissues surrounding the treatment site.

Environmental sources of radiation damage are typically from UV radiation. UVC rays are filtered by the ozone layer, so the only UV rays that humans typically encounter are UVA (320–400 nm) and UVB (290–320 nm). The amount of exposure to UV radiation is dependent on seasonal, temporal, geographic and environmental variables. Ninety-five percent of the UV rays that reach the earth’s surface are UVA rays. This radiation is less energetic (longer wavelength) than UVB rays and affects the cutaneous tissues differently. UVA waves penetrate deeper into the tissues, with 20% to 30% reaching the deep dermis. UVB rays are mostly absorbed in the epidermis, with 70% reaching the stratum corneum, 20% reaching the deep epidermis, and only 10% reaching the papillary dermis. Major chromophores in the cutaneous tissue include nucleic acids, aromatic amino acids, and melanin.

The short-term effects of solar radiation include erythema and pigmentation. The resultant erythema peaks at 6 to 24 hours...
after exposure. The pigmentation occurs differently for UVA and UVB rays. Partial fading of this pigment change occurs within an hour after exposure, but with higher and repeated doses of UVA, stable residual pigmentation is observed. UVB waves induce neomelanization, increasing the total amount of melanin in the epidermal tissues and resulting in an effect that is observable 72 hours after exposure. The increase in melanin as a result of UVB exposure serves as a protective mechanism to defend the nuclei of the basal keratinocytes from further radiation-induced damage by absorbing the high-energy radiation in future exposures. Long-term effects of exposure to UV radiation can lead to chronic skin changes, such as irregular pigmentation, melasma, postinflammatory pigmentation, and actinic lentigines (sun spots). Lysozyme, an enzyme secreted by cells of the immune system, typically inhibits the activity of collagenase and elastase, playing a role in turnover of the elastin and collagen network of the dermis. Long-term exposure to UV radiation increases the activity of lysozyme, thus impairing the natural turnover of these fibers, resulting in a disorganized accumulation of elastin, and an increase in the ratio of type III to type I collagen. This results in loss of firmness and resilience of the skin, leading to wrinkles and an aged appearance.

The other major source of radiation injury that a surgeon will likely encounter is from therapeutic radiation. The various forms of radiation work to destroy the replicative potential of the target cells via damage to the nucleic acid structures in the cell. This is typically used to treat oncologic disease, but it can also be used to treat benign disease like eczema, psoriasis, and keloid scarring at relatively low exposures. While this goal is accomplished, surrounding tissues are also affected and damaged. The most radiosensitive components of the cutaneous tissue are the basal keratinocytes, hair follicle stem cells, and melanocytes. Exposure to this intense radiation results in disorganized, uncontrolled cell death, leading to the release of reactive oxygen species and further damage and inflammation to the surrounding cellular network. Damage to the basal keratinocytes and fibroblasts hinders the replicative capacity of the epidermis and dermis, respectively.

Acute skin changes to these structures manifest within weeks as erythema, edema, and alopecia. Permanent hyperpigmentation, tightening, thickening, and fibrosis of the skin become apparent as the tissue attempts to heal. In severe radiation injury, there can be complete loss of the epidermis, resulting in partial-thickness wounds and fibrinous exudate. Reepithelialization typically occurs 14 days following initial injury, provided other variables affecting wound healing are optimized (bacterial colonization, nutrition.) Long-term effects include compromise of the functional integrity of the skin secondary to thrombosis and necrosis of capillaries, hypovascularity, telangiectasia, ulceration, fibrosis, poor wound healing, and infection. These can present weeks to years after exposure.

Treatment of minor radiation injury includes skin moisturizers and local wound care when appropriate. Severe radiation injury may warrant surgical excision and reconstruction with free-tissue transfer from a part of the body unaffected by radiation.

**Trauma-Induced Injuries**

**Mechanical Injury.** Physical disruption of the skin can occur via numerous mechanisms. Treatment of the wound is dependent on the size of the defect left behind by the insult, any exposed structures that remain in the wound bed, and the presence of contaminating debris or infection. Clean, simple lacerations can be irrigated, debrided, and closed primarily. There is no systematic evidence to guide the optimal timing of closure within 24 hours, but many surgeons will close primarily within 6 hours of injury. Grossly contaminated or infected wounds should be allowed to heal by secondary intention or delayed primary closure. In wounds allowed to heal secondarily, negative pressure wound therapy can increase the rate of granulation tissue formation. Tangential abrasions are treated similarly to burn wounds, with depth of injury dictating management. Partial thickness injuries with preservation of the regenerative pilosebaceous units can be allowed to heal on their own while maintaining a moist, antimicrobial wound environment. Full thickness wounds may require reconstruction with split- or full-thickness skin grafting depending on the size of the defect and the need for future cosmesis and durability. In the setting of devitalization of full thickness tissue, the damaged tissue may be used as a full thickness graft, provided the wound is appropriately cleaned.

**Bite Wounds.** Dog bites alone recently accounted for 4.5 million bites to humans in a single year. Bites from dogs, humans, and other animals can quickly lead to severe deep-tissue infections if not properly recognized and treated. The most common location of bite wounds is the hand. This area is of particular importance, as the anatomy of the hand allows for rapid progression of deep infection long relatively avascular structures and can lead to long term morbidity if not adequately treated. Bite bacteriology is influenced by normal mouth flora, as well as the content of the offending animal’s diet. Early presentation bite wounds yield polymicrobial cultures, while cultures from a late infection will typically exhibit one dominant pathogen. Common aerobic bacteria include *Pasteurella multocida*, *Streptococcus*, *Staphylococcus*, *Neisseria*, and *Corynebacterium*; anaerobic organisms include *Fusobacterium*, *Porphyromonas*, *Prevotella*, *Propionibacterium*, *Bacteroides*, and *Peptostreptococcus*. *Capnocytophaga canimorsus* bacteria after a dog bite are rare, and it appears that immunocompromised patients are most susceptible to this type of infection and its complications. The bacterial load in dog bites is heavily influenced by the last meal of the animal, increasing with wet food and shorter time since the last meal (Fig. 16-3). Cat bite bacteriology is similar, with slightly higher prevalence of *Pasteurella* species. Infections from *Francisella tularensis* (tularemia) and *Yersinia pestis* (human plague) have been reported.

Bacteria colonizing human bites are those present on the skin or in the mouth. These include the gram-positive aerobic organisms *Staphylococcus aureus*, *Staphylococcus epidermidis*, and *Streptococcus* species, and anaerobes including *Peptococcus* species, *Peptostreptococcus* species, *Bacteroides* species, and *Eikenella corrodens* (facultative anaerobe). Human bites are characterized by a higher bacterial load (>10⁶). Antibiotic prophylaxis after a human bite is recommended as it has been shown to significantly decrease the rate of infection. A course of 3 to 7 days of amoxicillin/clavulanate is typically used. Alternatives are doxycycline or clindamycin with ciprofloxacin.

There is controversy over the closure of bite wounds. Typically, in areas of aesthetic importance, the wound is thoroughly irrigated and debrided and primarily closed with a short course of antibiotics and close follow-up to monitor for signs of infection. In areas that are less cosmetically sensitive and bites that look grossly contaminated or infected, the wounds
Figure 16-3. A. Dog bite to the face involving the lip. B. Primary multilayer closure following debridement and irrigation. Closure was performed due to aesthetic and functional considerations. C. Follow up 1 week after injury following suture removal.

are allowed to close secondarily. Special consideration should be paid to puncture wounds in areas like the hands, which have multiple small compartments. Some groups have found that as long as wounds are properly irrigated and cleansed with povidone iodine solution while a short course of antibiotics is prescribed, there is no difference in infection rates in dog bite wounds closed primarily.62

Rabies in domestic animals in the United States is rare, and most cases are contracted from bat bites. In developing countries, dog bites remain the most common source of rabies. Management of this is beyond the scope of this chapter.

Caustic Injury
Chemical burns make up to 10.7% of all burns but account for up to 30% of all burn-related deaths.63 The number of cases of industrial chemical burns is declining while chemical burns in the domestic setting is on the rise. The extent of tissue destruction from a chemical burn is dependent on type of chemical agent, concentration, volume, and time of exposure, among other variables.

Injuries from acidic solutions are typically not as severe as those from basic solutions. This is due to the mechanism of injury of each. Acidic injuries typically result in superficial eschar formation because the coagulative necrosis caused by acids limits tissue penetration. Acids can cause thermal injury in addition to the coagulative necrosis due to exothermic reactions. Without treatment, acid injuries will progress to erythema and ulcers through the subcutaneous tissue. Injuries from basic solutions undergo liquefactive necrosis, unlike acids, and thus have no barrier preventing them from causing deeper tissue injury.
Common examples of agents that often cause alkaline chemical burns are sodium hydroxide (drain decloggers and paint removers) and calcium hydroxide (cement).

Treatment for acidic or alkaline chemical burns is first and foremost centered around dilution of the offending agent, typically using distilled water or saline for 30 minutes for acidic burns and 2 hours for alkaline injuries. Attempting to neutralize the offending agent is typically discouraged, as it does not offer an advantage over dilution and the neutralization reaction could be exothermic, increasing the amount of tissue damage. After removal of the caustic agent, the burn is treated like other burns and is based on the depth of tissue injury. Topical antimicrobials and nonadherent dressings are used for partial-thickness wounds with surgical debridement and reconstruction if needed for full-thickness injuries. Liposuction and saline dilution have been used in cases were injury to deeper structures was suspected. Prophylactic use of antibiotics is generally avoided.

There are several chemical agents that have specific treatments, including the use of calcium gluconate for hydrofluoric acid burns and polyethylene glycol for phenol burns. These types of treatments are specific to the offending agent and outside of the scope of this chapter.

One type of caustic injury that is commonly seen in the hospital is extravasation injury, especially in the setting of chemotherapy administration. Extravasation is estimated to occur in 0.1% to 0.7% of all cytotoxic drug administrations. Like other chemical burns, extravasation injuries depend on properties of the offending agent, time of exposure, concentration, and volume of drug delivered to the tissues. Extravasation injuries typically cause little damage, but they can cause significant morbidity in those with thin skin, fragile veins, and poor tissue perfusion, like neonates and the critically ill. Extravasation injuries usually involve swelling, pain, erythema, and blistering. It may take days or longer for the extent of tissue damage to demarcate. Thorough evaluation to rule out injury to deeper tissues should be conducted. The treatment for extravasation injuries is usually conservative management with limb elevation, but saline aspiration with a liposuction cannula in an effort to dilute and remove the offending agent has been used soon after injury presentation. Infiltration of specific antidotes directed toward the offending agent has been described, but it lacks the support of randomized controlled trials, and no consensus in treatment has been reached. It is best to avoid cold or warm compression because the impaired temperature regulation of the damaged tissue may lead to thermal injury. After the wound demarcates, full-thickness skin death should be surgically debrided and managed like other wounds based on depth of injury.

**Thermal Injury**

Thermal injury involves the damage or destruction of the soft tissue due to extremes of temperature, and the extent of injury is dependent on the degree temperature to which the tissue is exposed and the duration of exposure. The pathophysiology and management are discussed in detail in a separate chapter. Briefly, the management of thermal wounds is initially guided by the concept of three distinct zones of injury. The focus of thermal injury that has already undergone necrosis is known as the zone of coagulation. Well outside the zone of coagulation is the zone of hyperemia, which exhibits signs of inflammation but
will likely remain viable. In between these two zones is a zone of stasis with questionable tissue viability, and it is this area at which proper burn care can salvage viable tissue and decrease the extent of injury\(^6\) (Fig. 16-6).

The mechanisms of injury in hypothermic situation differ. Direct cellular damage can occur as a result of the crystallization of intracellular and extracellular components with resultant dehydration of the cell and disruption of lipid protein

---

complexes. During rewarming, further damage occurs because of the shifts of fluid in response to melting ice. Indirect effects of hypothermic injury include microvascular thrombosis and tissue ischemia. This, together with subsequent edema and inflammation upon rewarming, propagates tissue injury even further. Even so, the standard treatment of frostbite injury begins with rapid rewarming to 40°C to 42°C. In addition, further treatment includes debridement of all devitalized tissue, hydrotherapy, elevation, topical antimicrobials, topical antithromboxanes (aloe vera), and systemic antiprostaglandins (aspirin).

**Pressure Injury**

A problem that all surgeons will encounter very early in their careers is pressure necrosis. The development of pressure ulcers is increasingly being regarded as a marker of quality of care, and strategies aimed at prevention have been the source of recent study. Pressure ulcers are known to affect the critically ill (22% to 49% of all critically ill patients are affected), but pressure sources can also affect the chronically bed- or wheelchair-bound, patients undergoing surgical procedures, and those with Foley catheters, artificial airways, or other medical equipment (Fig. 16-7).

Pressure ulcers can present in several ways depending on the stage at presentation. They are typically grouped into 4 stages: stage 1, nonblanching erythema over intact skin; stage 2, partial-thickness injury with blistering or exposed dermis; stage 3, full-thickness injury extending down to, but not including, fascia and without undermining of adjacent tissue; and stage 4, full-thickness skin injury with destruction or necrosis of muscle, bone, tendon, or joint capsule. Tissue destruction occurs most easily at bony prominences due to the inability to redistribute forces along a greater surface area. The average perfusion pressure of the microcirculation is about 30 mmHg, and pressures greater than that cause local tissue ischemia. In animal models, pressure greater than twice the capillary perfusion pressure produces irreversible tissue necrosis in just 2 hours. The most common areas affected are the ischial tuberosity (28%), greater trochanter (19%), sacrum (17%), and heel (9%). Tissue pressures can measure up to 300 mmHg in the ischial region during sitting and 150 mmHg over the sacrum while lying supine. Tissues with a higher metabolic demand are
typically susceptible to insult from tissue hypoperfusion more rapidly than tissues with a lower metabolic demand. Because of this, it is possible to have muscle necrosis beneath cutaneous tissue that has yet to develop signs of irreversible damage.

Management of pressure sores first and foremost involves avoidance of prolonged pressure to at-risk areas. Strategies typically employed are pressure-offloading hospital beds or assist devices, patient repositioning every 2 hours, early mobilization, prophylactic silicone dressings, and nursing education. From a wound healing perspective, patients should be nutritionally optimized and surgically debrided as appropriate. The presence of stage III or IV pressure ulcers is not necessarily an indication for surgery, and fevers in a patient with chronic pressure ulcers are often from a urinary or pulmonary source. Goals of surgical intervention are drainage of fluid collections, wide debridement of devitalized and scarred tissue, excision of pseudobursa, ostectomy of involved bones, hemostasis, and tension-free closure of dead space with well-vascularized tissue (muscle, musculocutaneous, or fasciocutaneous flaps). Stage 2 and 3 ulcers may be left to heal secondarily after debridement. Subatmospheric pressure wound therapy devices (vacuum-assisted closure) play a role in wound management by removing excess interstitial fluid, promoting capillary circulation, decreasing bacterial colonization, increasing vascularity and granulation tissue formation, and contributing to wound size reduction.

**BIOENGINEERED SKIN SUBSTITUTES**

The management of soft tissue defects is more commonly including the use of bioengineered skin substitutes. These products are typically derived from or designed to imitate dermal tissue, providing a regenerative matrix or stimulating autogenous dermal regeneration while protecting the underlying soft tissue and structures. There are generally four types of skin substitutes: (a) autografts, which are taken from the patient and placed over a soft tissue defect (split-thickness and full-thickness skin grafts); (b) allografts, which are taken from human organ donors; (c) xenografts, which are taken from members of other animal species; and (d) synthetic and semisynthetic biomaterials that are constructed de novo and may be combined with biologic materials. Acellular dermal matrices are one type of skin substitute and are used quite often for wound healing and support of soft tissue reconstruction. They are from allogenic or xenogeneic sources and are composed of collagen, elastin, laminin, and glycosaminoglycans. Tissue incorporation generally occurs within 1 to 2 weeks. Dermal matrices have been shown to be an effective bridge to split-thickness skin grafting for wounds that have exposed nerves, vessels, tendons, bones, or cartilage. Bilayered matrices can also be used to promote dermal regeneration in acute or chronic wounds. These products can be temporary, needing to be removed prior to grafting, or permanent, integrating into the host tissue and being grafted directly.

**BACTERIAL INFECTIONS OF THE SKIN AND SUBCUTANEOUS TISSUE**

**Introduction**

In 1998, the Food and Drug Administration (FDA) categorized infections of the skin and skin structures for the purpose of clinical trials. A revision of this categorization in 2010 excluded specific diagnoses such as bite wounds, decubitus ulcers, diabetic foot ulcers, perirectal abscesses, and necrotizing fasciitis. The general division into “uncomplicated” and “complicated” skin infections can be applied to help guide management.

The agent most commonly responsible for skin and soft tissue infections is *S. aureus* and is isolated in 44% of specimens. Less common isolates include other gram-positive bacteria such as *Enterococcus* species (9%), β-hemolytic streptococci (4%), and coagulase-negative staphylococci (3%). *S. aureus* is more commonly responsible for causing abscesses. Patients with an impaired immune system (diabetic, cirrhotic, or neutropenic patients) are at higher risk of infection from gram-negative species like *Pseudomonas aeruginosa* (11%), *Escherichia coli* (7.2%), *Enterobacter* (5%), *Klebsiella* (4%), and *Serratia* (2%), among others.

**Uncomplicated Skin Infections**

Uncomplicated infections involve relatively small surface area (<75 cm²) and bacterial invasion limited to the skin and its appendages. Impetigo, erysipelas, cellulitis, folliculitis, and simple abscess fall into this category. Impetigo is a superficial infection, typically of the face, that occurs most frequently in infants or children, resulting in honey-colored crusting. Erysipelas is a cutaneous infection localized to the upper layers of the dermis, while cellulitis is a deeper infection, affecting the deeper dermis and subcutaneous tissue. Folliculitis describes inflammation of the hair follicle, and a furuncle describes a follicle with swelling and a collection of purulent material. These lesions can sometimes coalesce into a carbuncle, an abscess with multiple different draining sinuses.

It is recommended to culture infectious lesions to help identify the causative agent, but treatment without these studies is reasonable in typical cases. Minor infections can be safely treated with topical antimicrobials like 2% mupirocin to provide coverage for methicillin-resistant *S. aureus* (MRSA). Folliculitis generally resolves with adequate hygiene and warm soaks. Furuncles, carbuncles and other simple abscesses can be incised, drained, and packed, typically without the use of systemic antibiotics. The decision to use systemic antibiotics after incision and drainage of abscess should be made based upon presence or absence of systemic inflammatory response syndrome (SIRS) criteria.

For nonpurulent, uncomplicated cellulitis in which there is no drainable collection, systemic antibiotic coverage for β-hemolytic streptococcus is recommended. If there is no improvement in 48 to 72 hours or worsening of symptoms, antibiotic coverage should be added for MRSA. Systemic therapy for purulent cellulitis, which includes cutaneous abscesses, should cover MRSA, and empiric coverage for streptococcus is likely unnecessary. Antibiotic coverage for streptococcus is generally accomplished with β-lactam antibiotics like penicillins or first-generation cephalosporins. MRSA coverage is accomplished with clindamycin, trimethoprim-sulfamethoxazole, linezolid, and tetracyclines. Clindamycin, trimethoprim-sulfamethoxazole, linezolid, or tetracycline combined with a β-lactam can all be used for dual coverage of streptococcus and MRSA.

**Complicated Skin Infections**

Complicated skin infections include superficial cellulitis encompassing a large surface area (>75 cm²) or deeper infections extending below the dermis. Necrotizing soft tissue infections (NSTIs), including necrotizing fasciitis, can rapidly cause extensive morbidity and mortality, thus their prompt diagnosis and appropriate management is crucial. A thorough history and
exam should be performed to elicit information (e.g., history of trauma, diabetes mellitus, cirrhosis, neutropenia, bites, IV or subcutaneous drug abuse) as well as physical findings such as crepitus (gas-forming organism), fluctuance (abscess), purpura (sepsis in streptococcal infections), bullae (streptococci, *Vibrio vulnificus*), lymphangitis, and signs of a systemic inflammatory response.

Extensive cellulitis is managed in a similar fashion as simple cellulitis. Initial treatment consists of intravenous antibiotics that cover β-hemolytic streptococcus, such as cephalosporins, with the addition of MRSA coverage if there is no improvement in symptoms. Vancomycin is typically the first choice for MRSA coverage, but this drug is inferior to β-lactams for coverage of MSSA. Alternative antibiotics that are typically effective against MRSA are linezolid, daptomycin, tigecycline, and telavancin. Clindamycin is approved for use against MRSA, but resistance rates are increasing, and its use is discouraged if institutional rates of clindamycin resistance are >15%.

Necrotizing soft tissue infections occur 500 to 1500 times a year in the United States and are frequently associated with diabetes mellitus, intravenous drug abuse, obesity, alcohol abuse, immune suppression, and malnutrition. Because NSTIs can often present initially with nonspecific findings, the physician should always have a high index of suspicion when evaluating a patient. The threshold for surgical exploration and debridement should be low, particularly in a weakened host. Occasionally an inciting event or point of entry can be identified, but in 20% to 50% of cases, the exact cause is unknown. These infections are associated with a high mortality, ranging from 25% to 40%, with higher rates in the truncal and perineal cases.

NSTIs are classified based on anatomic site, involved tissues, and the offending organisms. NSTIs commonly originate at the genitalia, perineum (Fournier’s gangrene), and abdominal wall. Subcutaneous tissue, fascia and muscle can all be affected. Necrotizing fasciitis involves infection of the fascia, and the infection can quickly travel along the easily separable, avascular planes. There are three types of NSTIs when classified by the offending agent. The most common is type 1, which is caused by a polymicrobial source including gram-positive cocci, gram-negative rods, and anaerobic bacteria, specifically *Clostridium perfringens* and *C. septicum*. Type 2 is caused by a monomicrobial source of β-hemolytic *Streptococcus* or *Staphylococcus* species, with MRSA contributing to the increasing number of community-acquired NSTIs. A history of trauma is often elicited and can be associated with toxic shock syndrome. Type 3 is a rare but fulminant subset resulting from a *V. vulnificus* infection of traumatized skin exposed to a body of salt-water.

In addition to signs of SIRS, patients can present with skin changes like erythema, bullae, necrosis, pain, and crepitis. They may exhibit signs of hemodynamic instability, and gas within the soft tissues on imaging is pathognomonic. Patients can present with a range of symptoms, from minimal skin change to frank necrosis, and the time of progression to fulminant disease varies in each patient. Laboratory values are nonspecific and resemble values seen in sepsis. There have been attempts at creating scoring systems to assist in the diagnosis of NSTI. One study in 2000 used the criteria of a white blood cell count >15,400 and a serum sodium level <135 mmol/L. This test was found to have a negative predictive value of 99%, but a positive predictive value of only 26%. In 2004, six criteria were used and referred to as the Laboratory Risk Indicator for Necrotizing Fasciitis, or LRINEC, and included C-reactive protein (CRP), white blood cell (WBC) count, hemoglobin, plasma sodium, creatinine, and glucose. A score of 8 or greater
suggested a high probability of NSTI, 6 or 7 an intermediate probability, and <5 a low probability. This test was internally validated and found to have a PPV of 92% and an NPV of 96%. However, some have criticized this study because of its small sample size and over-reliance on CRP, which can be elevated in multiple other conditions. Blood cultures are not always positive, and tissue samples will demonstrate necrosis, white blood cell infiltration, thrombosis, angiitis, and microorganisms. The use of cross-sectional imaging in the diagnosis of NSTI is limited, and it should not delay appropriate surgical treatment.

Three principles form the foundation of the management of NSTIs: (a) source control with wide surgical debridement, (b) broad-spectrum intravenous antibiotics, and (c) supportive care and resuscitation. As soon as the diagnosis is clear or the suspicion is high, the patient should be taken for operative exploration and debridement. Incisions should be made parallel to neurovascular structures and through the fascial plane, removing any purulent or devitalized tissue until viable, bleeding tissue is encountered. On inspection, the tissue will appear necrotic with dead muscle, thrombosed vessels, the classic “dishwater” fluid, and a positive finger test, in which the tissue layers can be easily separated from one another. In Fourmier’s gangrene, one should aim to preserve the anal sphincter as well as the testicles (blood supply is independent of the overlying tissue and is usually not infected). Return to the OR should be planned for the next 24 to 48 hours to verify source control and the extent of damage. Broad spectrum antibiotic therapy should be initiated as soon as possible, with the intent of covering gram positives (including MRSA), gram negatives, and anaerobic organisms. The Infectious Diseases Society of America recommends initiating therapy with intravenous vancomycin and piperacillin/tazobactam, unless a monomicrobial agent is identified, in which case more directed therapy would be appropriate.81 Antibiotic therapy should continue until the patient requires no further debridement, is clinically improving, and has been afebrile for 48 to 72 hours.

Adjuncts to surgery include topical antimicrobial creams, subatmospheric pressure wound dressings, and optimization of nutrition. Controversial topics include the role of hyperbaric oxygen82 (may inhibit infection by creating an oxidative burst, with anecdotally fewer debridements required and improved survival, but limited availability) and IVIG (may modulate the immune response to streptococcal superantigens). Wound closure is performed once bacteriologic, metabolic, and nutritional balances are obtained.

**Actinomycosis**

*Actinomyces* is a genus of gram positive rods that inhabit the oropharynx, gastrointestinal tract, and female genital tract. The most commonly isolated species causing disease in humans is *A. israelii*. The cervicofacial form of *Actinomyces* infection is the most common presentation, representing 55% of cases, and typically presenting as an acute pyogenic infection in the submandibular or paramandibular area. Patients can also exhibit chronic soft tissue swelling, fibrosis, and sinus discharge of sulfur granules.86 Demonstration of gram-positive filamentous organisms and sulfur granules on histological examination is strongly supportive of a diagnosis of actinomycosis.86 These infections are typically treated with high doses of intravenous followed by oral penicillin therapy. Surgical treatment is utilized if there is extensive necrotic tissue, poor response to antibiotics, or the need for tissue biopsy to rule out malignancy.

**VIRAL INFECTIONS WITH SURGICAL IMPLICATIONS**

**Human Papillomavirus Infections**

Human papillomaviruses represent a group of over 100 isolated types of small DNA viruses of the *Papovavirus* family that is highly host-specific to humans.83 These viruses are transmitted via cutaneous contact with individuals who have clinical or subclinical infection and occur more frequently in immunocompromised individuals. The viruses are responsible for the development of verrucae, or warts. These are histologically characterized by nonspecific findings of hyperkeratosis, papillomatosis, and acanthosis, as well as the hallmark koilocytes (clear halo around nucleus). Clinically, these generally arise as slow-growing papules on the skin or mucosal surfaces. Regression of HPV lesions is frequently an immune-mediated, spontaneous event that is exemplified by the persistent and extensive manifestation of this virus in the immune-compromised patient.

The subtypes are generally grouped, based on their presentation, as cutaneous or mucosal. Cutaneous types most commonly affect the hands and fingers. Verruca vulgaris, or common warts, are caused by HPV types 1, 2, and 4, with a prevalence of up to 33% in school children and 3.5% in adults, and a higher prevalence in the immunosuppressed population.81 Plantar and palmar warts (HPV-1 and -4) typically occur at points of pressure and are characterized by a keratotic plug surrounded by a hyperkeratotic ring with black dots (thrombosed capillaries) on the surface. Plane warts occur on the face, dorsum of hands, and shins. They are caused by HPV-3 and -10 and tend to be multiple, flat-topped lesions with a smooth surface and light brown color. Cutaneous warts typically regress spontaneously in the immunocompetent patient. Erythrodysplasia verruciformis is a rare, autosomal recessive inherited genetic skin disorder that confers increased susceptibility to certain types of HPV. This presents with difficult-to-treat and often widespread verrucae that carry a higher risk of malignant transformation (30%-50% risk of squamous cell carcinoma), especially when caused by HPV types 5 and 8.82 A similar clinical picture has been described in human immunodeficiency virus (HIV) and transplant patients.83,84

Mucosal HPV types cause lesions in the mucosal or genital areas and behave like sexually transmitted infections. The most common mucosal types are HPV-6, -11, -16, -18, -31, and -33. These lesions present as condylomata acuminata, genital or veneral warts, papules that occur on the perineum, external genitalia, anus, and can extend into the mucosal surfaces of the vagina, urethra and rectum. These lesions are at risk for malignant transformation, with types 6 and 11 conferring low risk, and types 16, 18, 31 and 33 conferring a high risk. The recently developed quadrivalent HPV vaccine, targeting HPV types -6, -11, -16, and -18, is now available to both males and females age 9 to 26 and is associated with an up to 90% reduction of infections from those HPV types.85

Treatment is aimed at physical destruction of the affected cells. Children often require no treatment as spontaneous regression is common. In cases causing physical or emotional discomfort, or in cases of immunocompromise or risk of transmission, treatment may be indicated. Cryotherapy using liquid nitrogen is an effective treatment for most warts, but care must be taken not to damage underlying structures.86 Topical preparations of salicylic acid, silver nitrate, and glutaraldehyde may also be
used. Treatment of recalcitrant lesions includes a variety of therapeutic options aimed at physically destroying the lesions by electrodessication, cryoablation, and pulsed dye laser therapy. Additional modalities such as H2-antagonists and zinc sulfate may have a role in augmenting the immune response and reducing recurrence rates.

**Cutaneous Manifestations of Human Immunodeficiency Virus**

The HIV-infected patient is significantly more susceptible to infectious and inflammatory skin conditions than the rest of the population. These skin disorders may be due to the HIV infection itself or from opportunistic infections secondary to immunosuppression. During early stages, nonspecific cutaneous manifestations may occur. Acute retroviral syndrome occurs following inoculation in one-half to two-thirds of patients, and 30% to 50% of these patients can present with an acute viral exanthem. This is usually a morbilliform rash affecting the face, trunk, and upper extremities. Other skin changes, as well as common skin disorders with atypical features, can occur, including recurrent varicella zoster, hyperkeratotic warts, and seborrheic dermatitis. Condylomata acuminata and verrucae appear early; however, their frequency and severity do not change with disease progression.

Late-presenting cutaneous manifestations include chronic herpes simplex virus (HSV), cytomegalovirus, and, to a lesser extent, molluscum contagiosum, which is typically treatable with imiquimod. HSV is the most common viral infection in the patient with HIV, and is more likely to display atypical features and less likely to spontaneously resolve in these patients. Mycobacterial infections and mucocutaneous candidiasis also occur. Bacterial infections such as impetigo and folliculitis may be more persistent and widespread.

Malignant lesions such as Kaposi’s sarcoma occur in less than 5% of HIV-infected patients in the United States, although the worldwide prevalence in acquired immunodeficiency syndrome (AIDS) patients exceeds 30%. Kaposi’s sarcoma is a vascular neoplasm that can affect cutaneous and visceral tissues. While the rates of Kaposi’s sarcoma development have sharply declined since the widespread use of antiretroviral therapy, the rates of other cutaneous malignancies have remained stable. The risk of an HIV-infected patient developing a cutaneous malignancy is about 5.7%, with basal cell carcinoma being the most common type encountered.

With regard to general surgical considerations in HIV patients, contributing related morbidities such as malnutrition, decreased CD4 count, and presence of opportunistic infection may result in delayed and attenuated wound healing capacity.

**BENIGN TUMORS**

**Hemangioma**

Hemangiomas are benign vascular tumors that arise from the proliferation of endothelial cells that surround blood-filled cavities. They occur in about 4% of children by 1 year of age. Their natural history is typically presentation shortly after birth, a period of rapid growth during the first year, and then gradual involution over childhood in more than 90% of cases. These hemangiomas are generally managed nonsurgically prior to involution. Occasionally, during the rapid growth phase, the lesions can obstruct the airway, GI tract, vision, and musculoskeletal function. In these cases, surgical resection is indicated prior to the involution phase. Hemangiomas can sometimes consume a large percentage of cardiac output, resulting in high-output heart failure or a consumptive coagulopathy, which may also necessitate resection. These lesions characteristically express the GLUT-1 glucose transporter protein, which is absent in cells of the normal cutaneous vasculature. First-line therapy for these infantile hemangiomas is propranolol, which causes cessation of growth and, in most cases, actual regression of the lesions. Systemic corticosteroids and interferon-α can impede tumor progression, and laser therapy has been used as well. If tumors persist into adolescence leaving a cosmetically undesirable defect, surgical resection may be considered. When surgical resection or debulking is considered, upfront selective embolization can help with planned resection.

**Nevi**

Nevi (singular, nevus) are areas of melanocytic hyperplasia or neoplasia. These collections can be found in the epidermis (junctional), partially in the dermis (compound), or completely within the dermis (dermal). They commonly develop in childhood and young adulthood, and will sometimes spontaneously regress. Exposure to UV radiation is associated with increased density of these lesions. Nevus are typically symmetric and small. Congenital nevi are the result of abnormal development of melanocytes. The events leading to this abnormal development may also affect the surrounding cells, resulting in longer, darker hair. Congenital nevi are found in less than 1% of neonates, and when characterized as giant congenital nevi, they have up to a 5% chance of developing into a malignant melanoma, and may do so even in the first years of childhood. Treatment, therefore, consists of surgical excision of the lesion as early as is feasible. For larger lesions, serial excision and tissue expansion may be required, with the goal of lesion excision being maintenance of function and form while decreasing oncologic risk.

**Cystic Lesions**

Cutaneous cysts are benign lesions that are characterized by overgrowth of epidermis towards the center of the lesion, resulting in keratin accumulation. Epidermoid cysts (often mistakenly referred to as sebaceous cysts) are classically the result of keratin-plugged pilosebaceous units. They commonly affect adult men and women, and present as a dermal or subcutaneous cyst with a single, keratin-plugged punctum at the skin surface, often at or above the upper chest and back. Epidermoid cysts are the most common cutaneous cyst and are histologically characterized by mature epidermis complete with granular layer. Another type of cystic lesion is known as a trichilemmal cyst. These cysts are derived from the outer sheath of hair follicles, and, in contrast to epidermoid cysts, lack a granular layer. They are almost always found on the scalp and more commonly in women. A third type of cutaneous cyst is a dermoid cyst. Dermoid cysts are congenital variants that occur as the result of persistent epithelium within embryonic lines of fusion. They occur most commonly between the forehead and nose tip, and the most frequent site is the eyebrow. They can lie in the subcutaneous tissue or intracranially, and often communicate with the skin surface via a small fistula. These cystic structures contain epithelial tissue, hair, and a variety of epidermal appendages. Treatment for these cystic structures includes surgical excision with care taken to remove the cyst lining to prevent recurrence.
Keratosis

Actinic Keratosis. Actinic keratoses are neoplasms of epidermal keratinocytes that represent a range in a spectrum of disease from sun damage to squamous cell carcinoma. They typically occur in fair-skinned, elderly individuals in primarily sun-exposed areas, and UV radiation exposure is the greatest risk factor. There are multiple variants, and they can present as erythematous and scaly to hypertrophic, keratinized lesions. They can become symptomatic, causing bleeding, pruritus and pain. They can regress spontaneously, persist without change, and transform into invasive squamous cell carcinoma. It is estimated that approximately 10% of actinic keratoses will transform into invasive squamous cell carcinoma, and that progression takes about 2 years on average. About 60% to 65% of squamous cell carcinomas are believed to originate from actinic keratoses. The presence of actinic keratoses also serves as a predictor of development of other squamous cell and basal cell carcinomas. Treatment options are excision, cautery and destruction, and dermabrasion.

Seborrhiec Keratosis. Seborrhiec keratoses are benign lesions of the epidermis that typically present as well-demarcated, “stuck on” appearing papules or plaques over elderly individuals. Clonal expansion of keratinocytes and melanocytes make up the substance of these lesions. They carry no malignant potential and treatment is primarily for cosmetic purposes.

Soft Tissue Tumors

Acrochordons. Acrochordons, also known as skin tags, are benign, pedunculated lesions on the skin made up of epidermal keratinocytes surrounding a collagenous core. Although they can become irritated or necrotic, their removal is generally cosmetic.

Dermatofibromas. Dermatofibromas are benign cutaneous proliferations that appear most commonly on the lower extremities of women. They appear as pink to brown papules that pucker or dimple in the center when the lesion is pinched. It remains unclear whether these lesions have a neoplastic etiology or if they are the result of minor trauma or infection. These lesions are typically asymptomatic, and treatment is only indicated for cosmetic concerns or when a histologic diagnosis is required. Surgical excision is the recommended treatment, although cryotherapy and laser treatment may be used.

Lipomas. Lipomas are the most common subcutaneous neoplasm and have no malignant potential. They present as a painless, slow-growing, mobile mass of the subcutaneous tissue. Usually less than 5 cm in diameter, these neoplasms can reach much larger sizes. Lipomas are largely asymptomatic but may cause pain due to regional nerve deformation. Surgical resection is indicated in cases of local pain, mass effect, or cosmetically sensitive areas. The tumors are usually well circumscribed and amenable to surgical resection. Liposarcoma is a malignant fatty tumor that can mimic a lipoma, but it is often deep-seated, rapidly growing, painful, and invasive. In these cases, cross-sectional imaging is recommended prior to any surgical resection.

Neural Tumors

Neuromas. Neuromas do not represent a true clonal proliferation of neural tissue, but rather disordered growth of Schwann cells and nerve axons, often at the site of previous trauma. They can present within surgical scar lines or at the site of previous trauma as flesh-colored papules or nodules and are typically painful.

Schwannomas. A schwannoma is a benign proliferation of the Schwann cells of the peripheral nerve sheath, and can arise sporadically or in association with type 2 neurofibromatosis. It contains no axons, but may displace the affected nerve and cause pain along the distribution of the nerve.

Neurofibromas. Neurofibromas, in contrast, are benign proliferations that are made up of all nerve elements, and arise as fleshy and nontender, sessile or pedunculated masses on the skin. They can arise sporadically or in association with type 1 neurofibromatosis, and in these cases, are associated with café-au-lait spots and Lisch nodules. They are often asymptomatic, but may be pruritic. The development of pain at the site of a previously asymptomatic neurofibroma may indicate a rare malignant transformation and requires surgical excision and biopsy.

MALIGNANT TUMORS

Basal Cell Carcinoma

Basal cell carcinoma (BCC) is the most common tumor diagnosed in the United States, with an estimated one million new cases occurring each year. It represents 75% of nonmelanoma skin cancers and 25% of all cancers diagnosed each year. BCC is seen slightly more commonly in males and individuals over the age of 60, though the incidence in younger age groups is increasing. The primary risk factor for disease development is sun exposure (UVB rays more than UVA rays), particularly during adolescence. The pathogenesis of BCC stems from mutations of genes involved in tumor suppression, often caused by ionizing radiation. The p53 tumor suppressor gene is defective in approximately 50% of cases. There is a latency period of 20 to 50 years.

BCC tends to occur on sun-exposed areas of the skin, most commonly the nose and other parts of the face. A malignant lesion on the upper lip is almost always BCC, and BCC is the most common malignant eyelid tumor. Because of the photoprotective effect of melanin, dark-skinned individuals are far less commonly affected. Other risk factors for development of BCC include immune suppression, chemical exposure, and ionizing radiation exposure. There are also genetic susceptibilities to development of BCC in conditions such as xeroderma pigmentosa, unilateral basal cell nevus syndrome, and nevoid BCC syndrome.

The natural history of BCC is typically one of local invasion rather than distant metastasis, but untreated BCC can often result in significant morbidity.

There are multiple variants of BCC, and presentation can range from red, flesh-colored, or white macule or papule, to nodules and ulcerated lesions. Growth patterns of these lesions can either be well-circumscribed or diffuse and the most common types of BCC are nodular and micronodular, superficial spreading, and infiltrative.

The most common subtype is the nodular variant, characterized by raised, pearly pink papules with telangiectasias and occasionally a depressed tumor center with raised borders giving the classic “rodent ulcer” appearance. Superficial spreading BCC is confined to the epidermis as a flat, pink, scaling or crusting lesion, often mistaken for eczema, actinic keratosis, fungal infection, or psoriasis. This subtype typically appears on the trunk or extremities and the mean age of diagnosis is 57 years. The infiltrative form appears on the
head and neck in the late 60s, often at embryonic fusion lines, with an opaque yellow-white color that blends with surrounding skin and has no raised edges. The morpheaform subtype represents 2% to 3% of all BCC and is the most aggressive subtype. It usually presents as an indurated macule or papule with the appearance of an enlarging scar. The clinical margins are often indistinct, and the rate of positive margins after excision is high. There is also a pigmented variant of BCC that can be difficult to distinguish from certain melanoma subtypes.

Treatment of BCC varies according to size, location, type, and high- or low-risk. Treatment options include surgical excision, medical, or destructive therapies. Surgical excision should include 4 mm margins for small, primary BCC on cosmetically sensitive areas, and 10 mm margins otherwise. Mohs microsurgical excision is sequential horizontal excision and has been shown to be cost-effective and associated with low recurrence rates for BCC (1%). It is the treatment of choice for morpheaform or other BCC with aggressive features, poorly delineated margins, recurrent tumors, or cosmetically sensitive areas, especially in the midface. A common approach used by dermatologists for very small (<2 mm) and low risk lesions is curettage and destruction, although it should be kept in mind that the local cure rates can be operator and institution dependent. Other destructive techniques include cryosurgery and laser ablation. Radiation therapy can be used as adjuvant therapy following surgery, or as primary therapy in poor surgical candidates with low-risk lesions. The practitioner must be aware of the potential consequences of radiation therapy, including poor cosmetic outcomes and future cancer risk.

Superficial medical therapies are generally reserved for patients in whom surgical and radiation treatment is not an option. Topical imiquimod or 5-fluorouracil have been used for periods of 6 to 16 weeks for small, superficial BCC of the neck, trunk or extremities. Lastly, topical photodynamic therapy has shown some benefit in treatment of premalignant or superficial low-risk lesions as well.

Patients with BCC need to have regular follow-up with full skin examinations every 6 to 12 months. Sixty-six percent of recurrences develop within 3 years, and with a few exceptions occurring decades after initial treatment, the remaining recur within 5 years of initial treatment. A second primary BCC may develop after treatment and, in 40% of cases, presents within the first 3 years after treatment.

Squamous Cell Carcinoma

Squamous cell carcinoma (SCC) is the second most common skin cancer and accounts for approximately 100,000 cases each year. The primary risk factor for the development of SCC is UV radiation exposure; however, other risks include light Fitzpatrick skin type (I or II), environmental factors such as chemical agents, physical agents (ionizing radiation), psoralen, HPV-16 and -18 infections, immunosuppression, smoking, chronic wounds, burn scars, and chronic dermatoses. Heritable risk factors include xeroderma pigmentosum, epidermolysis bullosa, and oculocutaneous albinism.

SCC classically appears as a scaly or ulcerated papule or plaque, and bleeding of the lesion with minimal trauma is not uncommon, but pain is rare. It can exhibit in situ (confined to the epidermis) or invasive subtypes. The most common in situ variant of SCC is actinic keratosis, described previously in this chapter. Invasive squamous cell carcinomas may arise de novo, but more commonly evolve from these precursors. Another in situ variant is known as Bowen disease. This is characterized by full-thickness epidermal dysplasia and clinically appears as a scaly, erythematous patch often with pigmentation and fissuring. When it occurs on the glans penis, it is known as erythroplasia of Queyrat. Ten percent of these cases will eventually become invasive. Outside of these instances, most in situ cases grow slowly and do not progress to invasive disease.

Invasive SCC is characterized by invasion through the basement membrane into the dermis of the skin. It usually arises from an actinic keratosis precursor, but de novo varieties do occur and are higher risk. De novo invasive SCC commonly occurs in organ transplant and immunocompromised patients, and has a metastatic rate as high as 14%. De novo invasive SCC arising in areas of chronic wounds or burn scars are known as Marjolin’s ulcers, and have a higher metastatic potential (Fig. 16-9). Keratoacanthoma is now being accepted as a subtype of SCC that is characterized by a rapidly growing nodule with a central keratin plug. The natural history of invasive disease depends on location and inherent tumor characteristics. Clinical risk factors for recurrence include presentation with neurologic symptoms, immunosuppression, tumor with poorly defined borders, and tumor that arises at a site of prior radiation. Perineural involvement also has a poorer survival with increased local recurrence and lymph node metastasis. Grades of differentiation are based on the ratio of differentiated to undifferentiated cells, with a lower ratio associated with a greater metastatic and recurrent potential. Large (>2 cm) lesions, depth of invasion >4 mm, rapid growth, and location on the ear, lips, nose, scalp, or genitals are all also indicators of worse prognosis.

When feasible, wide surgical excision including subcutaneous fat is the treatment of choice for SCC. Margins of 4 mm are recommended for low-risk lesions and 6 mm for high-risk lesions. Mohs microsurgical excision is indicated for positive margins, recurrent tumors, sites where cosmesis or function preservation is critical, poorly differentiated tumors, invasive lesions, and verrucous tumors. Using this modality often results in lower recurrence rates. It has also found use in nail bed lesions and in those arising in a background of osteomyelitis. The role of lymph node dissection in the setting of SCC continues to evolve. Lymphadenectomy is indicated following fine-needle aspiration or core biopsy for clinically palpable lymph nodes or nodes detected on cross-sectional imaging. Nodes
should also be removed from susceptible regional lymph node basins in patients with SCC in the setting of chronic wounds. Patients with parotid disease benefit from a superficial or total parotidectomy (with facial nerve preservation) and adjuvant radiotherapy. Sentinel lymph node dissection may be used in high-risk cases with clinically negative nodal disease. Radiation therapy is typically reserved as primary therapy for those who are poor surgical candidates, and as adjuvant therapy after surgical resection for large, high-risk tumors. When used as primary therapy, cure rates may approach 90%.^{121}

### Melanoma

**Background.** In 2017, an estimated 87,110 new cases of melanoma were diagnosed, as well as 9730 melanoma-related deaths. The incidence of melanoma is rising faster than most other solid malignancies, and these numbers likely represent an underestimation given the many in situ and thin melanoma cases that are underreported. These tumors primarily arise from melanocytes at the epidermal-dermal junction but may also originate from mucosal surfaces of the oropharynx, nasopharynx, eyes, proximal esophagus, anorectum, and female genitalia. Melanoma characteristically metastasizes quite often, and can travel to most other tissues in the body. This metastasis confers a poor prognosis in patients, with a median life span of 6 to 8 months after diagnosis.^{132}

The most important risk factor for the development of melanoma is exposure to UV radiation. It was recently reported that greater than 10 tanning bed sessions by adolescents and young adults increased their relative risk of developing melanoma twofold,^{133} and there is a positive association with intermittent childhood sunburns and melanoma development.^{134} There is also an association with residence at high altitudes or in close proximity to the equator. Both personal and family history of melanomas increase the risk of primary melanoma development. Individuals with dysplastic nevi have a 6% to 10% overall lifetime risk of melanoma, with tumors arising from preexisting nevi or de novo. Individuals with familial atypical multiple mole melanoma syndrome have numerous melanocytic nevi and a greatly increased risk of cutaneous melanoma. Congenital nevi increase the risk for melanoma proportionally with size, and giant congenital nevi (generally considered >20 cm in diameter) are associated with a 5% to 8% lifetime risk. Melanoma development is strongly associated with the p16/CDK4,6/Rb and p14ARF/HMD2/p53 tumor suppressor pathways and the RAF-MEK-ERK and PI3K-Akt oncogenic pathways.^{135}

**Clinical Presentation.** The presentation of melanoma is commonly used to determine subtype but often starts as a localized, radial growth phase followed by a more aggressive, vertical growth phase. Approximately 30% of melanoma lesions arise from a preexisting melanocytic nevus. The most common subtype of melanoma is superficial spreading (Fig. 16-10). This accounts for 50% to 70% of melanomas and typically arises from a precursor melanocytic nevus. Nodular subtype accounts for 15% to 30% of melanomas, and typically arises de novo, most commonly in men and on the trunk (Figs. 16-11 and 16-12). This subtype is aggressive with an early vertical growth pattern and is often diagnosed at a later stage. Up to 5% of these lesions will lack melanin and can be mistaken for other cutaneous lesions. Lentigo maligna represents 10% of melanoma cases and is a less aggressive subtype of melanoma in situ that typically arises on sun-exposed areas of the head and neck. Acral lentiginous melanoma accounts for 29% to 72% of melanomas in dark-skinned individuals, is occasionally seen in Caucasians, and is found on palmar, plantar, and subungual surfaces. This subtype is not thought to be due to sun exposure.

**Diagnosis and Staging.** Workup should begin with a history and physical exam. The entire skin should be checked for synchronous primaries, satellite lesions, and in-transit metastases, and all nodal basins should be examined for lymphadenopathy. Suspicious lesions should undergo excisional biopsy with 1- to 3-mm margins; however, tumors that are large or are in a cosmetically or anatomically challenging area can be approached by incisional biopsy, including punch biopsy.^{136}

---

**Figure 16-10.** Primary cutaneous melanoma seen in the scalp of a 61-year-old male.

**Figure 16-11.** Nodular melanoma seen in the leg of a 55-year-old male.
Melanoma is characterized according to the American Joint Committee on Cancer (AJCC) as localized disease (stage I and II), regional disease (stage III), or distant metastatic disease (stage IV). The Breslow tumor thickness replaced the Clark’s level as the most important prognostic indicator for melanoma staging.132,140 The Breslow tumor thickness measures the depth of penetration of the lesions from the top of the granular layer of the epidermis into the dermal layer and is directly related to the risk of disease progression. Tumor ulceration, mitotic rate $\geq 1$ per mm$^2$, and metastasis are all also associated with worse prognosis. In the presence of regional node metastasis, the number of nodes affected is the most important prognostic indicator. For stage IV disease, the site of metastasis is strongly associated with prognosis, and elevated lactate dehydrogenase (LDH) is associated with a worse prognosis.141

There is no supportive evidence for chest X-ray or computed tomography (CT) in the staging of patients unless there is positive regional lymph node disease, although it can be used to work up specific signs and symptoms when metastatic disease is suspected.136 In patients with stage III or greater disease, there is a high risk for distant metastasis, and imaging is recommended for baseline staging. These patients should receive additional imaging that includes CT of the chest, abdomen, and pelvis; whole-body positron emission tomography (PET)-CT; or brain magnetic resonance imaging (MRI).136

The sentinel lymph node biopsy (SLNB) technique for melanoma was introduced in 1992 and has become a cornerstone in the management of melanoma, although its role in management continues to be refined. SLNB is a standard staging procedure to evaluate the regional nodes for patients with clinically node-negative malignant melanoma. Detecting subclinical nodal metastasis may benefit from lymphadenectomy or adjuvant therapy. This technique identifies the first draining lymph node from the primary lesion and has shown excellent accuracy and significantly less morbidity compared to complete resection of nodal basins. It is almost always performed at the time of initial wide excision, as SLN mapping after lymphatic violation from surgical excision could decrease the accuracy of the test. Recently, the results of MSLT-1, an international, multicenter, phase III trial were published. This study randomized clinically node negative patients to either SLNB at the time of primary melanoma excision (and completion lymphadenectomy if positive) or nodal basin monitoring (and delayed complete lymphadenectomy for recurrent lymph node disease).142 The results of this study demonstrated that SLNB, with immediate lymphadenectomy if positive, improved disease-free survival by 7% and 10% in patients with intermediate thickness (1.2–3.5 mm) and thick (>3.5 mm) lesions respectively. The use of SLNB in lesions <1.2 mm thick did not affect disease-free survival. SLNB should also be offered to thin lesions with high-risk features (thickness >0.75, ulceration, mitoses $\geq 1$ per mm$^2$).136 The SLNB involves preoperative lymphoscintigraphy with intradermal injections of technetium-sulfur colloid to delineate lymphatic drainage and intraoperative intradermal injection of 1 mL of isosulfan or methylene blue dye near the tumor or biopsy site. (Figs. 16-13 and 16-14). The radioactive tracer-dye combination allows the sentinel node to be identified in 98% of cases. An incision over the lymph node basin of interest allows nodes to be excised and studied with hematoxylin and eosin and immunohistochemistry (S100, HMB45, and MART-1/Melan-A) staining (Fig. 16-15).
Surgical Management of the Primary Tumors and Lymph Nodes. The appropriate excision margin is based on primary tumor thickness. Several retrospective studies suggest that for melanoma in situ, 0.5 to 1 cm margins are sufficient.\textsuperscript{143-145} We believe that 1-cm margins should be obtained in anatomically feasible areas given the possibility of an incidental finding of a small invasive component in permanent sections. Several studies compared 1- to 3-cm margins and 2- to 5-cm margins in melanoma <2 mm thick, and 2- to 4-cm margins in melanoma lesions 1 to 4 mm thick and found no difference.\textsuperscript{146-149} A British trial suggested that there is a limit to how narrow margins can be for melanomas >2 mm thick by showing that 1-cm margins provide worse outcomes compared to 3-cm margins.\textsuperscript{150} Tumors <1 mm thick require 0.5 to 1 cm margins. Tumors 1 to 2 mm thick require 1 to 2 cm margins, and tumors >2 mm thick require 2-cm margins.

Completion lymphadenectomy is commonly performed in cases of sentinel nodes with metastatic disease, but it has been shown that most of these nodal basins do not have additional disease. Thus, many surgeons do not perform routine completion lymphadenectomy for positive nodes, and data from the MSLT-2 may provide guidance. It has been shown that those patients with nonsentinel lymph node positivity found on completion lymph node dissection after a positive SLN have higher rates of recurrence and lower rates of survival. The therapeutic value, however, has not been clearly demonstrated. In patients with clinically positive lymph nodes but absent signs of distant metastasis on PET-CT, therapeutic lymph node dissection is associated with 5-year survival rates of 30% to 50%. In these cases, resection of the primary melanoma lesion and a completion lymphadenectomy should be performed.

Individuals with face, anterior scalp, and ear primaries who have a positive SLNB should undergo a superficial parotidectomy in addition to a modified radical neck dissection.
Figure 16-15. Operation of sentinel lymph node biopsy for cutaneous melanoma. After preoperative injection of radioactive technetium-99m-labeled sulfur colloid tracer and intraoperative injection of Lymphazurin blue dye around the primary melanoma excision site, the nodal basin of interest is identified. An incision is made directly overlying the lymph node basin in the posterior axillary space. The sentinel lymph nodes are identified and excised.

Patients with positive sentinel nodes in the inguino-femoral nodal basin should undergo an inguino-femoral lymphadenectomy that includes removal of Cloquet’s node. If Cloquet’s node is positive or the patient has three or more nodes that contain melanoma metastases the probability of clinically occult positive pelvic nodes is increased. The effect of ileo-obturator lymph node dissection on the survival of these patients is unknown.

Surgery for Regional and Distant Metastasis. Nonmetastatic, in-transit disease should undergo excision to clear margins when feasible. However, disease not amenable to complete excision derives benefit from isolated limb perfusion (ILP) and isolated limb infusion (ILI) (Fig. 16-16). These two modalities are used to treat regional disease, and their purpose is to administer high doses of chemotherapy, commonly melphalan, to an affected limb while avoiding systemic drug toxicity. ILI was shown to provide a 31% response rate in one study, while hyperthermic ILP provided a 63% complete response rate in an independent study.151-154

The most common sites of metastasis of melanoma are the lung and liver. These are followed by the brain, gastrointestinal tract, distant skin, and subcutaneous tissue. A limited subset of patients with small-volume, limited distant metastases to the brain, gastrointestinal tract, or distant skin can be treated with surgical resection or directed radiation. Liver metastases are better dealt without surgical resection unless they arise from an ocular primary. Adjuvant therapy after resection of metastatic lesions is not standard of care. However, there are ongoing clinical trials addressing whether drugs and vaccines will be beneficial in this setting.115 Surgery may provide palliation for patients with gastrointestinal obstruction, gastrointestinal hemorrhage, and nongastrointestinal hemorrhage. Radiotherapy for symptomatic bony or brain metastases provides palliation in diffuse disease.

Adjuvant and Palliative Therapies. Eastern Cooperative Oncology Group (ECOG) Trials 1684, 1690, and 1694 were prospective randomized controlled trials that demonstrated...
disease-free survival advantages in patients with melanoma >4 mm in thickness with or without lymph node involvement if they received adjuvant treatment with high-dose interferon (IFN). A European Organization for Research and Treatment of Cancer (EORTC) trial also showed recurrence-free survival benefit with pegylated IFN. It is important to note that IFN therapy is not well tolerated and the pooled analysis of these trials did not show an improvement in overall survival benefit.

Most patients with melanoma will not be surgical candidates. Although medical options for melanoma have historically been poor, several recent studies have shown promise in drug therapy for metastatic melanoma. BRAF inhibitors (sorafenib), anti-PD1 antibodies, CTLA antibodies (ipilimumab), and high-dose interleukin-2 (IL-2) with and without vaccines have been shown in randomized studies to provide survival benefit in metastatic disease. Despite the excitement of recent drugs, surgery will likely play an adjunct role in treating individuals who develop resistance to these drugs over time.

Special Circumstances. Special circumstances of note are melanoma in pregnant women, melanoma of unknown primaries, and noncutaneous melanomas. The prognosis of pregnant patients is similar to women who are not pregnant. Extrapolation of studies examining the SLNB technique in pregnant women with breast cancer suggests lymphoscintigraphy may be done safely during pregnancy without risk to the fetus (blue dye is contraindicated). General anesthesia should be avoided during the first trimester, and local anesthetics should be used during this time. It has been suggested by some that after excising the primary tumor during pregnancy, the SLNB may be performed after delivery.

Unknown primary melanoma occurs in 2% to 5% of cases and most commonly occurs in the lymph nodes. In these cases, a thorough search for the primary lesion should be sought, including eliciting a history about prior skin lesions, skin procedures (e.g., curettage and electrodesiccation, excision, laser), and review of any prior “benign” pathology. The surgeon should be aware that melanoma is known to spontaneously regress because of an immune response. Melanoma of unknown primary has survival rates comparable to melanoma diagnosed with a known primary of the same stage.

The most common noncutaneous disease site is ocular melanoma, and treatment of this condition includes photoocoagulation, partial resection, radiation, or enucleation. Ocular melanomas exclusively metastasize to the liver and not regional lymph nodes, and some patients benefit from liver resection. Melanoma of the mucous membranes most commonly presents in the oral cavity, oropharynx, nasopharynx, paranasal sinus, anus, rectum, and female genitalia. Patients with this presentation have a worse prognosis (10% 5-year survival) than patients with cutaneous melanomas. Management should be excision to negative margins, and radical resections should be avoided because the role of surgery is loco-regional control, not cure. Generally speaking, lymph node dissection should be avoided because the benefit is unclear.

Merkel Cell Carcinoma
Merkel cell carcinoma (MCC) is an aggressive neuroendocrine tumor of the skin whose incidence has been rapidly increasing. Although it is a much rarer malignancy than melanoma, the prognosis is much worse, with a 5-year survival of 46%. Merkel cells are epidermal appendages involved in the sensation of light touch, and along with Merkel cell carcinoma, are cyto-keratin-20 positive. This stain is now used to confirm the diagnosis. Other risk factors include age >65 years (the median age of diagnosis is 70 years), UV exposure, Merkel cell polyoma virus, and immunosuppression. MCC typically presents as a rapidly growing, flesh-colored to red or purple papule or plaque (Fig. 16-17). Regional nodes are involved in 30% of patients at diagnosis, and 50% will develop systemic disease (skin, lymph nodes, liver, lung, bone, and brain). There are no standardized diagnostic imaging studies for staging, but CT of the chest, abdomen, pelvis and octreotide scans may provide useful information when clinically indicated.

After a thorough skin examination, treatment should begin by evaluating nodal basins. Patients without clinical nodal disease should undergo an SLNB prior to wide local excision because studies suggest a benefit. In patients with sentinel lymph nodes with metastatic disease, completion lymphadenectomy and/or radiation therapy may follow, and in patients with node-negative disease, observation or radiation therapy should be considered. SLNB is important for staging and treatment, and the literature suggests that it predicts recurrence and relapse-free survival. Elective lymph node dissection may decrease regional nodal recurrence and in-transit metastases. Patients with clinically positive nodes should have an FNA to confirm disease. If positive, a metastatic staging workup should follow, and, if negative, treatment of the primary and nodal basin as managed for sentinel lymph node-positive disease should be considered. A negative FNA and open biopsy-negative disease should be managed by treatment of the primary disease alone.

Figure 16-17. Merkel cell carcinoma seen just above the left knee in a 44-year-old female.
Patients with metastatic disease should be managed according to consensus from a multidisciplinary tumor board.

Important surgical principles for excision of the primary lesion are to excise with wide margins down to fascia and complete circumferential and peripheral deep-margin assessment. Recommended management for margins is 1 to 3 cm, but there are no randomized trials defining these margins. Chemotherapy and adjuvant radiation are commonly used, but there are no data to support a specific regimen or that demonstrate a definitive survival benefit.

Recurrence of MCC is common. One study of 95 patients showed a 47% recurrence, with 80% of recurrences occurring within 2 years and 96% occurring within 5 years.\textsuperscript{173,174} Regional lymph node disease is common, and 70% of patients will have nodal spread within 2 years of disease presentation. Five-year overall survival of head and neck disease in surgically treated patients is between 40% and 68%.

**Kaposi’s Sarcoma**

Kaposi’s sarcoma is characterized by the proliferation and inflammation of endothelial-derived spindle cell lesions. There are five major forms of this angioproliferative disorder: classic (Mediterranean), African endemic, HIV-negative men having sex with men (MSM)-associated, and immunosuppression-associated. They are all driven by the human herpesvirus (HHV-8).\textsuperscript{175} Kaposi’s sarcoma is diagnosed after the fifth decade of life and predominantly found on the skin but can occur anywhere in the body. In North America, the Kaposi’s sarcoma herpes virus is transmitted via sexual and nonsexual routes and predominantly affects individuals with compromised immune systems such as those with HIV and transplant recipients on immune-suppressing medications. Clinically, Kaposi’s sarcoma appears as multifocal, rubbery blue-red nodules. Treatment of AIDS-associated Kaposi’s sarcoma is with antiviral therapy, and many patients experience a dramatic treatment response.\textsuperscript{176,177} Those individuals who do not respond and have limited mucocutaneous disease may benefit from cryotherapy, photodynamic therapy, radiation therapy, intralesional injections, and topical therapy. Surgical biopsy is important for disease diagnosis, but given the high local recurrence and the fact that Kaposi’s sarcoma represents more of a systemic rather than local disease, the benefit of surgery is limited and generally should not be pursued except for palliation.

**Dermatofibrosarcoma Protuberans**

This rare, low-grade sarcoma of fibroblast origin commonly afflicts individuals during their third decade of life. It has low distant metastatic potential, but it behaves aggressively locally with finger-like extensions. Tumor depth is the most important prognostic variable. Presentation is characteristically a slow-growing, asymptomatic, violaceous plaque involving the trunk, head, neck, or extremities (Fig. 16-18). Nearly all cases are positive for CD34 and negative for factor XIIIa.\textsuperscript{178,179} Treatment is wide local excision with 3-cm margins down to deep underlying fascia or Mohs microsurgery in cosmetically sensitive areas where maximum tissue preservation will benefit.\textsuperscript{180} No nodal dissection is needed, and both approaches provide similar local control.\textsuperscript{181} Some clinicians have used radiation therapy and biologic agents (imatinib) as adjuvant therapy with some success in patients with advanced disease. Local recurrence occurs in 50% to 75% of cases, usually within 3 years of treatment. Thus, clinical follow-up is important. Recurrent tumors should be resected whenever possible.

**Malignant Fibrous Histiocytoma (Undifferentiated Pleomorphic Sarcoma and Myxofibrosarcoma)**

This uncommon, cutaneous, spindle-cell, soft tissue sarcoma occurs in the extremities, head, and neck of elderly patients. They present as solitary, soft to firm, skin-colored subcutaneous nodules. Complete surgical resection is the treatment of choice, and adjuvant radiation therapy provides local control; patients with positive margins benefit most from this combination. Nevertheless, patients undergoing complete gross resection will experience recurrence in 30% to 35% of cases.\textsuperscript{182} Up to 50% of patients may present with distant metastasis, and this is a contraindication to surgical resection.

**Angiosarcoma**

Angiosarcoma is an uncommon, aggressive cancer that arises from vascular endothelial cells and occurs in four variants, all of which have a poor prognosis.\textsuperscript{183} The 5-year survival estimate is 15%. The head and neck variant presents in individuals older than 40 years as an ill-defined red patch on the face or scalp, often with satellite lesions and distant metastasis, and has a median survival of 18 to 28 months. Lymphedema-associated angiosarcoma (Stewart-Treves) develops on an extremity ipsilateral to an axillary lymphadenectomy. It appears on the upper, medial arm as a violaceous plaque in an individual with nonpitting edema and has a poor survival. Radiation-induced angiosarcoma occurs 4 to 25 years after radiation therapy for benign and malignant conditions. Finally, the epithelioid variant of angiosarcoma involves the lower extremities and also has a poor prognosis. Surgical excision with wide margins is the treatment...
of choice for localized disease, but the rate of recurrence is high. Adjuvant radiation therapy can be considered in a multidisciplinary fashion. Cases of extremity disease can be considered for amputation. For widely metastatic disease, chemotherapy and radiation may provide palliation, but these modalities do not prolong overall survival.\textsuperscript{115}

**Extramammary Paget’s Disease**

This rare adenocarcinoma of apocrine glands arises in axillary, perianal, and genital regions of men and women.\textsuperscript{184} Clinical presentation is that of erythematous or nonpigmented plaques with an eczema-like appearance that often persist after failed treatment from other therapies. An important characteristic and one that the surgeon must be acutely aware of is the high incidence of concomitant other malignancies with this cutaneous disease. Forty percent of cases are associated with primary gastrointestinal and genitourinary malignancies, and a diligent search should be made after a diagnosis of extramammary Paget’s disease is made. Treatment is surgical resection with negative microscopic margins, and adjuvant radiation may provide additional locoregional control.

**CONCLUSION**

The skin is the largest organ in the human body and is composed of three organized layers that are the source of numerous pathologies. Recognition and management of cutaneous and subcutaneous diseases require an astute clinician to optimize clinical outcomes. Improvements in drugs, therapies, and healthcare practices have helped recovery from skin injuries. Skin and subcutaneous diseases are often managed medically, although surgery frequently complements treatment. Benign tumors are surgical diseases, while malignant tumors are primarily treated surgically, and additional modalities including chemotherapy and radiation therapy are sometimes required. The management of melanoma is at an exciting phase, requiring the coordinated multidisciplinary care of medical oncologists, surgical oncologists, radiation oncologists, dermatopathologists, and plastic and reconstructive surgeons. The advent of new drug therapies will redefine the role of surgery in this disease in the coming years.

**REFERENCES**

Entries highlighted in bright blue are key references.

Breast cancer has captured the attention of surgeons throughout the ages. The Smith Surgical Papyrus (3000–2500 B.C.) is the earliest known document to refer to breast cancer. The cancer was in a man, but the description encompassed most of the common clinical features. In reference to this cancer, the author concluded, “There is no treatment.” There were few other historical references to breast cancer until the first century. In De Medicina, Celsus commented on the value of operations for early breast cancer: “None of these may be removed but the cacoethes (early cancer), the rest are irritated by every method of cure. The more violent the operations are, the more angry they grow.” In the second century, Galen inscribed his classical clinical observation: “We have often seen in the breast a tumor exactly resembling the animal the crab. Just as the crab has legs on both sides of his body, so in this disease the veins extending out from the unnatural growth take the shape of a crab’s legs. We have often cured this disease in its early stages, but after it has reached a large size, no one has cured it. In all operations we attempt to excise the tumor in a circle where it borders on the healthy tissue.”

The Galenic system of medicine ascribed cancers to an excess of black bile and concluded that excision of a local bodily outbreak could not cure the systemic imbalance. Theories espoused by Galen dominated medicine until the Renaissance. In 1652, Tulp introduced the idea that cancer was contagious when he reported an elderly woman and her housemaid who both developed breast cancer (N. Tulp, Observationes medicæ 1652). This single incidence was accepted as conclusive.

</table>
The breast receives its principal blood supply from perforating branches of the internal mammary artery, lateral branches of the posterior intercostal arteries, and branches from the axillary artery, including the highest thoracic, lateral thoracic, and pectoral branches of the thoracoacromial artery.

The axillary lymph nodes usually receive >75% of the lymph drainage from the breast, and the rest flows through the lymph vessels that accompany the perforating branches of the internal mammary artery and enters the parasternal (internal mammary) group of lymph nodes.

Breast development and function are initiated by a variety of hormonal stimuli, with the major trophic effects being modulated by estrogen, progesterone, and prolactin.

Benign breast disorders and diseases are related to the normal processes of reproductive life and to involution, and there is a spectrum of breast conditions that ranges from normal to disorder to disease (aberrations of normal development and involution classification).

To calculate breast cancer risk using the Gail model, a woman’s risk factors are translated into an overall risk score by multiplying her relative risks from several categories. This risk score is then compared with an adjusted population risk of breast cancer to determine the woman’s individual risk. This model is not appropriate for use in women with a known BRCA1 or BRCA2 mutation or women with lobular or ductal carcinoma in situ.

Routine use of screening mammography in women ≥50 years of age reduces mortality from breast cancer by 25%. Magnetic resonance imaging (MRI) screening is recommended in women with BRCA mutations and may be considered in women with a greater than 20% to 25% lifetime risk of developing breast cancer.

Core-needle biopsy is the preferred method for diagnosis of palpable or nonpalpable breast abnormalities.

When a diagnosis of breast cancer is made, the surgeon should determine the clinical stage, histologic characteristics, and appropriate biomarker levels before initiating local therapy.

Sentinel node dissection is the preferred method for staging of the regional lymph nodes in women with clinically node-negative invasive breast cancer. Axillary dissection may be avoided in women with one to two positive sentinel nodes who are treated with breast conserving surgery, whole breast radiation, and systemic therapy.

Local-regional and systemic therapy decisions for an individual patient with breast cancer are best made using a multidisciplinary treatment approach. The sequencing of therapies is dependent on patient and tumor related factors including breast cancer subtype.
Adjuvant Breast and Bowel Project (NSABP) conducted a randomized trial in the early 1970s to determine the impact of local and regional treatments on survival in operable breast cancer. In the B-04 trial, 1665 women were enrolled and stratified by clinical assessment of the axillary lymph nodes. The clinically node-negative women were randomized into three treatment groups: (a) Halsted radical mastectomy; (b) total mastectomy plus radiation therapy; and (c) total mastectomy alone. Clinically node-positive women were randomized to Halsted radical mastectomy or total mastectomy plus radiation therapy. This trial accrued patients between 1971 and 1974, an era that predated widespread availability of effective systemic therapy for breast cancer and therefore reflect survival associated with local-regional therapy alone. There were no differences in survival between the three groups of node-negative women or between the two groups of node-positive women. These overall survival equivalence patterns persisted at 25 years of follow-up.9

The next major advance in the surgical management of breast cancer was the development of breast conserving surgery. Breast conserving surgery and radiation treatment was first reported by Geoffrey Keynes of St Bartholomew’s Hospital, London in the British Medical Journal in 1937.10 Several decades later, the NSABP launched the B-06 trial, a phase 3 study that randomized 1851 patients to total mastectomy, lumpectomy alone, or lumpectomy with breast irradiation. The results showed no difference in disease-free, distant disease-free, and overall survival among the three groups; however, the omission of radiation therapy resulted in significantly higher rates of ipsilateral breast tumor recurrence in those who received lumpectomy alone.11 The B-06 trial excluded patients who had palpable axillary lymph nodes, and those patients randomized to breast conserving surgery had frozen sections performed. If on frozen section the margins were involved, the surgeon proceeded to perform a mastectomy, but the patient was included in the analysis as having had a breast conserving operation. Furthermore, in B-06, local in-breast recurrences were regarded as “nonevents” in terms of disease-free survival. Both the NSABP B-04 and B-06 trials were taken to refute the Halstedian concept that cancer spread throughout a region of the breast to lymphatics and then on to distant sites. Bernard Fisher proposed the “alternative hypothesis” that breast cancer was a systemic disease at diagnosis and that tumor cells had access to both the blood and lymphatic systems and that regional lymph nodes were a marker of systemic disease and not a barrier to the dissemination of cancer cells. He proposed that host factors were important in the development of metastasis and that variations in the local-regional approach to breast cancer treatment were not likely to substantially impact survival. This idea was dominant for a number of years but has been challenged by the Early Breast Cancer Trialists’ Collaborative Group (EBCTCG) overview analysis, which reported that “the avoidance of recurrence in a conserved breast . . . avoids about one breast cancer death over the next 15 years for every four such recurrences avoided,”12 indicating that not all breast cancer is a systemic disease at presentation.

During the 1970s, clinical trials were initiated to determine the value of systemic therapy in the postoperative setting as an adjuvant to surgery. The EBCTCG was established in 1985 to coordinate the meta-analysis of data from randomized clinical trials in order to examine the impact of adjuvant treatments for breast cancer on recurrence and mortality. The EBCTCG overview has demonstrated that anthracycline containing regimens are superior to cyclophosphamide, methotrexate, and 5-fluorouracil (CMF), and more recently, that the addition of a taxane to an anthracycline-based regimen reduces cancer mortality by one-third.13 The overview has also demonstrated that tamoxifen is of benefit only in patients with estrogen receptor (ER) positive breast cancer and that tamoxifen may decrease mortality from breast cancer by as much as 30%.14 Importantly, the EBCTCG data have shown that proportional reduction in risk was not significantly affected by standard clinical and pathologic factors such as tumor size, ER status, and nodal status.14 This underscores the importance of stratification of risk in determining adjuvant therapy decisions in order to minimize the toxicities of therapies in those unlikely to benefit, yet realize the substantial benefits gained in local-regional control and survival in those at higher risk.

Many early randomized clinical trials considered all patients similarly in terms of treatment viewing breast cancer as more of a homogeneous disease. Breast cancer has traditionally been defined by pathologic determinants using conventional light microscopy and basic histologic techniques. In the 1980s, immunohistochemistry allowed assessment of the expression of individual tumor markers (most commonly proteins) while DNA was initially assessed in terms of its ploidy status. Subsequently, breast cancer specimens have been interrogated at the level of the DNA by labeling genes of interest and allowing fluorescent dyes to quantify the abundance of a particular gene and comparing a large number of genes simultaneously in a single breast cancer specimen. Gene expression arrays have shown that breast cancers cluster according to their intrinsic gene expression patterns into at least five intrinsic subtypes and these intrinsic subtypes correlate with breast cancer outcomes.15 Breast cancers are now classified by molecular subtypes and these are being used for risk stratification and decision making in terms of local-regional and systemic therapies.

Currently, 50% of American women will consult a surgeon regarding breast disease, 25% will undergo breast biopsy for diagnosis of an abnormality, and 12% will develop some variant of breast cancer. Considerable progress has been made in the integration of surgery, radiation therapy, and systemic therapy to control local-regional disease, enhance survival, and improve the quality of life of breast cancer survivors. Surgeons are traditionally the first physician consulted for breast care, and it is critical for them to be well trained in all aspects of the breast from embryologic development, to growth and development, to benign and malignant disease processes. This will allow the greatest opportunity to achieve optimal outcomes for patients and their families.

**EMBRYOLOGY AND FUNCTIONAL ANATOMY OF THE BREAST**

**Embryology**

At the fifth or sixth week of fetal development, two ventral bands of thickened ectoderm (mammary ridges, milk lines) are evident in the embryo.16 In most mammals, paired breasts develop along these ridges, which extend from the base of the forelimb (future axilla) to the region of the hind limb (inguinal area). These ridges are not prominent in the human embryo and disappear after a short time, except for small portions that may persist in the pectoral region. Accessory breasts (polymastia) or accessory nipples (polythelia) may
occur along the milk line (Fig. 17-1) when normal regression fails. Each breast develops when an ingrowth of ectoderm forms a primary tissue bud in the mesenchyme. The primary bud, in turn, initiates the development of 15 to 20 secondary buds. Epithelial cords develop from the secondary buds and extend into the surrounding mesenchyme. Major (lactiferous) ducts develop, which open into a shallow mammary pit. During infancy, a proliferation of mesenchyme transforms the mammary pit into a nipple. If there is failure of a pit to elevate above skin level, an inverted nipple results. This congenital malformation occurs in 4% of infants. At birth, the breasts are identical in males and females, demonstrating only the presence of major ducts. Enlargement of the breast may be evident, and a secretion, historically referred to as witch’s milk, may be produced. These transitory events occur in response to maternal hormones that cross the placenta.

The breast remains undeveloped in the female until puberty, when it enlarges in response to ovarian estrogen and progesterone, which initiate proliferation of the epithelial and connective tissue elements. However, the breasts remain incompletely developed until pregnancy occurs. Absence of the breast (amastia) is rare and results from an arrest in mammary ridge development that occurs during the sixth fetal week. Poland’s syndrome consists of hypoplasia or complete absence of the breast, costal cartilage and rib defects, hypoplasia of the subcutaneous tissues of the chest wall, and brachysyndactyly. Breast hypoplasia also may be iatrogenically induced before puberty by trauma, infection, or radiation therapy. Symmastia is a rare anomaly recognized as webbing between the breasts across the midline. Accessory nipples (polythelia) occur in <1% of infants and may be associated with abnormalities of the urinary and cardiovascular systems. Supernumerary breasts may occur in any configuration along the mammary milk line but most frequently occur between the normal nipple location and the symphysis pubis. Turner’s syndrome (ovarian agenesis and dysgenesis) and Fleischer’s syndrome (displacement of the nipples and bilateral renal hypoplasia) may have polymastia as a component. Accessory axillary breast tissue is uncommon and usually is bilateral.

**Functional Anatomy**

The breast is composed of 15 to 20 lobes (Fig. 17-2), which are each composed of several lobules.17 Fibrous bands of connective tissue travel through the breast (Cooper’s suspensory ligaments), insert perpendicularly into the dermis, and provide structural support. The mature female breast extends from the level of the second or third rib to the inframammary fold at the sixth or seventh rib. It extends transversely from the lateral border of the sternum to the anterior axillary line. The deep or posterior surface of the breast rests on the fascia of the pectoralis major, serratus anterior, and external oblique abdominal muscles, and the upper extent of the rectus sheath. The retro-mammary bursa may be identified on the posterior aspect of the breast between the investing fascia of the breast and the fascia of the pectoralis major muscles. The axillary tail of Spence extends laterally across the anterior axillary fold. The upper outer quadrant of the breast contains a greater volume of tissue than do the other quadrants. The breast has a protuberant conical form. The base of the cone is roughly circular, measuring 10 to 12 cm in diameter. Considerable variations in the size, contour, and density of the breast are evident among individuals. The nulliparous breast has a hemispheric configuration with distinct flattening above the nipple. With the hormonal stimulation that accompanies pregnancy and lactation, the breast becomes larger and increases in volume and density, whereas with senescence, it assumes a flattened, flaccid, and more pendulous configuration with decreased volume.

**Nipple-Areola Complex.** The epidermis of the nipple-areola complex is pigmented and is variably corrugated. During puberty, the pigment becomes darker and the nipple assumes an elevated configuration. Throughout pregnancy, the areola
enlarges and pigmentation is further enhanced. The areola contains sebaceous glands, sweat glands, and accessory glands, which produce small elevations on the surface of the areola (Montgomery’s tubercles). Smooth muscle bundle fibers, which lie circumferentially in the dense connective tissue and longitudinally along the major ducts, extend upward into the nipple, where they are responsible for the nipple erection that occurs with various sensory stimuli. The dermal papilla at the tip of the nipple contains numerous sensory nerve endings and Meissner’s corpuscles. This rich sensory innervation is of functional importance because the sucking of the infant initiates a chain of neurohumoral events that results in milk letdown.

**Inactive and Active Breast.** Each lobe of the breast terminates in a major (lactiferous) duct (2–4 mm in diameter), which opens through a constricted orifice (0.4–0.7 mm in diameter) into the ampulla of the nipple (see Fig. 17-2). Immediately below the nipple-areola complex, each major duct has a dilated portion (lactiferous sinus), which is lined with stratified squamous epithelium. Major ducts are lined with two layers of cuboidal cells, whereas minor ducts are lined with a single layer of columnar or cuboidal cells. Myoepithelial cells of ectodermal origin reside between the epithelial cells in the basal lamina and contain myofibrils. In the inactive breast, the epithelium is sparse and consists primarily of ductal epithelium (Fig. 17-3). In the early phase of the menstrual cycle, minor ducts are cord-like with small lumina. With estrogen stimulation at the time of ovulation, alveolar epithelium increases in height, duct lumina become more prominent, and some secretions accumulate. When the hormonal stimulation decreases, the alveolar epithelium regresses.

With pregnancy, the breast undergoes proliferative and developmental maturation. As the breast enlarges in response to hormonal stimulation, lymphocytes, plasma cells, and eosinophils accumulate within the connective tissues. The minor ducts branch and alveoli develop. Development of the alveoli is asymmetric, and variations in the degree of development may occur within a single lobule (Fig. 17-4). With parturition, enlargement of the breasts occurs via hypertrophy of alveolar epithelium and accumulation of secretory products in the lumina of the minor ducts. Alveolar epithelium contains abundant endoplasmic reticulum, large mitochondria, Golgi complexes, and dense lysosomes. Two distinct substances are produced by the alveolar epithelium: (a) the protein component of milk, which is synthesized in the endoplasmic reticulum (merocrine secretion); and (b) the lipid component of milk (apocrine secretion), which forms as free lipid droplets in the cytoplasm. Milk released in the first few days after parturition is called *colostrum* and has low lipid content but contains considerable quantities of antibodies. The lymphocytes and plasma cells that accumulate within the connective tissues of the breast are the source of the antibody component. With subsequent reduction in the number of these cells, the production of colostrum decreases and lipid-rich milk is released.

**Blood Supply, Innervation, and Lymphatics.** The breast receives its principal blood supply from: (a) perforating branches of the internal mammary artery; (b) lateral branches of the posterior intercostal arteries; and (c) branches from the axillary artery, including the highest thoracic, lateral thoracic, and pectoral branches of the thoracoacromial artery (Fig. 17-5). The second, third, and fourth anterior intercostal perforators and branches of the internal mammary artery arborize in the breast as the medial mammary arteries. The lateral thoracic artery gives off branches to the serratus anterior, pectoralis major and pectoralis minor, and subscapularis muscles. It also gives rise to lateral mammary branches. The veins of the breast and chest wall follow the course of the arteries, with venous drainage being toward the axilla. The three principal groups of veins are: (a) perforating branches of the internal thoracic vein, (b) perforating branches of the posterior intercostal veins, and (c) tributaries of the axillary vein. Batson’s vertebral venous plexus, which invests the vertebral columns and extends from the base of the skull to the sacrum, may provide a route for breast cancer metastases to the vertebrae, skull, pelvic bones, and central nervous system. Lymph vessels generally parallel the course of blood vessels.
Lateral cutaneous branches of the third through sixth intercostal nerves provide sensory innervation of the breast (lateral mammary branches) and of the anterolateral chest wall. These branches exit the intercostal spaces between slips of the serratus anterior muscle. Cutaneous branches that arise from the cervical plexus, specifically the anterior branches of the supraclavicular nerve, supply a limited area of skin over the upper portion of the breast. The intercostobrachial nerve is the lateral cutaneous branch of the second intercostal nerve and may be visualized during surgical dissection of the axilla. Resection of the intercostobrachial nerve causes loss of sensation over the medial aspect of the upper arm.

The boundaries for lymph drainage of the axilla are not well demarcated, and there is considerable variation in the position of the axillary lymph nodes. The six axillary lymph node groups recognized by surgeons (Figs. 17-6 and 17-7) are: (a) the axillary vein group (lateral), which consists of four to six lymph nodes that lie medial or posterior to the vein and receive most of the lymph drainage from the upper extremity; (b) the external mammary group (anterior or pectoral group), which consists of five to six lymph nodes that lie along the lower border of the pectoralis minor muscle contiguous with the lateral thoracic vessels and receive most of the lymph drainage from the lateral aspect of the breast; (c) the scapular group (posterior or subscapular), which consists of five to seven lymph nodes that lie along the posterior wall of the axilla at the lateral border of the scapula contiguous with the subscapular vessels and receive lymph drainage principally from the lower posterior neck, the posterior trunk, and the posterior shoulder; (d) the central group, which consists of three or four sets of lymph nodes that are embedded in the fat of the axilla lying immediately posterior to the pectoralis minor muscle and receive lymph drainage both from the axillary vein, external mammary, and scapular groups of lymph nodes, and directly from the breast; (e) the subclavicular group (apical), which consists of six to twelve sets of lymph nodes that lie posterior and superior to the upper border of the pectoralis minor muscle and receive lymph drainage from all of the other groups of axillary lymph nodes; and (f) the interpectoral group (Rotter’s lymph nodes), which consists of one to four lymph nodes that are interposed between the pectoralis major and pectoralis minor muscles and receive lymph drainage directly from the breast. The lymph fluid that passes
through the interpectoral group of lymph nodes passes directly into the central and subclavicular groups.

As indicated in Fig. 17-7, the lymph node groups are assigned levels according to their anatomic relationship to the pectoralis minor muscle. Lymph nodes located lateral to or below the lower border of the pectoralis minor muscle are referred to as level I lymph nodes, which include the axillary vein, external mammary, and scapular groups. Lymph nodes located superficial or deep to the pectoralis minor muscle are referred to as level II lymph nodes, which include the central and interpectoral groups. Lymph nodes located medial to or above the upper border of the pectoralis minor muscle are referred to as level III lymph nodes, which consist of the subclavicular group. The plexus of lymph vessels in the breast arises in the interlobular connective tissue and in the walls of the lactiferous ducts and communicates with the subareolar plexus of lymph vessels. Efferent lymph vessels from the breast pass around the lateral edge of the pectoralis major muscle and pierce the clavipectoral fascia, ending in the external mammary (anterior, pectoral) group of lymph nodes. Some lymph vessels may travel directly to the subscapular (posterior, scapular) group of lymph nodes. From the upper part of the breast, a few lymph vessels pass directly to the subclavicular (apical) group of lymph nodes. The axillary lymph nodes usually receive >75% of the lymph drainage from the breast. The rest is derived primarily from the medial aspect of the breast, flows through the lymph vessels that accompany the perforating branches of the internal mammary artery, and enters the parasternal (internal mammary) group of lymph nodes.

PHYSIOLOGY OF THE BREAST

Breast Development and Function

Breast development and function are initiated by a variety of hormonal stimuli, including estrogen, progesterone, prolactin, oxytocin, thyroid hormone, cortisol, and growth hormone. Estrogen, progesterone, and prolactin especially have profound trophic effects that are essential to normal breast development and function. Estrogen initiates ductal development, whereas progesterone is responsible for differentiation of epithelium and for lobular development. Prolactin is the primary hormonal stimulus for lactogenesis in late pregnancy and the postpartum period. It upregulates hormone receptors and stimulates epithelial development. Fig. 17-8 depicts the secretion of neurotrrophic hormones from the hypothalamus, which is responsible for regulation of the secretion of the hormones that affect the breast tissues. The gonadotropins luteinizing hormone (LH) and follicle-stimulating hormone (FSH) regulate the release of estrogen and progesterone from the ovaries. In turn, the release of LH and FSH from the basophilic cells of the anterior pituitary is regulated by the secretion of gonadotropin-releasing hormone (GnRH) from the hypothalamus. Positive and negative feedback effects of circulating estrogen and progesterone regulate the secretion of LH, FSH, and GnRH. These hormones are responsible for the development, function, and maintenance of breast tissues (Fig. 17-9A). In the female neonate, circulating estrogen and progesterone levels decrease after birth and remain low throughout childhood because of the sensitivity of

Figure 17-8. Overview of the neuroendocrine control of breast development and function. ADH = antidiuretic hormone; CRF = corticotropin-releasing factor; GRF = growth hormone releasing factor; LH-RH = luteinizing hormone–releasing hormone; Oxy = oxytocin; TRH = thyrotropin-releasing hormone. (Reproduced with permission from Bland KI, Copeland EMI: The Breast: Comprehensive Management of Benign and Malignant Diseases, 4th ed. Philadelphia, PA: Elsevier/Saunders; 2009.)
the hypothalamic-pituitary axis to negative feedback from these hormones. With the onset of puberty, there is a decrease in the sensitivity of the hypothalamic-pituitary axis to negative feedback and an increase in its sensitivity to positive feedback from estrogen. These physiologic events initiate an increase in GnRH, FSH, and LH secretion and ultimately an increase in estrogen and progesterone secretion by the ovaries, leading to establishment of the menstrual cycle. At the beginning of the menstrual cycle, there is an increase in the size and density of the breasts, which is followed by engorgement of the breast tissues and epithelial proliferation. With the onset of menstruation, the breast engorgement subsides and epithelial proliferation decreases.

**Pregnancy, Lactation, and Senescence**

A dramatic increase in circulating ovarian and placental estrogens and progestins is evident during pregnancy, which initiates striking alterations in the form and substance of the breast (see Fig. 17-9B).\(^{17-19}\) The breast enlarges as the ductal and lobular epithelium proliferates, the areolar skin darkens, and the accessory areolar glands (Montgomery’s glands) become prominent. In the first and second trimesters, the minor ducts branch and develop. During the third trimester, fat droplets accumulate in the alveolar epithelium, and colostrum fills the alveolar and ductal spaces. In late pregnancy, prolactin stimulates the synthesis of milk fats and proteins.

After delivery of the placenta, circulating progesterone and estrogen levels decrease, permitting full expression of the lactogenic action of prolactin. Milk production and release are controlled by neural reflex arcs that originate in nerve endings of the nipple-areola complex. Maintenance of lactation requires regular stimulation of these neural reflexes, which results in prolactin secretion and milk letdown. Oxytocin release results from the auditory, visual, and olfactory stimuli associated with nursing. Oxytocin initiates contraction of the myoepithelial cells, which results in compression of alveoli and expulsion of milk into the lactiferous sinuses. After weaning of the infant, prolactin and oxytocin release decreases. Dormant milk causes increased pressure within the ducts and alveoli, which results in atrophy of the epithelium (Fig. 17-9C). With menopause, there is a decrease in the secretion of estrogen and progesterone by

![Figure 17-9. The breast at different physiologic stages. The central column contains three-dimensional depictions of microscopic structures. A. Adolescence. B. Pregnancy. C. Lactation. D. Senescence.](image-url)
Gynecomastia

Gynecomastia refers to an enlarged breast in the male. Physiologic gynecomastia usually occurs during three phases of life: the neonatal period, adolescence, and senescence. Common to each of these phases is an excess of circulating estrogens in relation to circulating testosterone. Neonatal gynecomastia is caused by the action of placental estrogens on neonatal breast tissues, whereas in adolescence, there is an excess of estradiol relative to testosterone, and with senescence, the circulating testosterone level falls, which results in relative hyperestrinism. In gynecomastia, the ductal structures of the male breast enlarge, elongate, and branch with a concomitant increase in epithelium. During puberty, the condition often is unilateral and typically occurs between ages 12 and 15 years. In contrast, senescent gynecomastia is usually bilateral. In the nonobese male, breast tissue measuring at least 2 cm in diameter must be present before a diagnosis of gynecomastia may be made. Mammography and ultrasonography are used to differentiate breast tissues. Dominant masses or areas of firmness, irregularity, and asymmetry suggest the possibility of a breast cancer, particularly in the older male. Gynecomastia generally does not predispose the male breast to cancer. However, the hypoandrogeic state of Klinefelter’s syndrome (XXY), in which gynecomastia is usually evident, is associated with an increased risk of breast cancer. Gynecomastia is graded based on the degree of breast enlargement, the position of the nipple with reference to the inframammary fold, and the degree of breast ptosis and skin redundancy: Grade I—mild breast enlargement without skin redundancy; Grade II—moderate breast enlargement without skin redundancy; Grade IIb—moderate breast enlargement with skin redundancy; and Grade III—marked breast enlargement with skin redundancy and ptosis.

Table 17-1 identifies the pathophysiologic mechanisms that may initiate gynecomastia: estrogen excess states; androgen deficiency states; pharmacologic causes; and idiopathic causes. Estrogen excess results from an increase in the secretion of estradiol by the testicles or by nontesticular tumors, nutritional alterations such as protein and fat deprivation, endocrine disorders (hyperthyroidism, hypothyroidism), and hepatic disease (nonalcoholic and alcoholic cirrhosis). Refeeding gynecomastia is related to the resumption of pituitary gonadotropin secretion after pituitary shutdown. Androgen deficiency may initiate gynecomastia. Concurrently occurring with decreased circulating testosterone levels is an elevated level of circulating testosterone-binding globulin, which results in a reduction of free testosterone. This senescent gynecomastia usually occurs in men age 50 to 70 years. Hypoandrogenic states can be from primary testicular failure or secondary testicular failure. Klinefelter’s syndrome (XXY) is an example of primary testicular failure that is manifested by gynecomastia, hypogonadotropic hypogonadism, and azoospermia. Secondary testicular failure may result from trauma, orchitis, and cryptorchidism. Renal failure, regardless of cause, also may initiate gynecomastia.

Pharmacologic causes of gynecomastia include drugs with estrogenic activity (digitalis, estrogens, anabolic steroids, marijuana) or drugs that enhance estrogen synthesis (human chorionic gonadotropin). Drugs that inhibit the action or synthesis of testosterone (cimetidine, ketoconazole, phenytoin, spironolactone, antineoplastic agents, diazepam) also have been implicated. Drugs such as reserpine, theophylline, verapamil, tricyclic antidepressants, and furosemide induce gynecomastia through idiopathic mechanisms.

When gynecomastia is caused by androgen deficiency, then testosterone administration may cause regression. When it is caused by medications, then these are discontinued if possible. When endocrine defects are responsible, then these receive specific therapy. As soon as gynecomastia is progressive and does not respond to other treatments, surgical therapy is considered. Techniques include local excision, liposuction or subcutaneous mastectomy. Attempts to reverse gynecomastia with danazol have been successful, but the androgenic side effects of the drug are considerable.
Infections in the postpartum period remain proportionately the most common time for breast infections to occur. Infections of the breast unrelated to lactation are proportionately less common, however, are still a relatively common presentation to breast specialists. The latter are classified as intrinsic (secondary to abnormalities in the breast) or extrinsic (secondary to an infection in an adjacent structure, e.g., skin, thoracic cavity) the most common being probably periductal mastitis and infected sebaceous cysts, respectively.

**Bacterial Infection**

*Staphylococcus aureus* and *Streptococcus* species are the organisms most frequently recovered from nipple discharge from an infected breast. Typically breast abscesses are seen in staphylococcal infections and present with point tenderness, erythema, and hyperthermia. When these abscesses are related to lactation they usually occur within the first few weeks of breastfeeding. If there is progression of a staphylococcal infection, this may result in subcutaneous, subareolar, interlobular (periductal), and retromammary abscesses (unicentric or multicentric). Previously almost all breast abscesses were treated by operative incision and drainage, but now the initial approach is antibiotics and repeated aspiration of the abscess, usually ultrasound-guided aspiration. Operative drainage is now reserved for those cases that do not resolve with repeated aspiration and antibiotic therapy or cases in which there is some other indication for incision and drainage (e.g., thinning or necrosis of the overlying skin). Preoperative ultrasonography is effective in delineating the required extent of the drainage procedure. While staphylococcal infections tend to be more localized and may be situated deep in the breast tissues, streptococcal infections usually present with diffuse superficial involvement. They are treated with local wound care, including application of warm compresses, and the administration of IV antibiotics (penicillins or cephalosporins). Breast infections may be chronic, possibly with recurrent abscess formation. In this situation, cultures are performed to identify acid-fast bacilli, anaerobic and aerobic bacteria, and fungi. Uncommon organisms may be encountered, and long-term antibiotic therapy may be required.

Biopsy of the abscess cavity wall should be considered at the time of incision and drainage to rule out underlying breast cancer in patients where antibiotics and drainage have been ineffective.

Nowadays hospital-acquired puerperal infections of the breast are much less common, but nursing women who present with milk stasis or noninfectious inflammation may still develop this problem. Epidemic puerperal mastitis is initiated by highly virulent strains of methicillin-resistant *S. aureus* that are transmitted via the suckling neonate and may result in substantial morbidity and occasional mortality. Purulent fluid may be expressed from the nipple. In this circumstance, breastfeeding is stopped, antibiotics are started, and surgical therapy is initiated. *Nonepidemic* (sporadic) puerperal mastitis refers to involvement of the interlobular connective tissue of the breast by an infectious process. The patient develops nipple fissuring and milk stasis, which initiates a retrograde bacterial infection. Emptying of the breast using breast suction pumps shortens the duration of symptoms and reduces the incidence of recurrences. The addition of antibiotic therapy results in a satisfactory outcome in >95% of cases.

**Mycotic Infections**

Fungal infections of the breast are rare and usually involve blastomycosis or sporotrichosis. Intraoral fungi that are inoculated into the breast tissue by the suckling infant initiate these infections, which present as mammary abscesses in close proximity to the nipple-areola complex. Pus mixed with blood may be expressed from skin tracts. Antifungal agents can be administered for the treatment of systemic (noncutaneous) infections. This therapy generally eliminates the necessity of surgical intervention, but occasionally drainage of an abscess, or even partial mastectomy, may be necessary to eradicate a persistent fungal infection. *Candida albicans* affecting the skin of the breast presents as erythematous, scaly lesions of the inframammary or axillary folds. Scrapings from the lesions demonstrate fungal elements (filaments and binding cells). Therapy involves the removal of predisposing factors such as maceration and the topical application of nystatin.

**Hidradenitis Suppurativa**

Hidradenitis suppurativa of the nipple-areola complex or axilla is a chronic inflammatory condition that originates within the accessory areolar glands of Montgomery or within the axillary sebaceous glands. Women with chronic acne are predisposed to developing hidradenitis. When located in and about the nipple-areola complex, this disease may mimic other chronic inflammatory states, Paget’s disease of the nipple, or invasive breast cancer. Involvement of the axillary skin is often multifocal and contiguous. Antibiotic therapy with incision and drainage of fluctuant areas is appropriate treatment. Excision of the involved areas may be required. Large areas of skin loss may necessitate coverage with advancement flaps or split-thickness skin grafts.

**Mondor’s Disease**

Mondor’s disease is a variant of thrombophlebitis that involves the superficial veins of the anterior chest wall and breast. In 1939, Mondor described the condition as “string phlebitis,” a thrombosed vein presenting as a tender, cord-like structure. Frequently involved veins include the lateral thoracic vein, the thoracoepigastric vein, and, less commonly, the superficial epigastric vein. Typically, a woman presents with acute pain in the lateral aspect of the breast or the anterior chest wall. A tender, firm cord is found to follow the distribution of one of the major superficial veins. Rarely, the presentation is bilateral, and most women have no evidence of thrombophlebitis in other anatomic sites. This benign, self-limited disorder is not indicative of a cancer. When the diagnosis is uncertain, or when a mass is present near the tender cord, biopsy is indicated. Therapy for Mondor’s disease includes the liberal use of anti-inflammatory medications and application of warm compresses along the symptomatic vein. The process usually resolves within 4 to 6 weeks. When symptoms persist or are refractory to therapy, excision of the involved vein segment may be considered.
COMMON BENIGN DISORDERS AND DISEASES OF THE BREAST

Benign breast disorders and diseases encompass a wide range of clinical and pathologic entities. Surgeons require an in-depth understanding of benign breast disorders and diseases so that clear explanations may be given to affected women, appropriate treatment is instituted, and unnecessary long-term follow up is avoided.

Aberrations of Normal Development and Involution

The basic principles underlying the aberrations of normal development and involution (ANDI) classification of benign breast conditions are the following: (a) benign breast disorders and diseases are related to the normal processes of reproductive life and to involution; (b) there is a spectrum of breast conditions that ranges from normal to disorder to disease; and (c) the ANDI classification encompasses all aspects of the breast condition, including pathogenesis and the degree of abnormality. The horizontal component of Table 17-2 defines ANDI along a spectrum from normal, to mild abnormality (disorder), to severe abnormality (disease). The vertical component indicates the period during which the condition develops.

Early Reproductive Years. Fibroadenomas are seen and present symptomatically predominantly in younger women age 15 to 25 years (Fig. 17-10). Fibroadenomas usually grow to 1 or 2 cm in diameter and then are stable but may grow to a larger size. Small fibroadenomas (≤1 cm in size) are considered normal, whereas larger fibroadenomas (≤3 cm) are disorders, and giant fibroadenomas (>3 cm) are disease. Similarly, multiple fibroadenomas (more than five lesions in one breast) are very uncommon and are considered disease. It is noted that with the introduction of mammographic screening, asymptomatic fibroadenomas are sometimes found in an older screened population. The precise etiology of adolescent breast hypertrophy is unknown. A spectrum of changes from limited to massive stromal hyperplasia (gigantomastia) is seen. Nipple inversion is a disorder of development of the major ducts, which prevents normal protrusion of the nipple. Mammary duct fistulas arise when nipple inversion predisposes to major duct obstruction, leading to recurrent subareolar abscess and mammary duct fistula.

Later Reproductive Years. Cyclic mastalgia and nodularity usually are associated with premenstrual enlargement of the breast and are regarded as normal. Cyclic pronounced mastalgia and severe painful nodularity are viewed differently than are physiologic discomfort and lumpiness. Painful nodularity that persists for >1 week of the menstrual cycle is considered a disorder. In epithelial hyperplasia of pregnancy, papillary projections sometimes give rise to bilateral bloody nipple discharge.

Involutions. Involutions of lobular epithelium is dependent on the specialized stroma around it. However, an integrated involutions of breast stroma and epithelium is not always seen, and disorders of the process are common. When the stroma involutes too quickly, alveoli remain and form microcysts, which are precursors of macrocysts. The macrocysts are common, often subclinical, and do not require specific treatment. Sclerosing adenosis is considered a disorder of both the proliferative and the involutions phases of the breast cycle. Duct ectasia (dilated ducts) and periductal mastitis are other important components of the ANDI classification. Periductal fibrosis is a sequela of periductal mastitis and may result in nipple retraction. About 60% of women ≥70 years of age exhibit some degree of epithelial hyperplasia (Fig. 17-11). Atypical proliferative diseases include ductal and lobular hyperplasia, both of which display some features of carcinoma in situ. Women with atypical ductal or lobular hyperplasia have a fourfold increase in breast cancer risk (Table 17-3).

Pathology of Nonproliferative Disorders

Of paramount importance for the optimal management of benign breast disorders and diseases is the histologic differentiation of benign, atypical, and malignant changes. Determining the clinical significance of these changes is a problem that is compounded by inconsistent nomenclature. The classification system originally developed by Page separates the various types of benign breast disorders and diseases into three clinically relevant groups: nonproliferative disorders, proliferative disorders without atypia, and proliferative disorders with atypia (Table 17-4). Nonproliferative disorders of the breast account for 70% of benign breast conditions and carry no increased risk.

for the development of breast cancer. This category includes cysts, duct ectasia, periductal mastitis, calcifications, fibroadenomas, and related disorders.

Breast macrocysts are an involutional disorder, have a high frequency of occurrence, and are often multiple. Duct ectasia is a clinical syndrome characterized by dilated subareolar ducts that are palpable and often associated with thick nipple discharge. Haagensen regarded duct ectasia as a primary event that led to stagnation of secretions, epithelial ulceration, and leakage of duct secretions (containing chemically irritating fatty acids) into periductal tissue. This sequence was thought to produce a local inflammatory process with periductal fibrosis and subsequent nipple retraction. An alternative theory considers periductal mastitis to be the primary process, which leads to weakening of the ducts and secondary dilatation. It is possible that both processes occur and together explain the wide spectrum of problems seen, which include nipple discharge, nipple retraction, inflammatory masses, and abscesses.

Calcium deposits are frequently encountered in the breast. Most are benign and are caused by cellular secretions and debris or by trauma and inflammation. Calcifications that are associated with cancer include microcalcifications, which vary in shape and density and are <0.5 mm in size, and fine, linear calcifications, which may show branching. Fibroadenomas have abundant stroma with histologically normal cellular elements. They show hormonal dependence similar to that of normal breast lobules in that they lactate during pregnancy and involute in the postmenopausal period. Adenomas of the breast are well circumscribed and are composed of benign epithelium with sparse stroma, which is the histologic feature that differentiates them from fibroadenomas. They may be divided into tubular adenomas and lactating adenomas. Tubular adenomas are seen in young nonpregnant women, whereas lactating adenomas are seen during pregnancy or during the postpartum period. Hamartomas are discrete breast tumors that are usually 2 to 4 cm in diameter, firm, and sharply circumscribed. Adenolipomas consist of sharply circumscribed nodules of fatty tissue that contain normal breast lobules and ducts.

**Fibrocystic Disease.** The term fibrocystic disease is nonspecific. Too frequently, it is used as a diagnostic term to describe symptoms, to rationalize the need for breast biopsy, and to explain biopsy results. Synonyms include fibrocystic changes, cystic mastopathy, chronic cystic disease, chronic cystic mastitis, Schimmelbusch’s disease, mazoplasia, Cooper’s disease, Reclus’ disease, and fibroadenomatosis. Fibrocystic disease refers to a spectrum of histopathologic changes that are best diagnosed and treated specifically.

**Pathology of Proliferative Disorders Without Atypia**

Proliferative breast disorders without atypia include sclerosing adenosis, radial scars, complex sclerosing lesions, ductal epithelial hyperplasia, and intraductal papillomas. Sclerosing adenosis is prevalent during the childbearing and perimenopausal years and has no malignant potential. Histologic changes are both proliferative (ductal proliferation) and involutorial (stromal fibrosis, epithelial regression). Sclerosing adenosis is characterized by distorted breast lobules and usually occurs in the context of multiple microcysts, but occasionally presents as a palpable mass. Benign calcifications are often associated with this disorder. Sclerosing adenosis can be managed by observation as long as the imaging features and pathologic findings are concordant. Central sclerosis and various degrees of epithelial proliferation, apocrine metaplasia, and papilloma formation characterize radial scars and complex sclerosing lesions of the breast. Lesions up to 1 cm in diameter are called radial scars, whereas larger lesions are called complex sclerosing lesions. Radial scars originate at sites of terminal duct branching where the characteristic histologic changes radiate from a central area of fibrosis. All of the histologic features of a radial scar are seen in the larger complex sclerosing lesions, but there is a greater disturbance of structure with papilloma formation, apocrine metaplasia, and occasionally sclerosing adenosis. Distinguishing between a radial scar and invasive breast carcinoma can be challenging based on core-needle biopsy sampling. Often the imaging features of a radial scar (which can be quite similar to an invasive cancer) will dictate the need for either a vacuum-assisted biopsy or surgical excision in order to exclude the possibility of carcinoma.

Mild ductal hyperplasia is characterized by the presence of three or four cell layers above the basement membrane. Moderate ductal hyperplasia is characterized by the presence of five or more cell layers above the basement membrane. Florid ductal epithelial hyperplasia occupies at least 70% of a minor duct lumen. It is found in >20% of breast tissue specimens, is either solid or papillary, and is associated with an increased cancer risk (see Table 17-3). Intraductal papillomas arise in the major ducts, usually in premenopausal women. They generally are <0.5 cm in diameter but may be as large as 5 cm. A common presenting symptom is nipple discharge, which may be serous or bloody. Grossly, intraductal papillomas are pinkish tan, friable, and usually attached to the wall of the involved duct by a stalk. They rarely undergo malignant transformation, and their presence does not increase a woman’s risk of developing breast cancer (unless accompanied by atypia). However, multiple intraductal papillomas, which occur in younger women and are less frequently associated with nipple discharge, are susceptible to malignant transformation.

**Pathology of Atypical Proliferative Diseases**

The atypical proliferative diseases have some of the features of carcinoma in situ but either lack a major defining feature of carcinoma in situ or have the features in less than fully developed form. Atypical ductal hyperplasia (ADH) appears similar to low grade ductal carcinoma in situ (DCIS) histologically and is composed of monotonous round, cuboidal, or polygonal cells enclosed by basement membrane with rare mitoses. A lesion will be considered to be ADH if it is up to 2 or 3 mm in size but would be called DCIS if it is larger than 3 mm. The diagnosis can be difficult to establish with core-needle biopsy specimen alone and many cases will require excisional biopsy specimen for classification. Individuals with a diagnosis of ADH are at increased risk for development of breast cancer and should be counseled appropriately regarding risk reduction strategies.

In 1978, Haagensen et al described lobular neoplasia, a spectrum of disorders ranging from atypical lobular hyperplasia to lobular carcinoma in situ (LCIS). Atypical lobular hyperplasia (ALH) results in minimal distention of lobular units with cells that are similar to those seen in LCIS. The diagnosis of LCIS is made when small monomorphic cells that distend the terminal ductal lobular unit are noted. In cases of LCIS, the acini are full and distended while the overall lobular architecture is maintained (Fig. 17-12). Classic LCIS is not associated with a specific mammographic or palpable abnormality but is
SPECIFIC CONSIDERATIONS

PART II

Figure 17-12. Lobular carcinoma in situ (100x). There are small monomorphous cells that distend the terminal duct lobular unit, without necrosis or mitoses. (Used with permission from Dr. Sindhu Menon, Consultant Histopathologist and Dr. Rahul Deb, Consultant Histopathologist and Lead Breast Pathologist, Royal Derby Hospital, Derby, UK.)

an incident finding noted on breast biopsy. There is a variant of LCIS that has been termed pleomorphic LCIS. In the case of pleomorphic LCIS, there can be calcifications or other suspicious mammographic changes that dictate the need for biopsy. Classic LCIS is not treated with excision as the patient is at risk for developing invasive breast cancer in either breast and therefore the patient is counseled regarding appropriate risk reduction strategies. Pleomorphic LCIS can be difficult to distinguish from high-grade DCIS and there are some proponents who have suggested that patients with pleomorphic LCIS be managed similar to those with DCIS with attention to margins and consideration for radiation therapy in the setting of breast conserving treatment. The use of immunohistochemical staining for E-cadherin can help to discriminate between LCIS and DCIS. In lobular neoplasias, such as ALH and LCIS, there is a lack of E-cadherin expression, whereas the majority of ductal lesions will demonstrate E-cadherin reactivity.

Treatment of Selected Benign Breast Disorders and Diseases

Cysts. Because needle biopsy of breast masses may produce artifacts that make mammography assessment more difficult, many multidisciplinary teams prefer to image breast masses before performing either fine-needle aspiration or core-needle biopsy.36,37 In practice, however, the first investigation of palpable breast masses may be a needle biopsy, which allows for the early diagnosis of cysts. A 21-gauge needle attached to a 10-mL syringe is placed directly into the mass, which is fixed by fingers of the nondominant hand. The volume of a typical cyst is 5 to 10 mL, but it may be 75 mL or more. If the fluid that is aspirated is not bloodstained, then the cyst is aspirated to dryness, the needle is removed, and the fluid is discarded because cytologic examination of such fluid is not cost effective. After aspiration, the breast is carefully palpated to exclude a residual mass. In most cases, however, imaging has been performed prior to a needle being introduced into the breast, and indeed the majority of cysts are now aspirated under ultrasound guidance. If a mass was noted on initial ultrasound or there is a residual mass post aspiration, then a tissue specimen is obtained, usually by core biopsy. When cystic fluid is bloodstained, fluid can be sent for cytologic examination. A simple cyst is rarely of concern, but a complex cyst may be the result of an underlying malignancy. A pneumocystogram can be obtained by injecting air into the cyst and then obtaining a repeat mammogram. When this technique is used, the wall of the cyst cavity can be more carefully assessed for any irregularities.

Fibroadenomas. Most fibroadenomas are self-limiting and many go undiagnosed, so a more conservative approach is reasonable. Careful ultrasound examination with core-needle biopsy will provide for an accurate diagnosis. Ultrasonography may reveal specific features that are pathognomonic for fibroadenoma, and in a young woman (e.g., under 25 years) where the risk of breast cancer is already very low a core-needle biopsy may not be necessary. In patients where biopsy is performed, the patient is counseled concerning the ultrasound and biopsy results, and surgical excision of the fibroadenoma may be avoided. Cryoaublation and ultrasound-guided vacuum-assisted biopsy are approved treatments for fibroadenomas of the breast, especially lesions <3 cm. Larger lesions are often still best treated by excision. With short-term follow-up, a significant percentage of fibroadenomas will decrease in size and will no longer be palpable.38 However, many will remain palpable, especially those larger than 2 cm.38 Therefore, women should be counseled that the options for treatment include surgical removal, cryoablation, vacuum assisted biopsy, or observation.

Sclerosing Disorders. The clinical significance of sclerosing adenosis lies in its imitation of cancer. On physical examination, it may be confused with cancer, by mammography, and at gross pathologic examination. Excisional biopsy and histologic examination are frequently necessary to exclude the diagnosis of cancer. The diagnostic work-up for radial scars and complex sclerosing lesions frequently involves stereotactic biopsy. It usually is not possible to differentiate these lesions with certainty from cancer by mammographic features, so a larger tissue biopsy is recommended either by way of vacuum-assisted biopsy or an open surgical excisional biopsy. The mammographic appearance of a radial scar or sclerosing adenosis (mass density with spiculated margins) will usually lead to an assessment that the results of a core-needle biopsy specimen showing benign disease are discordant with the radiographic findings.

Periductal Mastitis. Painful and tender masses behind the nipple-areola complex are aspirated with a 21-gauge needle attached to a 10-mL syringe. Any fluid obtained is submitted for culture using a transport medium appropriate for the detection of anaerobic organisms. In the absence of pus, women are started on a combination of antibiotics to cover polymicrobial infections while awaiting the results of culture. Antibiotics are then continued based on sensitivity tests. Many cases respond satisfactorily to antibiotics alone, but when considerable purulent material is present, repeated ultrasound guided aspiration is performed, and ultimately in a proportion of cases surgical treatment is required. Unlike puerperal abscesses, a subareolar abscess is usually unilocular and often is associated with a single duct system. Ultrasound will accurately delineate its extent. In those cases that come to surgery, the surgeon may either undertake simple drainage with a view toward formal

**RISK FACTORS FOR BREAST CANCER**

**Hormonal and Nonhormonal Risk Factors**

Increased exposure to estrogen is associated with an increased risk for developing breast cancer, whereas reducing exposure is thought to be protective. Correspondingly, factors that increase the number of menstrual cycles, such as early menarche, nulliparity, and late menopause, are associated with increased risk. Moderate levels of exercise and a longer lactation period, factors that decrease the total number of menstrual cycles, are protective. The terminal differentiation of breast epithelium associated with a full-term pregnancy is also protective, so older age at first live birth is associated with an increased risk of breast cancer. Finally, there is an association between obesity and increased breast cancer risk. Because the major source of estrogen in postmenopausal women is the conversion of androstenedione to estrone by adipose tissue, obesity is associated with a long-term increase in estrogen exposure.

Nonhormonal risk factors include radiation exposure. Young women who receive mantle radiation therapy for Hodgkin’s lymphoma have a breast cancer risk that is 75 times greater than that of age-matched control subjects. Survivors of the atomic bomb blasts in Japan during World War II have a very high incidence of breast cancer, likely because of somatic mutations induced by the radiation exposure. In both circumstances, radiation exposure during adolescence, a period of active breast development, magnifies the deleterious effect. Studies also suggest that the risk of breast cancer increases as the amount of alcohol a woman consumes increases. Alcohol consumption is known to increase serum levels of estradiol. Finally, evidence suggests that long-term consumption of foods with a high fat content contributes to an increased risk of breast cancer by increasing serum estrogen levels.

**Risk Assessment Models**

The average lifetime risk of breast cancer for newborn U.S. women is 12%. The longer a woman lives without cancer, the lower her risk of developing breast cancer. Thus, a woman age 50 years has an 11% lifetime risk of developing breast cancer, and a woman age 70 years has a 7% lifetime risk of developing breast cancer. Because risk factors for breast cancer interact, evaluating the risk conferred by combinations of risk factors is difficult. There are several risk assessment models available to predict the risk of breast cancer. From the Breast Cancer Detection Demonstration Project, a mammography screening program conducted in the 1970s, Gail et al developed the model most frequently used in the United States, which incorporates age, age at menarche, age at first live birth, the number of breast biopsy specimens, any history of atypical hyperplasia, and number of first-degree relatives with breast cancer. It predicts the cumulative risk of breast cancer according to decade of life. To calculate breast cancer risk using the Gail model, a woman’s risk factors are translated into an overall risk score by multiplying her relative risks from several categories (Table 17-6). This risk score is then compared to an adjusted population risk of breast cancer to determine a woman’s individual or absolute risk. The output is a 5-year risk and a lifetime risk of developing breast cancer. A software program incorporating the Gail model is available from the National Cancer Institute at [http://bcra.nci.nih.gov/brc](http://bcra.nci.nih.gov/brc). This model was recently modified to more accurately assess risk in African American women. There have also been modifications that project individualized absolute

invasive breast cancer risk for Asian and Pacific Island American women. The Gail model is the most widely used model in the United States. Gail and colleagues have also described a revised model that includes body weight and mammographic density but excludes age at menarche.54

Claus et al, using data from the Cancer and Steroid Hormone Study, a case-control study of breast cancer, developed the other frequently used risk assessment model, which is based on assumptions about the prevalence of high-penetration breast cancer susceptibility genes.55 Compared with the Gail model, the Claus model incorporates more information about family history but excludes other risk factors. The Claus model provides individual estimates of breast cancer risk according to decades of life based on presence of first- and second-degree relatives with breast cancer and their age at diagnosis. Risk factors that are less consistently associated with breast cancer (diet, use of oral contraceptives, lactation) or are rare in the general population (radiation exposure) are not included in either the Gail or Claus risk assessment model. Other models have been proposed that account for mammographic breast density in assessing breast cancer risk.54,56

Neither the Gail model nor the Claus model accounts for the risk associated with mutations in the breast cancer susceptibility genes BRCA1 and BRCA2 (described in detail in the following section). The BRCAPRO model is a Mendelian model that calculates the probability that an individual is a carrier of a mutation in one of the breast cancer susceptibility genes based on their family history of breast and ovarian cancer.57 The probability that an individual will develop breast or ovarian cancer is derived from this mutation probability based on age-specific incidence curves for both mutation carriers and noncarriers.58 Use of the BRCAPRO model in the clinic is challenging since it requires input of all family history information regarding breast and ovarian cancer. The Tyrer-Cuzick model attempts to utilize both family history information and individual risk information. It uses the family history to calculate the probability that an individual carries a mutation in one of the breast cancer susceptibility genes, and then the risk is adjusted based on personal risk factors, including age at menarche, parity, age at first live birth, age at menopause, history of atypical hyperplasia or LCIS, height, and body mass index.59 Once a risk model has been utilized to assess breast cancer risk, this must be communicated to the individual and put into context with competing risk and medical comorbidities. This information can then be used to discuss options that are available to the individual for managing risk.

Risk Management

Several important medical decisions may be affected by a woman’s underlying risk of developing breast cancer.60-68 These decisions include when to use postmenopausal hormone replacement therapy, at what age to begin mammography screening or incorporate magnetic resonance imaging (MRI) screening, when to use tamoxifen to prevent breast cancer, and when to perform prophylactic mastectomy to prevent breast cancer. Postmenopausal hormone replacement therapy was widely prescribed in the 1980s and 1990s because of its effectiveness in controlling the symptoms of estrogen deficiency, namely vasomotor symptoms such as hot flashes, night sweats and their associated sleep deprivation, osteoporosis, and cognitive changes. Furthermore, these hormone supplements were thought to reduce coronary artery disease as well. Use of combined estrogen and progesterone became standard for women who had not undergone hysterectomy because unopposed estrogen increases the risk of uterine cancer. Concerns of prolonging a woman’s lifetime exposure to estrogen, coupled with conflicting data regarding the impact of these hormones on cardiovascular health, motivated the implementation of large-scale phase 3 clinical trials to definitively evaluate the risks vs. benefits of postmenopausal hormone replacement therapy. The Women’s Health Initiative (WHI) was therefore designed by the National Institutes of Health as a series of clinical trials to study the effects of diet, nutritional supplements, and hormones on the risk of cancer, cardiovascular disease, and bone health in postmenopausal women. Findings from primary studies of postmenopausal hormone replacement therapy were released in 2002, demonstrating conclusively that
breast cancer risk is threefold to fourfold higher after >4 years of use and there is no significant reduction in coronary artery or cerebrovascular risks. The Collaborative Group on Hormonal Factors in Breast Cancer combined and reanalyzed data from a number of studies totaling 52,705 women with breast cancer and 108,411 women without breast cancer. They found an increased risk of breast cancer with every use of estrogen replacement therapy. They also reported increased risk among current users but not past users and risk increased with increasing duration of use of hormone replacement therapy. Chebblawi et al also reported from the WHI study that estrogen + progesterone increased the incidence of breast cancer. This was confirmed by the Million Women study, which also showed that the increased risk was substantially greater for the combined estrogen + progesterone replacement therapy than other types of hormone replacement therapy.

**Breast Cancer Screening.** Routine use of screening mammography in women ≥50 years of age has been reported to reduce mortality from breast cancer by 25%. This reduction comes at an acceptable economic cost. More recently, there has been debate over the potential harms associated with breast screening. Controversy over the age to initiate screening mammography is evident in the current recommendations. The U.S. Preventive Services Task Force (USPSTF), the American Cancer Society (ACS), and the National Comprehensive Cancer Network (NCCN) are three organizations with differing recommendations for screening mammography in average risk women. The guidelines, however, similarly define high-risk women as those with personal history of breast cancer, history of chest radiation at young age, and confirmed or suspected genetic mutation known to increase risk for developing breast cancer. The USPSTF recommends biennial screening mammography for women age 50 to 74 years. The USPSTF applies these guidelines to asymptomatic women age ≥40 years who do not have a preexisting breast cancer or who were not previously diagnosed with a high-risk breast lesion, and who are not at high risk for breast cancer because of a known underlying genetic mutation or history of chest radiation at a young age. In October 2015, the ACS released updated guidelines stating average-risk women should start annual screening mammography at 45 years of age. Women age 45 to 54 years should be screened annually, and those 55 years and older should transition to biennial screening or have the opportunity to continue annual screening. Women should have the opportunity to begin annual screening between the ages of 40 and 44 years and should continue screening as long as their overall health is good and have a life expectancy of 10 years or longer. The ACS recommends that average-risk women begin annual screening mammograms at ≥40 years of age, along with annual clinical breast exams and breast awareness.

The United Kingdom recently established an independent expert panel to review the published literature and estimate the benefits and harms associated with screening women >50 years of age in its national screening program. The expert panel estimated that an invitation to breast screening delivers about a 20% reduction in breast cancer mortality. At the same time, however, the panel estimated that in women invited to the screening, about 11% of the cancers diagnosed in their lifetime constitute overdagnosis. Despite the overdagnosis, the panel concluded that breast screening confers significant benefit and should continue. The use of screening mammography in women <50 years of age is more controversial for several reasons: (a) breast density is greater, and screening mammography is less likely to detect early breast cancer (i.e., reduced sensitivity); (b) screening mammography results in more false-positive test findings (i.e., reduced specificity), which results in unnecessary biopsy specimens; and (c) younger women are less likely to have breast cancer (i.e., lower incidence), so fewer young women will benefit from screening. In the United States, on a population basis, however, the benefits of screening mammography in women between the ages of 40 and 49 years is still felt to outweigh the risks; although targeting mammography to women at higher risk of breast cancer improves the balance of risks and benefits and is the approach some health care systems have taken. In one study of women age 40 to 49 years, an abnormal mammography finding was three times more likely to be cancer in a woman with a family history of breast cancer than in a woman without such a history. Furthermore, as noted previously in the section *Risk Assessment Models*, mounting data regarding mammographic breast density demonstrate an independent correlation with breast cancer risk. Incorporation of breast density measurements into breast cancer risk assessment models appears to be a promising strategy for increasing the accuracy of these tools. Unfortunately, widespread application of these modified models is hampered by inconsistencies in the reporting of mammographic density. Ultrasonography can also be used for breast cancer screening in women with dense breasts, but there is no data available that the additional cancers detected with this modality reduce mortality from breast cancer.

Current recommendations by the United States Preventive Services Task Force are that women undergo biennial mammographic screening between the ages of 50 and 74 years. The use of MRI for breast cancer screening is recommended by the ACS for women with a 20% to 25% or greater lifetime risk using risk assessment tools based mainly on family history. *BRCA* mutation carriers, those individuals who have a family member with a *BRCA* mutation who have not been tested themselves, individuals who received radiation to the chest between the ages of 10 and 30 years, and those individuals with a history of Li-Fraumeni syndrome, Cowden syndrome, or Bannayan-Riley-Ruvalcaba syndrome or those who have a first-degree relative with one of these syndromes. MRI is an extremely sensitive screening tool that is not limited by the density of the breast tissue as mammography is; however, its specificity is moderate, leading to more false-positive events and the increased need for biopsy.

**Chemoprevention.** Tamoxifen, a selective estrogen receptor modulator, was the first drug shown to reduce the incidence of breast cancer in healthy women. There have been four prospective studies published evaluating tamoxifen vs. placebo for reducing the incidence of invasive breast cancer for women at increased risk. The largest trial was the Breast Cancer Prevention Trial (NSABP P-01), which randomly assigned >13,000 women with a 5-year Gail relative risk of breast cancer of 1.66% or higher or LCIS to receive tamoxifen or placebo. After a mean follow-up period of 4 years, the incidence of breast cancer was reduced by 49% in the group receiving tamoxifen. The decrease was evident only in ER-positive breast cancers with no significant change in ER-negative tumors. The Royal Marsden Hospital Tamoxifen Chemoprevention Trial, the Italian Tamoxifen Prevention Trial, and the International Breast Cancer Intervention Study I (IBIS-I) trial all showed a reduction in...
ER-positive breast cancers with the use of tamoxifen compared with placebo. There was no effect on mortality; however, the trials were not powered to assess either breast cancer mortality or all-cause mortality events. The adverse events were similar in all four randomized trials, including an increased risk of endometrial cancer, thromboembolic events, cataract formation, and vasomotor disturbances in individuals receiving tamoxifen.

Tamoxifen therapy currently is recommended only for women who have a Gail relative risk of 1.66% or higher, who are age 35 to 59, women over the age of 60, or women with a diagnosis of LCIS or atypical ductal or lobular hyperplasia. In addition, deep vein thrombosis occurs 1.6 times as often, pulmonary emboli 3.0 times as often, and endometrial cancer 2.5 times as often in women taking tamoxifen. The increased risk for endometrial cancer is restricted to early stage cancers in postmenopausal women. Cataract surgery is required almost twice as often among women taking tamoxifen. Gail et al subsequently developed a model that accounts for underlying risk of breast cancer as well as comorbidities to determine the net risk-benefit ratio of tamoxifen use for chemoprevention.84

The NSABP completed a second chemoprevention trial, designed to compare tamoxifen and raloxifene for breast cancer risk reduction in high-risk postmenopausal women. Raloxifene, another selective estrogen receptor modulator, was selected for the experimental arm in this follow-up prevention trial because its use in managing postmenopausal osteoporosis suggested that it might be even more effective at breast cancer risk reduction, but without the adverse effects of tamoxifen on the uterus. The P-2 trial, the Study of Tamoxifen and Raloxifene (known as the STAR trial), randomly assigned 19,747 postmenopausal women at high-risk for breast cancer to receive either tamoxifen or raloxifene. The initial report of the P-2 trial showed the two agents were nearly identical in their ability to reduce breast cancer risk, but raloxifene was associated with a more favorable adverse event profile.85 An updated analysis revealed that raloxifene maintained 76% of the efficacy of tamoxifen in prevention of invasive breast cancer with a more favorable side effect profile. The risk of developing endometrial cancer was significantly higher with tamoxifen use at longer follow-up.86 Although tamoxifen has been shown to reduce the incidence of LCIS and DCIS, raloxifene did not have an effect on the frequency of these diagnoses.

Aromatase inhibitors (AIs) have been shown to be more effective than tamoxifen in reducing the incidence of contralateral breast cancers in postmenopausal women receiving AIs for adjuvant treatment of invasive breast cancer. The MAP3 trial was the first study to evaluate an AI as a chemopreventive agent in postmenopausal women at high risk for breast cancer. The trial randomized 4560 women to exemestane 25 mg daily vs. placebo for 5 years. After a median follow-up of 35 months, exemestane was shown to reduce invasive breast cancer incidence by 65%. Side effect profiles demonstrated more grade II or higher arthritis and hot flashes in patients taking exemestane.87 The IBIS II trial on the other hand, randomized 3864 postmenopausal women to either anastrozole, a nonsteroidal aromatase inhibitor, vs. placebo with a further randomization to bisphosphate or not based on bone density.88,89 After a median follow-up of 5 years, anastrozole reduced the incidence of invasive breast cancer by about 50%. The trial also had an initial sub-study that looked at the effect of the aromatase inhibitor on cognitive function and reported no adverse effects.90 The American Society of Clinical Oncology recommends tamoxifen for chemoprevention in premenopausal or postmenopausal women and consideration for raloxifene or exemestane in postmenopausal women who are noted to be at increased risk of breast cancer.91,92 The discussion with an individual patient should include risk assessment and potential risks and benefits with each agent.

Risk-Reducing Surgery. A retrospective study of women at high risk for breast cancer found that prophylactic mastectomy reduced their risk by >90%.93 However, the effects of prophylactic mastectomy on the long-term quality of life are poorly quantified. A study involving women who were carriers of a breast cancer susceptibility gene (BRCA1) mutation found that the benefit of prophylactic mastectomy differed substantially according to the breast cancer risk conferred by the mutations. For women with an estimated lifetime risk of 40%, prophylactic mastectomy added almost 3 years of life, whereas for women with an estimated lifetime risk of 85%, prophylactic mastectomy added >5 years of life.94 Domchek et al evaluated a cohort of BRCA1 and 2 mutation carriers who were followed prospectively and reported on outcomes with risk-reducing surgery.95 They found that risk-reducing mastectomy was highly effective at preventing breast cancer in both BRCA1 and 2 mutation carriers. Risk-reducing salpingo-oophorectomy was highly effective at reducing the incidence of ovarian cancer and breast cancer in BRCA1 mutation carriers and was associated with a reduction in breast cancer-specific mortality, ovarian cancer-specific mortality, and all-cause mortality. While studies of bilateral prophylactic or risk-reducing mastectomy have reported dramatic reductions in breast cancer incidence among those without known BRCA1 mutations, there is little data to support a survival benefit. Another consideration is that while most patients are satisfied with their decision to pursue risk-reducing surgery, some are dissatisfied with the cosmetic outcomes mostly due to reconstructive issues.

BRCA Mutations

BRCA1. Up to 5% of breast cancers are caused by inheritance of germline mutations such as BRCA1 and BRCA2, which are inherited in an autosomal dominant fashion with varying degrees of penetrance (Table 17–7).94–100 BRCA1 is located on chromosome arm 17q, spans a genomic region of approximately 100 kilobases (kb) of DNA, and contains 22 coding exons for 1863 amino acids. Both BRCA1 and BRCA2 function as tumor-suppressor genes, and for each gene, loss of both alleles is required for the initiation of cancer. Data accumulated since the isolation of the BRCA1 gene suggest a role in transcription, cell-cycle control, and DNA damage repair pathways. More than 500 sequence variations in BRCA1 have been identified. It now is known that germline mutations in BRCA1 represent a predisposing genetic factor in as many as 45% of hereditary breast cancers and in at least 80% of hereditary ovarian cancers. Female mutation carriers have been reported to have up to an 85% lifetime risk (for some families) for developing breast cancer and up to a 40% lifetime risk for developing ovarian cancer. The initial families reported had high penetrance and subsequently the average lifetime risk has been reported to lie between 60% and 70%. Breast cancer susceptibility in these families appears as an autosomal dominant trait with high penetrance. Approximately 50% of children of carriers inherit the trait. In general, BRCA1-associated breast cancers are invasive ductal carcinomas, are poorly differentiated, are in the majority
hormone receptor negative, and have a triple receptor negative (immunohistochemical profile: ER-negative, PR-negative, and HER2-negative) or basal phenotype (based on gene expression profiling). **BRCA1**-associated breast cancers have a number of distinguishing clinical features, such as an early age of onset compared with sporadic cases; a higher prevalence of bilateral breast cancer; and the presence of associated cancers in some affected individuals, specifically ovarian cancer and possibly colon and prostate cancers.

Several founder mutations have been identified in **BRCA1**. The two most common mutations are 185delAG and 5382insC, which account for 10% of all the mutations seen in **BRCA1**. These two mutations occur at a 10-fold higher frequency in the Ashkenazi Jewish population than in non-Jewish Caucasians. The carrier frequency of the 185delAG mutation in the Ashkenazi Jewish population is 1% and, along with the 5382insC mutation, accounts for almost all **BRCA1** mutations in this population. Analysis of germline mutations in Jewish and non-Jewish women with early-onset breast cancer indicates that 20% of Jewish women who develop breast cancer before age 40 carry the 185delAG mutation. There are founder **BRCA1** mutations in other populations including, among others, Dutch, Polish, Finnish, and Russian populations.

**BRCA2**. **BRCA2** is located on chromosome arm 13q and spans a genomic region of approximately 70 kb of DNA. The 11.2 kb coding region contains 26 coding exons. It encodes a protein of 3418 amino acids. The **BRCA2** gene bears no homology to any previously described gene, and the protein contains no previously defined functional domains. The biologic function of **BRCA2** is not well defined, but like **BRCA1**, it is postulated to play a role in DNA damage response pathways. **BRCA2** messenger RNA also is expressed at high levels in the late G1 and S phases of the cell cycle. The kinetics of **BRCA2** protein regulation in the cell cycle is similar to that of **BRCA1** protein, which suggests that these genes are coregulated. The mutational spectrum of **BRCA2** is not as well established as that of **BRCA1**. To date, >250 mutations have been found. The breast cancer risk for **BRCA2** mutation carriers is close to 85%, and the lifetime ovarian cancer risk, while lower than for **BRCA1**, is still estimated to be close to 20%. Breast cancer susceptibility in **BRCA2** families is an autosomal dominant trait and has a high penetrance. Approximately 50% of children of carriers inherit the trait. Unlike male carriers of **BRCA1** mutations, men with germline mutations in **BRCA2** have an estimated breast cancer risk of 6%, which represents a 100-fold increase over the risk in the general male population. **BRCA2**-associated breast cancers are invasive ductal carcinomas, which are more likely to be well differentiated and to express hormone receptors than are **BRCA1**-associated breast cancers. **BRCA2**-associated breast cancer has a number of distinguishing clinical features, such as an early age of onset compared with sporadic cases, a higher prevalence of bilateral breast cancer, and the presence of associated cancers in some affected individuals, specifically ovarian, colon, prostate, pancreatic, gallbladder, bile duct, and stomach cancers, as well as melanoma. A number of founder mutations have been identified in **BRCA2**. The 6174delT mutation is found in Ashkenazi Jews with a prevalence of 1.2% and accounts for 60% of ovarian cancer and 30% of early-onset breast cancer patients among Ashkenazi women. Another **BRCA2** founder mutation, 999del5, is observed in Icelandic and Finnish populations, while more recently 3036delA has been observed in a number of Spanish families.

^(a) Affected gene.

**Identification of BRCA Mutation Carriers**. Identifying hereditary risk for breast cancer is a four-step process that includes: (a) obtaining a complete, multigenerational family history, (b) assessing the appropriateness of genetic testing for a particular patient, (c) counseling the patient, and (d) interpreting the results of testing. Genetic testing should not be offered in isolation, but only in conjunction with patient education and counseling, including referral to a genetic counselor. Initial determinations include whether the individual is an appropriate candidate for genetic testing and whether genetic testing will be informative for personal and clinical decision-making. A thorough and accurate family history is essential to this process, and the maternal and paternal sides of the family are both assessed because 50% of the women with a **BRCA** mutation have inherited the mutation from their fathers. To help clinicians advise women about genetic testing, statistically based models that determine the probability that an individual carries a **BRCA** mutation have been developed. A method for calculating carrier probability that has been demonstrated to have acceptable performance (i.e., both in terms of calibration and discrimination) such as the Manchester scoring system and BODICEA should be used to offer referral to a specialist genetic clinic. A hereditary risk of breast cancer is considered if a family includes Ashkenazi Jewish heritage; a first-degree relative with breast cancer before age 50; a history of ovarian cancer at any age in the patient or first- or second-degree relative with ovarian cancer; breast and ovarian cancer in the same individual; two or more first- or second-degree relatives with breast cancer at any age; patient or relative with bilateral breast cancer; and male breast cancer in a relative at any age. The threshold for genetic testing is lower in individuals who are members of ethnic groups in whom the mutation prevalence is increased.

**BRCA Mutation Testing**. Appropriate counseling for the individual being tested for a **BRCA** mutation is strongly recommended, and documentation of informed consent is required. The test that is clinically available for analyzing **BRCA** mutations is gene sequence analysis. In a family with a history suggestive of hereditary breast cancer and no previously
tested member, the most informative strategy is first to test an affected family member. This person undergoes complete sequence analysis of both the *BRCA1* and *BRCA2* genes. If a mutation is identified, relatives are usually tested only for that specific mutation. An individual of Ashkenazi Jewish ancestry is tested initially for the three specific mutations that account for hereditary breast and ovarian cancer in that population. If results of that test are negative, it may then be appropriate to fully analyze the *BRCA1* and *BRCA2* genes.

A positive test result is one that discloses the presence of a *BRCA* mutation that interferes with translation or function of the *BRCA* protein. A woman who carries a deleterious mutation has a breast cancer risk of up to 85% (in some families) as well as a greatly increased risk of ovarian cancer. A negative test result is interpreted according to the individual’s personal and family history, especially whether a mutation has been previously identified in the family, in which case the woman is generally tested only for that specific mutation. If the mutation is not present, the woman’s risk of breast or ovarian cancer may be no greater than that of the general population. In addition, no *BRCA* mutation can be passed on to the woman’s children. In the absence of a previously identified mutation, a negative test result in an affected individual generally indicates that a *BRCA* mutation is not responsible for the familial cancer. However, the possibility remains of an unusual abnormality in one of these genes that cannot yet be identified through clinical testing. It also is possible that the familial cancer is indeed caused by an identifiable *BRCA* mutation but that the individual tested had sporadic cancer, a situation known as *phenocopy*. This is especially possible if the individual tested developed breast cancer close to the age of onset of the general population (age 60 years or older) rather than before age 50 years, as is characteristic of *BRCA* mutation carriers. Overall, the false-negative rate for *BRCA* mutation testing is <5%. Some test results, especially when a single base-pair change (missense mutation) is identified, may be difficult to interpret. This is because single base-pair changes do not always result in a nonfunctional protein. Thus, missense mutations not located within critical functional domains, or those that cause only minimal changes in protein structure, may not be disease associated and are usually reported as indeterminate results. In communicating indeterminate results to women, care must be taken to relay the uncertain cancer risk associated with this type of mutation and to emphasize that ongoing research might clarify its meaning. In addition, testing other family members with breast cancer to determine if a genetic variant tracks with their breast cancer may provide clarification as to its significance. Indeterminate genetic variance currently accounts for 12% of the test results.

Concern has been expressed that the identification of hereditary risk for breast cancer may interfere with access to affordable health insurance. This concern refers to discrimination directed against an individual or family based solely on an apparent or perceived genetic variation from the normal human genotype. The Health Insurance Portability and Accountability Act of 1996 (HIPAA) made it illegal in the United States for group health plans to consider genetic information as a preexisting condition or to use it to deny or limit coverage. Most states also have passed laws that prevent genetic discrimination in the provision of health insurance. In addition, individuals applying for health insurance are not required to report whether relatives have undergone genetic testing for cancer risk, only whether those relatives have actually been diagnosed with cancer. Currently, there is little documented evidence of genetic discrimination resulting from findings of available genetic tests.

**Cancer Prevention for *BRCA* Mutation Carriers.** Risk management strategies for *BRCA1* and *BRCA2* mutation carriers include the following:

1. Risk-reducing mastectomy and reconstruction
2. Risk-reducing salpingo-oophorectomy
3. Intensive surveillance for breast and ovarian cancer
4. Chemoprevention

Although removal of breast tissue reduces the likelihood that *BRCA1* and *BRCA2* mutation carriers will develop breast cancer, mastectomy does not remove all breast tissue, and women continue to be at risk because a germline mutation is present in any remaining breast tissue. For postmenopausal *BRCA1* and *BRCA2* mutation carriers who have not had a mastectomy, it may be advisable to avoid hormone replacement therapy because no data exist regarding the effect of the therapy on the penetrance of breast cancer susceptibility genes. Because breast cancers in *BRCA* mutation carriers have the same mammographic appearance as breast cancers in noncarriers, a screening mammogram is likely to be effective in *BRCA* mutation carriers, provided it is performed and interpreted by an experienced radiologist with a high level of suspicion. Present screening recommendations for *BRCA* mutation carriers who do not undergo risk-reducing mastectomy include clinical breast examination every 6 months and mammography every 12 months beginning at age 25 years because the risk of breast cancer in *BRCA* mutation carriers increases after age 30 years. Recent attention has been focused on the use of MRI for breast cancer screening in high-risk individuals and known *BRCA* mutation carriers. MRI appears to be more sensitive at detecting breast cancer in younger women with dense breasts. However, as noted previously, MRI does lead to the detection of benign breast lesions that cannot easily be distinguished from malignancy, and these false-positive events can result in more interventions, including biopsy specimens. The current recommendations from the American Cancer Society are for annual MRI in women with a 20% to 25% or greater lifetime risk of developing breast cancer (mainly based on family history), women with a known *BRCA1* or *BRCA2* mutation, those who have a first-degree relative with a *BRCA1* or *BRCA2* mutation and have not had genetic testing themselves, women who were treated with radiation therapy to the chest between the ages of 10 and 30 years, and those who have Li-Fraumeni syndrome, Cowden syndrome, or Bannayan-Riley-Ruvalcaba syndrome, or a first-degree relative with one of these syndromes. Despite a 49% reduction in the overall incidence of breast cancer and a 69% reduction in the incidence of estrogen receptor positive tumors in high-risk women taking tamoxifen reported in the NSABP P1 trial, there is insufficient evidence to recommend the use of tamoxifen uniformly for *BRCA1* mutation carriers. Cancers arising in *BRCA1* mutation carriers are usually high grade and are most often hormone receptor negative. Approximately 66% of *BRCA1*-associated DCIS lesions are estrogen receptor negative, which suggests early acquisition of the hormone-independent phenotype. In the NSABP P1 trial there was a 62% reduction in the incidence of breast cancer in *BRCA2* carriers, similar to the overall reduction seen in the P1 trial. In contrast, there was no reduction seen in breast cancer incidence in *BRCA1* carriers who started tamoxifen in P1 age 35 years or...
older. Tamoxifen appears to be more effective at preventing estrogen receptor-positive breast cancers.

The risk of ovarian cancer in BRCA1 and BRCA2 mutation carriers ranges from 20% to 40%, which is 10 times higher than that in the general population. Risk-reducing salpingo-oophorectomy is a reasonable prevention option in mutation carriers. In women with a documented BRCA1 or BRCA2 mutation, consideration for bilateral risk-reducing salpingo-oophorectomy should be between the ages of 35 and 40 years at the completion of childbearing. Removing the ovaries reduces the risk of ovarian cancer and breast cancer when performed in premenopausal BRCA mutation carriers. Hormone replacement therapy is discussed with the patient at the time of oophorectomy. The Cancer Genetics Studies Consortium recommends yearly transvaginal ultrasound timed to avoid ovulation and annual measurement of serum cancer antigen 125 levels beginning at age 25 years as the best screening modalities for ovarian carcinoma in BRCA mutation carriers who have opted to defer risk-reducing surgery.

PALB2 (partner and localizer of BRCA2) has recently been characterized as a potential high-risk gene for breast cancer. PALB2 allows nuclear localization of BRCA2 and provides a scaffold for the BRCA1–PALB2–BRCA2 complex. Analysis by Antoniou et al has suggested that the risk of breast cancer for PALB2 mutation carriers is as high as that of BRCA2 mutation carriers. The absolute risk of breast cancer for PALB2 female mutation carriers by 70 years of age ranged from 33% (95% CI, 25–44) for those with no family history of breast cancer to 58% (95% CI, 50–66) for those with two or more first-degree relatives with breast cancer at 30 years of age. The risk of breast cancer for female PALB2 mutation carriers, depending on the age, was about five to nine times as high compared with the general population. While screening with mammogram along with MRI has been suggested for PALB2 mutation carriers starting at age 30 with consideration of risk-reducing mastectomy, there is currently insufficient evidence regarding the risk of ovarian cancer and its management.

Other hereditary syndromes associated with an increased risk of breast cancer include Cowden disease (PTEN mutations, in which cancers of the thyroid, GI tract, and benign skin and subcutaneous nodules are also seen), Li-Fraumeni syndrome (TP53 mutations, also associated with sarcomas, lymphomas, and adrenocortical tumors), hereditary diffuse gastric cancer syndrome (CDH1 mutations, associated with diffuse gastric cancer and lobular breast cancers), and syndromes of breast and melanoma. With the discovery of additional genes related to breast cancer susceptibility, panel testing is available for a number of genes in addition to BRCA1 and BRCA2. The interpretation of results is complex and is best done with a genetic counselor.

**Epidemiology and Natural History of Breast Cancer**

**Epidemiology**

Breast cancer is the most common site-specific cancer in women and is the leading cause of death from cancer for women age 20 to 59 years. Based on Surveillance, Epidemiology, and End Results registries (SEER) data, 266,120 new cases were estimated in 2018 with 40,920 estimated deaths attributed to breast cancers. It accounts for 30% of all newly diagnosed cancers in women and is responsible for 14% of the cancer-related deaths in women.

Breast cancer was the leading cause of cancer-related mortality in women until 1987, when it was surpassed by lung cancer. In the 1970s, the probability that a woman in the United States would develop breast cancer at some point in her lifetime was estimated at 1 in 13; in 1980 it was 1 in 11; and in 2004 it was 1 in 8. Cancer registries in Connecticut and upper New York State document that the age-adjusted incidence of new breast cancer cases had steadily increased since the mid-1940s. The incidence in the United States, based on data from nine SEER registries, has been decreasing by 23% per year since 2000. The increase had been approximately 1% per year from 1973 to 1980, and there was an additional increase in incidence of 4% between 1980 and 1987, which was characterized by frequent detection of small primary cancers. The increase in breast cancer incidence occurred primarily in women age ≥55 years and paralleled a marked increase in the percentage of older women who had mammograms taken. At the same time, incidence rates for regional metastatic disease dropped and breast cancer mortality declined. From 1960 to 1963, 5-year overall survival rates for breast cancer were 63% and 46% in white and African American women, respectively, whereas the rates for 1981 to 1983 were 78% and 64%, respectively. For 2002 to 2008 rates were 92% and 78%, respectively.

There is a 10-fold variation in breast cancer incidence among different countries worldwide. Cyprus and Malta have the highest age-adjusted mortality for breast cancer (29.6 per 100,000 population), whereas Haiti has the lowest (2.0 deaths per 100,000 population). The United States has an age-adjusted mortality for breast cancer of 19.0 cases per 100,000 population. Women living in less industrialized nations tend to have a lower incidence of breast cancer than women living in industrialized countries, although Japan is an exception. In the United States, Mormons, Seventh Day Adventists, American Indians, Alaska natives, Hispanic/Latina Americans, and Japanese and Filipino women living in Hawaii have a below-average incidence of breast cancer, whereas nuns (due to nulliparity) and Ashkenazi Jewish women have an above-average incidence.

The incidence rates of breast cancer increased in most countries through the 1990s. Since the estimates for 1990, there was an overall increase in incidence rates of approximately 0.5% annually. It was predicted that there would be approximately 1.4 million new cases in 2010. The cancer registries in China have noted annual increases in incidence of up to 3% to 4%, and in eastern Asia, increases are similar.

Data from the SEER program reveal declines in breast cancer incidence over the past decade, and this is widely attributed to decreased use of hormone replacement therapy as a consequence of the Women’s Health Initiative reports.

Breast cancer burden has well-defined variations by geography, regional lifestyle, and racial or ethnic background. In general, both breast cancer incidence and mortality are relatively lower among the female populations of Asia and Africa, relatively underdeveloped nations, and nations that have not adopted Westernized reproductive and dietary patterns. In contrast, European and North American women and women from heavily industrialized or Westernized countries have a substantially higher breast cancer burden. These international patterns are mirrored in breast cancer incidence and mortality rates observed for the racially, ethnically, and culturally diverse population of the United States.
Although often related, the factors that influence breast cancer incidence may differ from those that affect mortality. Incidence rates are lower among populations that are heavily weighted with women who begin childbearing at young ages and who have multiple full-term pregnancies followed by prolonged lactation. These are features that characterize many underdeveloped nations and also many eastern nations. Breast cancer mortality rates should be lower in populations that have a lower incidence, but the mortality burden will simultaneously be adversely affected by the absence of effective mammographic screening programs for early detection and diminished access to multidisciplinary cancer treatment programs. These features are likely to account for much of the disproportionate mortality risks that are seen in underdeveloped nations. Similar factors probably account for differences in breast cancer burden observed among the various racial and ethnic groups within the United States. Interestingly, breast cancer incidence and mortality rates rise among second- and third-generation Asian Americans as they adopt Western lifestyles.

Disparities in breast cancer survival among subsets of the American population are generating increased publicity because they are closely linked to disparities in socioeconomic status. Poverty rates and proportions of the population that lack health care insurance are two to three times higher among minority racial and ethnic groups such as African Americans and Hispanic/Latino Americans. These socioeconomic disadvantages create barriers to effective breast cancer screening and result in delayed breast cancer diagnosis, advanced stage distribution, inadequacies in comprehensive treatment, and, ultimately, increased mortality rates. Furthermore, the rapid growth in the Hispanic population is accompanied by increasing problems in health education because of linguistic barriers between physicians and recently immigrated, non–English-speaking patients. Recent studies also are documenting inequities in the treatments delivered to minority breast cancer patients, such as increased rates of failure to provide systemic therapy, use of sentinel lymph node dissection, and breast reconstruction. Some of the treatment delivery disparities are related to inadequately controlled comorbidities (such as hypertension and diabetes), which are more prevalent in minority populations. However, some studies that adjust for these factors report persistent and unexplained unevenness in treatment recommendations. It is clear that breast cancer disparities associated with racial or ethnic background have a multifactorial cause, and improvements in outcome will require correction of many public health problems at both the patient and provider levels.

Advances in the ability to characterize breast cancer subtypes and the genetics of the disease are now provoking speculation regarding possible hereditary influences on breast cancer risk that are related to racial or ethnic ancestry. These questions become particularly compelling when one looks at disparities in breast cancer burden between African Americans and Caucasians. Lifetime risk of breast cancer is lower for African Americans, yet a paradoxically increased breast cancer mortality risk also is seen. African Americans also have a younger age distribution for breast cancer; among women <45 years of age, breast cancer incidence is highest among African Americans compared to other subsets of the American population. Lastly and most provocatively, African American women of all ages have notably higher incidence rates for estrogen receptor-negative tumors. These same patterns of disease are seen in contemporary female populations of western, sub-Saharan Africa, who are likely to share ancestry with African American women as a consequence of the Colonial-era slave trade. Interestingly, male breast cancer also is seen with increased frequency among both African Americans and Africans.

**Natural History**

Bloom and colleagues described the natural history of breast cancer based on the records of 250 women with untreated breast cancers who were cared for on charity wards in the Middlesex Hospital, London, between 1805 and 1933. The median survival of this population was 2.7 years after initial diagnosis (Fig. 17-13). The 5- and 10-year survival rates for these women were 18.0% and 3.6%, respectively. Only 0.8% survived for 15 years or longer. Autopsy data confirmed that 95% of these women died of breast cancer, whereas the remaining 5% died of other causes. Almost 75% of the women developed ulceration of the breast during the course of the disease. The longest surviving patient died in the 19th year after diagnosis.

**Primary Breast Cancer.** More than 80% of breast cancers show productive fibrosis that involves the epithelial and stromal tissues. With growth of the cancer and invasion of the surrounding breast tissues, the accompanying desmoplastic response entraps and shortens Cooper’s suspensory ligaments to produce a characteristic skin retraction. Localized edema (peau d’orange) develops when drainage of lymph fluid from the skin is disrupted. With continued growth, cancer cells invade the skin, and eventually ulceration occurs. As new areas of skin are invaded, small satellite nodules appear near the primary ulceration. The size of the primary breast cancer correlates with disease-free and overall survival, but there is a close association between cancer size and axillary lymph node involvement (Fig. 17-14). In general, up to 20% of breast cancer recurrences are local-regional, >60% are distant, and 20% are both local-regional and distant.
nodes adhere to each other and form a conglomerate mass. Cancer cells may grow through the lymph node capsule and fix to contiguous structures in the axilla, including the chest wall. Typically, axillary lymph nodes are involved sequentially from the low (level I) to the central (level II) to the apical (level III) lymph node groups. Approximately 95% of the women who die of breast cancer have distant metastases, and traditionally the most important prognostic correlate of disease-free and overall survival was axillary lymph node status (see Fig. 17-14A). Women with node-negative disease had less than a 30% risk of recurrence, compared with as much as a 75% risk for women with node-positive disease.

**Distant Metastases.** At approximately the 20th cell doubling, breast cancers acquire their own blood supply (neovascularization). Thereafter, cancer cells may be shed directly into the systemic venous blood to seed the pulmonary circulation via the axillary and intercostal veins or the vertebral column via Batson’s plexus of veins, which courses the length of the vertebral column. These cells are scavenged by natural killer lymphocytes and macrophages. Successful implantation of metastatic foci from breast cancer predictably occurs after the primary cancer exceeds 0.5 cm in diameter, which corresponds to the 27th cell doubling. For 10 years after initial treatment, distant metastases are the most common cause of death in breast cancer patients. For this reason, conclusive results cannot be derived from breast cancer trials until at least 5 to 10 years have elapsed. Although 60% of the women who develop distant metastases will do so within 60 months of treatment, metastases may become evident as late as 20 to 30 years after treatment of the primary cancer. Patients with estrogen receptor negative breast cancers are proportionately more likely to develop recurrence in the first 3 to 5 years, whereas those with estrogen receptor positive tumors have a risk of developing recurrence, which drops off more slowly beyond 5 years than is seen with ER-negative tumors. Recently, a report showed that tumor size and nodal status remain powerful predictors of late recurrences compared to more recently developed tools such as the immunohistochemical score (IHC4) and two gene expression profile tests (Recurrence Score and PAM50). Common sites of involvement, in order of frequency, are bone, lung, pleura, soft tissues, and liver. Brain metastases are less frequent overall, although with the advent of adjuvant systemic therapies it has been reported that CNS disease may be seen earlier. There are also reports of factors that are associated with the risk of developing brain metastases. For example, they are more likely to be seen in patients with triple receptor negative breast cancer (ER-negative, PR-negative, and HER2-negative) or patients with HER2-positive breast cancer who have received chemotherapy and HER2-directed therapies.

**HISTOPATHOLOGY OF BREAST CANCER**

**Carcinoma In Situ**

Cancer cells are in situ or invasive depending on whether or not they invade through the basement membrane. Broders’s original description of in situ breast cancer stressed the absence of invasion of cells into the surrounding stroma and their confinement within natural ductal and alveolar boundaries. Because areas of invasion may be minute, the accurate diagnosis of in situ cancer necessitates the analysis of multiple microscopic sections to exclude invasion. In 1941, Foote and Stewart published...
a landmark description of LCIS, which distinguished it from DCIS. 130 In the late 1960s, Gallagher and Martin published their study of whole-breast sections and described a stepwise progression from benign breast tissue to in situ cancer and subsequently to invasive cancer. Before the widespread use of mammography, diagnosis of breast cancer was by physical examination. At that time, in situ cancers constituted <6% of all breast cancers, and LCIS was more frequently diagnosed than DCIS by a ratio of >2:1. However, when screening mammography became popular, a 14-fold increase in the incidence of in situ cancer (45%) was demonstrated, and DCIS was more frequently diagnosed than LCIS by a ratio of >2:1. Table 17-8 lists the clinical and pathologic characteristics of DCIS and LCIS. Multicentricity refers to the occurrence of a second breast cancer outside the breast quadrant of the primary cancer (or at least 4 cm away), whereas multifocality refers to the occurrence of a second cancer within the same breast quadrant as the primary cancer (or within 4 cm of it). Multicentricity occurs in 60% to 90% of women with LCIS, whereas the rate of multicentricity for DCIS is reported to be 40% to 80%. LCIS occurs bilaterally in 50% to 70% of cases, whereas DCIS occurs bilaterally in 10% to 20% of cases.

**Lobular Carcinoma In Situ.** LCIS originates from the terminal duct lobular units and develops only in the female breast. It is characterized by distention and distortion of the terminal duct lobular units by cells that are large but maintain a normal normal to cytoplasmic ratio. Cytoplasmic mucoid globules are a distinctive cellular feature. LCIS may be observed in breast tissues that contain microcalcifications, but the calcifications associated with LCIS typically occur in adjacent tissues. This neighborhood calcification is a feature that is unique to LCIS and contributes to its diagnosis. The frequency of LCIS in the general population cannot be reliably determined because it usually presents as an incidental finding. The average age at diagnosis is 45 years, which is approximately 15 to 25 years younger than the age at diagnosis for invasive breast cancer. LCIS has a distinct racial predilection, occurring 12 times more frequently in white women than in African-American women. Invasive breast cancer develops in 25% to 35% of women with LCIS. Invasive cancer may develop in either breast, regardless of which breast harbored the initial focus of LCIS, and is detected synchronously with LCIS in 5% of cases. In women with a history of LCIS, up to 65% of subsequent invasive cancers are ductal, not lobular, in origin. For these reasons, LCIS is regarded as a marker of increased risk for invasive breast cancer rather than as an anatomic precursor. Individuals should be counseled regarding their risk of developing breast cancer and appropriate risk reduction strategies, including observation with screening, chemoprevention, and risk-reducing bilateral mastectomy.

**Ductal Carcinoma In Situ.** Although DCIS is predominantly seen in the female breast, it accounts for 5% of male breast cancers. Published series suggest a detection frequency of 7% in all biopsy tissue specimens. The term *intraductal carcinoma* is frequently applied to DCIS, which carries a high risk for progression to an invasive cancer. Histologically, DCIS is characterized by a proliferation of the epithelium that lines the minor ducts, resulting in papillary growths within the duct lumina. Early in their development, the cancer cells do not show pleomorphism, mitoses, or atypia, which leads to difficulty distinguishing early DCIS from benign hyperplasia. The papillary growths (papillary growth pattern) eventually coalesce and fill the duct lumina so that only scattered, rounded spaces remain between the clumps of atypical cancer cells, which show hyperchromasia and loss of polarity (cribriform growth pattern). Eventually pleomorphic cancer cells with frequent mitotic figures obliterate the lumina and distend the ducts (solid growth pattern). With continued growth, these cells outstrip their blood supply and become necrotic (comedo growth pattern). Calcium deposition occurs in the areas of necrosis and is a common feature seen on mammography. DCIS is now frequently classified based on nuclear grade and the presence of necrosis (Table 17-9). Based

### Table 17-8

| **Salient characteristics of in situ ductal (DCIS) and lobular (LCIS) carcinoma of the breast** |
|---------------------------------|------|------|
| **Age (years)** | LCIS | DCIS |
| 44–47 | 54–58 |
| **Incidence** | 2%–5% | 5%–10% |
| **Clinical signs** | None | Mass, pain, nipple discharge |
| **Mammographic signs** | None | Microcalcifications |
| **Premenopausal** | 2/3 | 1/3 |
| **Incidence of synchronous invasive carcinoma** | 5% | 2%–46% |
| **Multicentricity** | 60%–90% | 40%–80% |
| **Bilaterality** | 50%–70% | 10%–20% |
| **Axillary metastasis** | 1% | 1%–2% |
| **Subsequent carcinomas:** | | |
| **Incidence** | 25%–35% | 25%–70% |
| **Laterality** | Bilateral | Ipsilateral |
| **Interval to diagnosis** | 15–20 y | 5–10 y |
| **Histologic type** | Ductal | Ductal |

*In biopsy specimens of mammographically detected breast lesions.

### Table 17-9

| **Classification of breast ductal carcinoma in situ (DCIS)** |
|-------------------|------|------|------|
| **HISTOLOGIC SUBTYPE** | **DETERMINING CHARACTERISTICS** | **NUCLEAR GRADE** | **NECROSIS** | **DCIS GRADE** |
| Comedo | High | Extensive | High |
| Intermediate | Intermediate | Focal or absent | Intermediate |
| Noncomedo | Low | Absent | Low |

*Often a mixture of noncomedo patterns.
*Solid, cribriform, papillary, or focal micropapillary.
on multiple consensus meetings, grading of DCIS has been recommended. Although there is no universal agreement on classification, most systems endorse the use of cytologic grade and presence or absence of necrosis. The risk for invasive breast cancer is increased nearly fivefold in women with DCIS. The invasive cancers are observed in the ipsilateral breast, usually in the same quadrant as the DCIS that was originally detected, which suggests that DCIS is an anatomic precursor of invasive ductal carcinoma (Fig. 17-15A and B).

**Invasive Breast Carcinoma**

Invasive breast cancers have been described as lobular or ductal in origin. Early classifications used the term lobular to describe invasive cancers that were associated with LCIS, whereas all other invasive cancers were referred to as ductal.

**Figure 17-15.** Ductal carcinoma in situ (DCIS). A. Craniocaudal mammographic view shows a poorly defined mass containing microcalcifications. (Used with permission from Dr. Anne Turnbull, Consultant Radiologist/Director of Breast Screening, Royal Derby Hospital, Derby, UK.) B. Histopathologic preparation of the surgical specimen confirms DCIS with necrosis (100x). (Used with permission from Dr. Sindhu Menon, Consultant Histopathologist and Dr. Rahul Deb, Consultant Histopathologist and Lead Breast Pathologist, Royal Derby Hospital, Derby, UK.)

Current histologic classifications recognize special types of breast cancers (10% of total cases), which are defined by specific histologic features. To qualify as a special-type cancer, at least 90% of the cancer must contain the defining histologic features. About 80% of invasive breast cancers are described as invasive ductal carcinoma of no special type (NST). These cancers generally have a worse prognosis than special-type cancers. Foote and Stewart originally proposed the following classification for invasive breast cancer:

1. Paget’s disease of the nipple
2. Invasive ductal carcinoma—Adenocarcinoma with productive fibrosis (scirrhous, simplex, NST), 80%
3. Medullary carcinoma, 4%
4. Mucinous (colloid) carcinoma, 2%
5. Papillary carcinoma, 2%
6. Tubular carcinoma, 2%
7. Invasive lobular carcinoma, 10%
8. Rare cancers (adenoid cystic, squamous cell, apocrine)

Paget’s disease of the nipple was described in 1874. It frequently presents as a chronic, eczematous eruption of the nipple, which may be subtle but may progress to an ulcerated, weeping lesion. Paget’s disease usually is associated with extensive DCIS and may be associated with an invasive cancer. A palpable mass may or may not be present. A nipple biopsy specimen will show a population of cells that are identical to the underlying DCIS cells (pagetoid features or pagetoid change). Pathognomonic of this cancer is the presence of large, pale, vacuolated cells (Paget cells) in the rete pegs of the epithelium. Paget’s disease may be confused with superficial spreading melanoma. Differentiation from pagetoid intraepithelial melanoma is based on the presence of S-100 antigen immunostaining in melanoma and carcinoembryonic antigen immunostaining in Paget’s disease. Surgical therapy for Paget’s disease may involve lumpectomy or mastectomy, depending on the extent of involvement of the nipple-areolar complex and the presence of DCIS or invasive cancer in the underlying breast parenchyma.

Invasive ductal carcinoma of the breast with productive fibrosis (scirrhous, simplex, NST) accounts for 80% of breast cancers and presents with macroscopic or microscopic axillary lymph node metastases in up to 25% of screen-detected cases and up to 60% of symptomatic cases. This cancer occurs most frequently in perimenopausal or postmenopausal women in the fifth to sixth decades of life as a solitary, firm mass. It has poorly defined margins, and its cut surfaces show a central stellate configuration with chalky white or yellow streaks extending into surrounding breast tissues. The cancer cells often are arranged in small clusters, and there is a broad spectrum of histologic types with variable cellular and nuclear grades (Fig. 17-16A and B). In a large patient series from the SEER database, 75% of ductal cancers showed estrogen receptor expression.

Medullary carcinoma is a special-type breast cancer; it accounts for 4% of all invasive breast cancers and is a frequent phenotype of BRCA1 hereditary breast cancer. Grossly, the cancer is soft and hemorrhagic. A rapid increase in size may occur secondary to necrosis and hemorrhage. On physical examination, it is bulky and often positioned deep within the breast. Bilaterality is reported in 20% of cases. Medullary carcinoma is characterized microscopically by: (a) a dense lympho- phoreticular infiltrate composed predominantly of lymphocytes and plasma cells; (b) large pleomorphic nuclei that are poorly
differentiated and show active mitosis; and (c) a sheet-like growth pattern with minimal or absent ductal or alveolar differentiation. Approximately 50% of these cancers are associated with DCIS, which characteristically is present at the periphery of the cancer, and <10% demonstrate hormone receptors. In rare circumstances, mesenchymal metaplasia or anaplasia is noted. Because of the intense lymphocyte response associated with the cancer, benign or hyperplastic enlargement of the lymph nodes of the axilla may contribute to erroneous clinical staging.

Women with this cancer have a better 5-year survival rate than those with NST or invasive lobular carcinoma.

Mucinous carcinoma (colloid carcinoma), another special-type breast cancer, accounts for 2% of all invasive breast cancers and typically presents in the older population as a bulky tumor. This cancer is defined by extracellular pools of mucin, which surround aggregates of low-grade cancer cells. The cut surface of this cancer is glistening and gelatinous in quality. Fibrosis is variable, and when abundant it imparts a firm consistency to the cancer. Over 90% of mucinous carcinomas display hormone receptors. Lymph node metastases occur in 33% of cases, and 5- and 10-year survival rates are 73% and 59%, respectively. Because of the mucinous component, cancer cells may not be evident in all microscopic sections, and analysis of multiple sections is essential to confirm the diagnosis of a mucinous carcinoma.

Papillary carcinoma is a special-type cancer of the breast that accounts for 2% of all invasive breast cancers. It generally presents in the seventh decade of life and occurs in a disproportionate number of nonwhite women. Typically, papillary carcinomas are small and rarely attain a size of 3 cm in diameter. These cancers are defined by papillae with fibrovascular stalks and multilayered epithelium. In a large series from the SEER database 87% of papillary cancers have been reported to express estrogen receptor. McDivitt and colleagues noted that these tumors showed a low frequency of axillary lymph node metastases and had 5- and 10-year survival rates similar to those for mucinous and tubular carcinoma.

Tubular carcinoma is another special-type breast cancer and accounts for 2% of all invasive breast cancers. It is reported in as many as 20% of women whose cancers are diagnosed by mammographic screening and usually is diagnosed in the perimenopausal or early menopausal periods. Under low-power magnification, a haphazard array of small, randomly arranged tubular elements is seen. In a large SEER database 94% of tubular cancers were reported to express estrogen receptor. Approximately 10% of women with tubular carcinoma or with invasive cribriform carcinoma, a special-type cancer closely related to tubular carcinoma, will develop axillary lymph node metastases. However, the presence of metastatic disease in one or two axillary lymph nodes does not adversely affect survival. Distant metastases are rare in tubular carcinoma and invasive cribriform carcinoma. Long-term survival approaches 100%.

Invasive lobular carcinoma accounts for 10% of breast cancers. The histopathologic features of this cancer include small cells with rounded nuclei, inconspicuous nucleoli, and scant cytoplasm (Fig. 17-17). Special stains may confirm the
presence of intracytoplasmic mucin, which may displace the nucleus (signet-ring cell carcinoma). At presentation, invasive lobular carcinoma varies from clinically inapparent carcinomas to those that replace the entire breast with a poorly defined mass. It is frequently multifocal, multicentric, and bilateral. Because of its insidious growth pattern and subtle mammographic features, invasive lobular carcinoma may be difficult to detect. Over 90% of lobular cancers express estrogen receptor.¹³³

**DIAGNOSIS OF BREAST CANCER**

In ∼30% of cases, the woman discovers a lump in her breast. Other less frequent presenting signs and symptoms of breast cancer include: (a) breast enlargement or asymmetry; (b) nipple changes, retraction, or discharge; (c) ulceration or erythema of the skin of the breast; (d) an axillary mass; and (e) musculoskeletal discomfort. However, up to 50% of women presenting with breast complaints have no physical signs of breast pathology. Breast pain usually is associated with benign disease.

Misdiagnosed breast cancer accounts for the greatest number of malpractice claims for errors in diagnosis and for the largest number of paid claims. Litigation often involves younger women, whose physical examination and mammogram may be misleading. If a young woman (≤45 years) presents with a palpable breast mass and equivocal mammographic findings, ultrasound examination and biopsy are used to avoid a delay in diagnosis.

**Examination**

**Inspection.** The clinician inspects the woman’s breast with her arms by her side (Fig. 17-18A), with her arms straight up in the air (Fig. 17-18B), and with her hands on her hips (with and without pectoral muscle contraction).¹³⁵,¹³⁶ Symmetry, size, and shape of the breast are recorded, as well as any evidence of edema (peau d’orange), nipple or skin retraction, or erythema. With the arms extended forward and in a sitting position, the woman leans forward to accentuate any skin retraction.

**Figure 17-18.** Examination of the breast. **A.** Inspection of the breast with arms at sides. **B.** Inspection of the breast with arms raised. **C.** Palpation of the breast with the patient supine. **D.** Palpation of the axilla.

**Palpation.** As part of the physical examination, the breast is carefully palpated. With the patient in the supine position (see Fig. 17-18C) the clinician gently palpates the breasts, making certain to examine all quadrants of the breast from the sternum laterally to the latissimus dorsi muscle and from the clavicle inferiorly to the upper rectus sheath. The examination is performed with the palmar aspects of the fingers, avoiding a grasping or pinching motion. The breast may be cupped or molded in the examiner’s hands to check for retraction. A systematic search for lymphadenopathy then is performed. Figure 17-18D shows the position of the patient for examination of the axilla. By supporting the upper arm and elbow, the examiner stabilizes the shoulder girdle. Using gentle palpation, the clinician assesses all three levels of possible axillary lymphadenopathy. Careful palpation of supraclavicular and parasternal sites also is performed. A diagram of the chest and contiguous lymph node sites is useful for recording location, size, consistency, shape, mobility, fixation, and other characteristics of any palpable breast mass or lymphadenopathy (Fig. 17-19).

**Imaging Techniques**

**Mammography.** Mammography has been used in North America since the 1960s, and the techniques used continue to be modified and improved to enhance image quality.¹³⁷-¹⁴⁰ Conventional mammography delivers a radiation dose of 0.1 cGy per study. By comparison, chest radiography delivers 25% of this dose. However, there is no increased breast cancer risk associated with the radiation dose delivered with screening mammography. Screening mammography is used to detect unexpected breast cancer in asymptomatic women. In this regard, it supplements history taking and physical examination. With screening mammography, two views of the breast are obtained: the craniocaudal (CC) view (Fig. 17-20A,B) and the mediolateral oblique (MLO) view (Fig. 17-20C,D). The MLO view images the greatest volume of breast tissue, including the upper outer quadrant and the axillary tail of Spence. Compared with the MLO view, the CC view provides better visualization of the medial aspect of the breast and permits greater breast compression. Diagnostic mammography is used to evaluate women with abnormal
Figure 17-20. A-D. Mammogram of a premenopausal breast with a dense fibroglandular pattern. E-H. Mammogram of a postmenopausal breast with a sparse fibroglandular pattern. (Used with permission from Dr. Anne Turnbull, Consultant Radiologist/Director of Breast Screening, Royal Derby Hospital, Derby, UK.)
findings such as a breast mass or nipple discharge. In addition to the MLO and CC views, a diagnostic examination may use views that better define the nature of any abnormalities, such as the 90° lateral and spot compression views. The 90° lateral view is used along with the CC view to triangulate the exact location of an abnormality. Spot compression may be done in any projection by using a small compression device, which is placed directly over a mammographic abnormality that is obscured by overlying tissues (Fig. 17-21C). The compression device minimizes motion artifact, improves definition, separates overlying tissues, and decreases the radiation dose needed to penetrate the breast. Magnification techniques (×1.5) often are combined with spot compression to better resolve calcifications and the margins of masses. Mammography also is used to guide interventional procedures, including needle localization and needle biopsy.
Specific mammographic features that suggest a diagnosis of breast cancer include a solid mass with or without stellate features, asymmetric thickening of breast tissues, and clustered microcalcifications. The presence of fine, stippled calcium in and around a suspicious lesion is suggestive of breast cancer and occurs in as many as 50% of nonpalpable cancers. These microcalcifications are an especially important sign of cancer in younger women, in whom it may be the only mammographic abnormality. The clinical impetus for screening mammography came from the Health Insurance Plan study and the Breast Cancer Detection Demonstration Project, which demonstrated a 33% reduction in mortality for women after screening mammography. Mammography was more accurate than clinical examination for the detection of early breast cancers, providing a true-positive rate of 90%. Only 20% of women with nonpalpable cancers had axillary lymph node metastases, compared with 50% of women with palpable cancers. Current guidelines of the National Comprehensive Cancer Network suggest that normal-risk women ≥20 years of age should have a breast examination at least every 3 years. Starting at age 40 years, breast examinations should be performed yearly, and a yearly mammogram should be taken. Screening mammography in women ≥50 years of age is more controversial for previously noted reasons: (a) reduced sensitivity, (b) reduced specificity, and (c) lower incidence of breast cancer. Because of the combination of these three reasons, targeting mammography screening to women <50 years of age, who are at higher risk of breast cancer, improves the balance of risks and benefits and is the approach some health care systems have taken. There are now a number of risk assessment models—as described earlier in this chapter—that can be used to estimate a younger woman’s risk of developing breast cancer and that help assess the risks and benefits of regular screening.

Screen film mammography has replaced xeromammography because it requires a lower dose of radiation and provides similar image quality. Digital mammography was developed to allow the observer to manipulate the degree of contrast in the image. This is especially useful in women with dense breasts and women <50 years of age. Recently, investigators directly compared digital vs. screen film mammography in a prospective (DMIST) trial that enrolled over 42,000 women. The investigators found that digital and screen film mammography had similar accuracy; however, digital mammography was more accurate in women <50 years of age, women with mammographically dense breasts, and premenopausal or perimenopausal women. The use of digital breast tomosynthesis with 3D images has been introduced as an alternative to standard 2D mammography imaging that is limited by superimposition of breast parenchyma and breast density. The STORM trial reported that in 7,292 women screened, 3D mammography had a higher cancer detection rate and fewer false-positive recalls than the standard 2D imaging. Randomized controlled trials are planned to further study tomosynthesis and its role in breast cancer screening. Standard two-dimensional mammography has limitations,
such as the parenchymal density or superimposition of breast tissue, which obscures cancers or causes normal structures to appear suspicious reducing the sensitivity of mammography and increasing the false-positive rates. Digital breast tomosynthesis is a technology developed to assist with overcoming these limitations. In digital breast tomosynthesis, multiple projection images are reconstructed to allow visual review of thin breast sections, each reconstructed slice as thin as 0.5 mm, which provides better characterization of noncalcified lesions. These multiple projection exposures are obtained by a digital detector from a mammography X-ray source that moves through a limited arc angle while the breast is compressed. Then these projection image data sets are reconstructed using specific algorithms, which provide the clinical reader a series of images through the entire breast.148

In 2011, tomosynthesis was approved by the U.S. Food and Drug Administration (FDA) to be used in combination with standard digital mammography for breast cancer screening. The total radiation dose when tomosynthesis is added is about twice the current dose of digital mammography alone but remains below the limits set by the FDA.149

The STORM-2 trial reported that synthetic 2D-3D mammography yields similar breast cancer detection as dual-acquisition 2D-3D mammography with the advantage of reducing radiation exposure.150

Contrast-enhanced digital mammography (CEDM) was also approved by the FDA in 2001, which utilizes an iodinated contrast material and modified digital mammography units for imaging.148 CEDM has been shown to be feasible and detects breast cancers at a rate similar to MRI, which has potential to offer an alternative to MRI.151 The advantages of CEDM over MRI are that the use of compression limits motion, there is decrease in cost, decrease in exam time, and there is an option for patients who are unable to tolerate MRI or who due to various reasons cannot have MRI due to incompatibility, such as the presence of a pacemaker or tissue expanders.148,152

Ductography. The primary indication for ductography is nipple discharge, particularly when the fluid contains blood. Radiopaque contrast media is injected into one or more of the major ducts, and mammography is performed. A duct is gently enlarged with a dilator, and then a small, blunt cannula is inserted under sterile conditions into the nipple ampulla. With the patient in a supine position, 0.1 to 0.2 mL of dilute contrast media is injected, and CC and MLO mammographic views are obtained without compression. Intraductal papillomas are seen as small filling defects surrounded by contrast media (Fig. 17-22). Cancers may appear as irregular masses or as multiple intraluminal filling defects.

Ultrasonography. Second only to mammography in frequency of use for breast imaging, ultrasonography is an important method of resolving equivocal mammographic findings, defining cystic masses, and demonstrating the echogenic qualities of specific solid abnormalities. On ultrasound examination, breast cysts are well circumscribed, with smooth margins and an echo-free center (Fig. 17-23). Benign breast masses usually show smooth contours, round or oval shapes, weak internal echoes, and well-defined anterior and posterior margins (Fig. 17-24). Breast cancer characteristically has irregular walls (Fig. 17-25) but may have smooth margins with acoustic enhancement. Ultrasonography is used to guide fine-needle aspiration biopsy, core-needle biopsy, and needle localization of breast lesions. Its findings are highly reproducible, and it has a high patient acceptance rate, but it does not reliably detect lesions that are ≤1 cm in diameter. Ultrasonography can also be utilized to image the regional lymph nodes in patients with breast cancer (Fig. 17-26). The sensitivity of examination for the status of axillary nodes ranges from 35% to 82% and specificity ranges from 73% to 97%. The features of a lymph node involved with cancer include cortical thickening, change in shape of the node to more circular appearance, size larger
Figure 17-24. Ultrasonography images of benign breast tumors. A. Fibroadenoma. B. Intraductal papilloma (see arrow). (Used with permission from Dr. Anne Turnbull, Consultant Radiologist/Director of Breast Screening, Royal Derby Hospital, Derby, UK.)

than 10 mm, absence of a fatty hilum and hypoechoic internal echoes.153

**Magnetic Resonance Imaging.** In the process of evaluating magnetic resonance imaging (MRI) as a means of characterizing mammographic abnormalities, additional breast lesions have been detected. However, in the circumstance of negative findings on both mammography and physical examination, the probability of a breast cancer being diagnosed by MRI is extremely low. There is current interest in the use of MRI to screen the breasts of high-risk women and of women with a newly diagnosed breast cancer. In the first case, women who have a strong family history of breast cancer or who carry known genetic mutations require screening at an early age because mammographic evaluation is limited due to the increased breast density in younger women. In the second case, an MRI study of the contralateral breast in women with a known breast cancer has shown a contralateral breast cancer in 5.7% of these women (Fig. 17-27). MRI can also detect additional tumors in the index breast (multifocal or multicentric disease) that may be missed on routine breast imaging and this may alter surgical decision making (Fig. 17-28). In fact, MRI has been advocated by some for routine use in surgical treatment planning based on the fact that additional disease can be identified with this advanced imaging modality and the

Figure 17-23. Breast cyst. A. Simple cyst. Ultrasound image of the mass shows it to be anechoic with a well-defined back wall, characteristic of a cyst. B. Complex solid and cystic mass. C. Complex solid and cystic mass characteristic of intracystic papillary tumor. (Used with permission from Dr. Anne Turnbull, Consultant Radiologist/Director of Breast Screening, Royal Derby Hospital, Derby, UK.)
extent of disease may be more accurately assessed. A randomized trial performed in the United Kingdom (COMICE trial) that enrolled 1623 women did not show a decrease in rates of reoperation in those women randomized to undergo MRI in addition to mammography and ultrasonography (19%) compared to those undergoing standard breast imaging without MRI (19%). Houssami and colleagues performed a meta-analysis including two randomized trials and seven comparative cohort studies to examine the effect of preoperative MRI compared to standard preoperative evaluation on surgical outcomes. They reported that the use of MRI was associated with increased mastectomy rates. This is problematic because there is no evidence that the additional disease detected by MRI is of clinical or biologic significance, particularly in light of the low local-regional failure rates currently reported in patients undergoing breast conserving surgery who receive whole breast irradiation and systemic therapies. There is an ongoing trial in the Alliance for Clinical Trials in Oncology that is randomizing patients to preoperative MRI vs. standard imaging to assess the impact of MRI on local regional recurrence rates in patients with triple receptor negative and HER2 positive breast cancers.

The use of dedicated breast coils is mandatory in the MRI imaging of the breast. A BIRADS lexicon is assigned to each examination and an abnormality noted on MRI that is not seen on mammography requires a focused ultrasound examination for further assessment. If the abnormality is not seen on corresponding mammogram or ultrasound, then MRI-guided biopsy is necessary. Some clinical scenarios where MRI may be useful include the evaluation of a patient who presents with nodal metastasis from breast cancer without an identifiable primary tumor; to assess response to therapy in the setting of neoadjuvant

systemic treatment; to select patients for partial breast irradiation techniques; and evaluation of the treated breast for tumor recurrence.

**Breast Biopsy**

**Nonpalpable Lesions.** Image-guided breast biopsy specimens are frequently required to diagnose nonpalpable lesions. Ultrasound localization techniques are used when a mass is present, whereas stereotactic techniques are used when no mass is present (microcalcifications or architectural distortion only). The combination of diagnostic mammography, ultrasound or stereotactic localization, and fine-needle aspiration (FNA) biopsy achieves almost 100% accuracy in the preoperative diagnosis of breast cancer. However, although FNA biopsy permits cytologic evaluation, core-needle permits the analysis of breast tissue architecture and allows the pathologist to determine whether invasive cancer is present. This permits the surgeon and patient to discuss the specific management of a breast cancer before therapy begins. Core-needle biopsy is preferred over open biopsy for nonpalpable breast lesions because a single surgical procedure can be planned based on the results of the core biopsy. The advantages of core-needle biopsy include a low complication rate, minimal scarring, and a lower cost compared with excisional breast biopsy.

**Palpable Lesions.** FNA or core biopsy of a palpable breast mass can usually be performed in an outpatient setting. A 1.5-in, 22-gauge needle attached to a 10-mL syringe or a 14-gauge core biopsy needle is used. For FNA, use of a syringe holder...

enables the surgeon performing the FNA biopsy to control the syringe and needle with one hand while positioning the breast mass with the opposite hand. After the needle is placed in the mass, suction is applied while the needle is moved back and forth within the mass. Once cellular material is seen at the hub of the needle, the suction is released and the needle is withdrawn. The cellular material is then expressed onto microscope slides. Both air-dried and 95% ethanol–fixed microscopic sections are prepared for analysis. When a breast mass is clinically and mammographically suspicious, the sensitivity and specificity of FNA biopsy approaches 100%. Core-needle biopsy of palpable breast masses is performed using a 14-gauge needle, such as the Tru-Cut needle. Automated devices also are available. Vacuum-assisted core biopsy devices (with 8–10 gauge needles) are commonly utilized with image guidance where between 4 and 12 samples can be acquired at different positions within a mass, area of architectural distortion or microcalcifications. If the target lesion was microcalcifications, the specimen should be radiographed to confirm appropriate sampling. A radiopaque marker should be placed at the site of the biopsy to mark the area for future intervention. In some cases the entire lesion is removed with the biopsy technique and clip placement allows for accurate targeting of the site for surgical resection. Tissue specimens are placed in formalin and then processed to paraffin blocks. Although the false-negative rate for core-needle biopsy specimens is very low, a tissue specimen that does not show breast cancer cannot conclusively rule out that diagnosis because a sampling error may have occurred. The clinical, radiographic, and pathologic findings should be in concordance. If the biopsy findings do not concur with the clinical and radiographic findings, the multidisciplinary team (including clinician, radiologist, and pathologist) should review the findings and decide whether or not to recommend an image-guided or open biopsy to be certain that the target lesion has been adequately sampled for diagnosis.

BREAST CANCER STAGING AND BIOMARKERS

Breast Cancer Staging
The clinical stage of breast cancer is determined primarily through physical examination of the skin, breast tissue, and regional lymph nodes (axillary, supraclavicular, and internal mammary). However, clinical determination of axillary lymph node metastases has an accuracy of only 33%. Ultrasound (US) is more sensitive than physical examination alone in determining axillary lymph node involvement during preliminary staging of breast carcinoma. FNA or core biopsy of sonographically indeterminate or suspicious lymph nodes can provide a more definitive diagnosis than US alone. Pathologic stage combines the findings from pathologic examination of the resected primary breast cancer and axillary or other regional lymph nodes. Fisher and colleagues found that accurate predictions regarding the occurrence of distant metastases were possible after resection and pathologic analysis of 10 or more levels I and II axillary lymph nodes. A frequently used staging system is the TNM (tumor, nodes, and metastasis) system. The American Joint Committee on Cancer (AJCC) has recently modified the TNM system for breast cancer to include both anatomic and biologic factors (Tables 17-10 and 17-11). Koscielny and colleagues demonstrated that tumor size correlates with the presence of axillary lymph node metastases (see Fig. 17-14B). Others have shown an association between tumor size, axillary lymph node metastases, and disease-free survival. One of the most important predictors of 10- and 20-year survival rates in breast cancer is the number of axillary lymph nodes involved with metastatic disease. Routine biopsy of internal mammary lymph nodes is not generally performed; however, it has been reported that in the context of a “triple node” biopsy approach either the internal mammary node or a low axillary node when positive alone carried the same prognostic weight. When both nodes were positive, the prognosis declined to the level associated with apical node positivity. A double node biopsy of the low axillary node and either the apical or the internal mammary node gave the same maximum prognostic information as a triple node biopsy. With the advent of sentinel lymph node dissection and the use of preoperative lymphoscintigraphy for localization of the sentinel nodes, surgeons have again begun to biopsy the internal mammary nodes but in a more targeted manner. The 8th edition of the AJCC staging system does allow for staging based on findings from the internal mammary sentinel nodes. Drainage to the internal mammary nodes is more frequent with central and medial quadrant cancers. Clinical or pathologic evidence of metastatic spread to supraclavicular lymph nodes is no longer considered stage IV disease, but routine scalene or supraclavicular lymph node biopsy is not indicated.

Biomarkers
Breast cancer biomarkers are of several types. Risk factor biomarkers are those associated with increased cancer risk. These include familial clustering and inherited germline abnormalities, proliferative breast disease with atypia, and mammographic density. Exposure biomarkers are a subset of risk factors that include measures of carcinogen exposure such as DNA adducts. Surrogate endpoint biomarkers are biologic alterations in tissue that occur between cancer initiation and development. These biomarkers are used as endpoints in short-term chemoprevention trials and include histologic changes, indices of proliferation, and genetic alterations leading to cancer. Prognostic biomarkers provide information regarding
### Primary tumor (T)

The T classification of the primary tumor is the same regardless of whether it is based on clinical or pathologic criteria, or both. Size should be measured to the nearest millimeter. If the tumor size is slightly less than or greater than a cutoff for a given T classification, it is recommended that the size be rounded to the millimeter reading that is closest to the cutoff. For example, a reported size of 1.1 mm is reported as 1 mm, or a size of 2.01 cm is reported as 2.0 cm. Designation should be made with the subscript “c” or “p” modifier to indicate whether the T classification was determined by clinical (physical examination or radiologic) or pathologic measurements, respectively. In general, pathologic determination should take precedence over clinical determination of T size.

*Note: Lobular carcinoma in situ (LCIS) is a benign entity and is removed from TNM staging in the AJCC Cancer Staging Manual, 8th edition.

### Regional lymph nodes—Clinical (N)

| cNX* | Regional lymph nodes cannot be assessed (e.g., previously removed) |
| cN0 | No regional lymph node metastases (by imaging or clinical examination) |
| cN1 | Metastases to movable ipsilateral Level I, II axillary lymph node(s) |
| cN1mi** | Micrometastases (approximately 200 cells, larger than 0.2 mm, but none larger than 2.0 mm) |
| cN2 | Metastases in ipsilateral Level I, II axillary lymph nodes that are clinically fixed or matted; or in ipsilateral internal mammary nodes in the absence of axillary lymph node metastases |
| cN2a | Metastases in ipsilateral Level I, II axillary lymph nodes fixed to one another (matted) or to other structures |
| cN2b | Metastases only in ipsilateral internal mammary nodes in the absence of axillary lymph node metastases |
| cN3 | Metastases in ipsilateral infraclavicular (Level III axillary) lymph node(s) with or without Level I, II axillary lymph node involvement; or in ipsilateral internal mammary lymph node(s) with Level I, II axillary lymph node metastases; or metastases in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement |
| cN3a | Metastases in ipsilateral infraclavicular lymph node(s) |
| cN3b | Metastases in ipsilateral infraclavicular lymph node(s) |
| cN3c | Metastases in ipsilateral internal mammary lymph node(s) and axillary lymph node(s) |
| cN3d | Metastases in ipsilateral supraclavicular lymph node(s) |

*Note: (sn) and (f) suffixes should be added to the N category to denote confirmation of metastasis by sentinel node biopsy or fine needle aspiration/core needle biopsy respectively.

*the cNX category is used sparingly in cases where regional lymph nodes have previously been surgically removed or where there is no documentation of physical examination of the axilla.

**cN1mi is rarely used but may be appropriate in cases where sentinel node biopsy is performed before tumor resection, most likely to occur in cases treated with neoadjuvant therapy.

---

Cancer outcome irrespective of therapy, whereas predictive biomarkers provide information regarding response to therapy. Candidate prognostic and predictive biomarkers and biologic targets for breast cancer include (a) the steroid hormone receptor pathway; (b) growth factors and growth factor receptors such as human epidermal growth factor receptor 2 (HER2)/neu, epidermal growth factor receptor (EGFR), transforming growth factor, platelet-derived growth factor, and the insulin-like growth factor family; (c) indices of proliferation such as proliferating cell nuclear antigen (PCNA) and Ki-67; (d) indices of angiogenesis such as vascular endothelial growth factor (VEGF) and the angiogenesis index; (e) the mammalian target of rapamycin (mTOR) signaling pathway; (f) tumor-suppressor genes such as p53; (g) the cell cycle, cyclins, and cyclin-dependent kinases; (h) the proteasome; (i) the COX-2 enzyme; (j) the peroxisome proliferator-activated receptors (PPARs); and (k) indices of apoptosis and apoptosis modulators such as bcl-2 and the bax:bcl-2 ratio.

**Steroid Hormone Receptor Pathway.** Hormones play an important role in the development and progression of breast cancer. Estrogens, estrogen metabolites, and other steroid hormones such as progesterone all have been shown to have an effect. Breast cancer risk is related to estrogen exposure over time. In postmenopausal women, hormone replacement therapy consisting of estrogen plus progesterone increases the risk of breast cancer by 26% compared to placebo. Patients with hormone receptor-positive tumors survive two to three times longer after a diagnosis of metastatic disease than do patients with hormone receptor-negative tumors. Patients with tumors negative for both estrogen receptors and progesterone receptors are not considered candidates for hormonal therapy. Tumors positive

**Notes:**
1. T1 includes T1 mi.
2. T0 and T1 tumors with nodal micrometastases (N1mi) are staged as Stage IB.
3. T2, T3, and T4 tumors with nodal micrometastases (N1mi) are staged using the N1 category.
4. M0 includes M0(i+).
5. The designation pM0 is not valid; any M0 is clinical.
6. If a patient presents with M1 disease prior to neoadjuvant systemic therapy, the stage is Stage IV and remains Stage IV regardless of response to neoadjuvant therapy.
7. Stage designation may be changed if postsurgical imaging studies reveal the presence of distant metastases, provided the studies are performed within 4 months of diagnosis in the absence of disease progression, and provided the patient has not received neoadjuvant therapy.
8. Staging following neoadjuvant therapy is denoted with a “yc” or “yp” prefix to the T and N classification. There is no anatomic stage group assigned if there is a complete pathological response (pCR) to neoadjuvant therapy, for example, ypT0ypN0cM0.

For estrogen or progesterone receptors, a higher response rate to endocrine therapy than tumors that do not express estrogen or progesterone receptors. The determination of estrogen and progesterone receptor status used to require biochemical evaluation of fresh tumor tissue. Today, however, estrogen and progesterone receptor status can be measured in archived tissue using immunohistochemical techniques. Hormone receptor status also can be measured in specimens obtained with fine-needle aspiration biopsy or core-needle biopsy, and this can help guide treatment planning. Testing for estrogen and progesterone receptors should be performed on all primary invasive breast cancer specimens. The tumor hormone receptor status should be ascertained for both premenopausal and postmenopausal patients to identify patients who are most likely to benefit from endocrine therapy.

**Growth Factor Receptors and Growth Factors.** Overexpression of EGFR in breast cancer correlates with estrogen receptor–negative status and with p53 overexpression. Similarly, increased immunohistochemical membrane staining for the HER2 growth factor receptor in breast cancer is associated with mutated TP53, Ki67 overexpression, and estrogen receptor–negative status. HER2 is a member of the ErbB family of growth factor receptors in which ligand binding results in receptor homodimerization and tyrosine phosphorylation by tyrosine kinase domains within the receptor. Tyrosine phosphorylation is followed by signal transduction, which results in changes in cell behavior. An important property of this family of receptors is that ligand binding to one receptor type also may result in heterodimerization between two different receptor types that are coexpressed; this leads to transphosphorylation and transactivation of both receptors in the complex (transmodulation). In this context, the lack of a specific ligand for the HER2/neu receptor suggests that HER2/neu may function solely as a co-receptor, modulating signaling by other EGFR family members. HER2/neu is both an important prognostic factor and a predictive factor in breast cancer. When overexpressed in breast cancer, HER2/neu promotes enhanced growth and proliferation, and increases invasive and metastatic capabilities. Clinical studies have shown that patients with HER2/neu–overexpressing breast cancer have poorly differentiated tumors with high proliferation rates, positive lymph nodes, decreased hormone receptor expression, and an increased risk of recurrence and death due to breast cancer. Routine testing of the primary tumor specimen for HER2/neu expression should be performed on all invasive breast cancers. This can be done with immunohistochemical analysis to evaluate for overexpression of the cell-surface receptor at the protein level or by using fluorescence in situ hybridization to evaluate for gene amplification. While HER2/ERBB2 activation can also be assessed based on mRNA expression and reverse transcription polymerase chain reaction (RT-PCR) (OncoType Dx, Genomic Health), this approach is not recommended for clinical decision-making because of the high false negative rate. Patients whose tumors show HER2 amplification or HER2/neu protein overexpression are candidates for anti-HER2/neu therapy. Trastuzumab (Herceptin) is a recombinant humanized monoclonal antibody directed against HER2. Randomized clinical trials have demonstrated that single-agent trastuzumab therapy is well tolerated and active in the treatment of women with HER2/neu–overexpressing metastatic breast cancer. Subsequent adjuvant trials demonstrated that trastuzumab also was highly effective in the treatment of women with early-stage breast cancer when used in combination with chemotherapy. Patients who received trastuzumab in combination with chemotherapy had between a 40% and 50% reduction in the risk of breast cancer recurrence and approximately a one-third reduction in breast cancer mortality compared with those who received chemotherapy alone.

**Indices of Proliferation.** PCNA is a nuclear protein associated with a DNA polymerase whose expression increases in phase G1 of the cell cycle, reaches its maximum at the G1/S interface, and then decreases through G2. Immunohistochemical staining for PCNA outlines the proliferating compartments in...
breast tissue. Good correlation is noted between PCNA expression and (a) cell-cycle distributions seen on flow cytometry based on DNA content, and (b) uptake of bromodeoxyuridine and the proliferation-associated Ki67 antigen. Individual proliferation markers are associated with slightly different phases of the cell cycle and are not equivalent. PCNA and Ki67 expression are positively correlated with p53 overexpression, high S-phase fraction, aneuploidy, high mitotic index, and high histologic grade in human breast cancer specimens, and are negatively correlated with estrogen receptor content. Ki67 was included with three other widely measured breast cancer markers (ER, PR, and HER2) into a panel of four immunohistochemical makers (IHC4), which together provided similar prognostic information to that in the 21 Gene Recurrence Score (Oncotype DX, Genomic Health). While there has been significant interest in using Ki67 as a biomarker, and while the IHC4 panel would be much less expensive than the 21 Gene Recurrence Score, there remain issues regarding reproducibility across laboratories.

Indices of Angiogenesis. Angiogenesis is necessary for the growth and invasiveness of breast cancer and promotes cancer progression through several different mechanisms, including delivery of oxygen and nutrients and the secretion of growth-promoting cytokines by endothelial cells. VEGF induces its effect by binding to transmembrane tyrosine kinase receptors. Overexpression of VEGF in invasive breast cancer is correlated with increased microvessel density and recurrence in node-negative breast cancer. An angiogenesis index has been developed in which microvessel density (CD31 expression) is combined with expression of thrombospondin (a negative modulator of angiogenesis) and p53 expression. Both VEGF expression and the angiogenesis index may have prognostic and predictive significance in breast cancer. Bevacizumab (a monoclonal antibody to VEGF) was approved by the FDA for use in metastatic breast cancer in combination with paclitaxel chemotherapy. This approval was based on results from a phase 3 trial by the Eastern Cooperative Oncology Group. The group’s E2100 trial showed that when bevacizumab was added to paclitaxel chemotherapy, median progression-free survival increased to 11.3 months from the 5.8 months seen in patients who received paclitaxel alone. The results were not reproduced in other trials, and the indication for the drug was revoked by the FDA in 2011.

Indices of Apoptosis. Alterations in programmed cell death (apoptosis), which may be triggered by p53-dependent or p53-independent factors, may be important prognostic and predictive biomarkers in breast cancer. Bcl-2 family proteins appear to regulate a step in the evolutionarily conserved pathway for apoptosis, with some members functioning as inhibitors of apoptosis and others as promoters of apoptosis. Bcl-2 is the only oncogene that acts by inhibiting apoptosis rather than by directly increasing cellular proliferation. The death-signal protein bax is induced by genotoxic stress and growth factor deprivation in the presence of wild-type (normal) p53 and/or AP-1/fo. The bax to bcl-2 ratio and the resulting formation of either bax-bax homodimers, which stimulate apoptosis, or bax–bcl-2 heterodimers, which inhibit apoptosis, represent an intracellular regulatory mechanism with prognostic and predictive implications. In breast cancer, overexpression of bcl-2 and a decrease in the bax to bcl-2 ratio correlate with high histologic grade, the presence of axillary lymph node metastases, and reduced disease-free and overall survival rates. Similarly, decreased bax expression correlates with axillary lymph node metastases, a poor response to chemotherapy, and decreased overall survival.

The remaining biomarkers and biologic targets listed earlier are still in preclinical testing, and clinical trials are evaluating their importance in breast cancer for both prognostic and predictive purposes.

Coexpression of Biomarkers. Selection of optimal therapy for breast cancer requires both an accurate assessment of prognosis and an accurate prediction of response to therapy. The breast cancer markers that are most important in determining therapy are estrogen receptor, progesterone receptor, and HER2/neu. Clinicians evaluate clinical and pathologic staging and the expression of estrogen receptor, progesterone receptor, and HER2/neu in the primary tumor to assess prognosis and assign therapy. Adjuvant! Online (http://www.adjuvantonline.com) is one of a number of programs available to clinicians that incorporates clinical and pathologic factors for an individual patient and calculates risk of recurrence and death due to breast cancer and then provides an assessment of the reduction in risk of recurrence that would be expected with the use of combination chemotherapy, endocrine therapy, or both of these. Adjuvant! Online was developed using information from the SEER database, the EBCTCG overview analyses, and results from other individual published trials. The website is updated and modified as new information becomes available. Clinicopathologic factors are used to separate breast cancer patients into broad prognostic groups, and treatment decisions are made on this basis (Table 17-12). Other indices and programs that are validated and used include the Nottingham Prognostic Index, and PREDICT. When an approach, which combines prognostic factors is used, up to 70% of early breast cancer patients receive adjuvant chemotherapy that is either unnecessary or ineffective. As described earlier, a wide variety of biomarkers have been shown to individually predict prognosis and response to therapy, but they do not improve the accuracy of either the assessment of prognosis or the prediction of response to therapy.

As knowledge regarding cellular, biochemical, and molecular biomarkers for breast cancer have improved, prognostic indices have developed that combine the predictive power

of several individual biomarkers with the relevant clinicopathologic factors.

Recent technological advances have enabled implementation of high-throughput gene expression assays in clinical practice. These assays enable detailed stratification of breast cancer patients for assessment of prognosis and for prediction of response to therapy. The Oncotype DX is a 21-gene RT-PCR–based assay that has been approved for use in newly diagnosed patients with node-negative, ER-positive breast cancer. A recurrence score is generated, and those patients with high recurrence scores are likely to benefit from chemotherapy, whereas those with low recurrence scores benefit most from endocrine therapy and may not require chemotherapy. Results from the Trial Assessing Individualized Options for Treatment for breast cancer (TAILORx), designed to prospectively validate the use of 21-gene expression assay, have shown that patients with low recurrence score (0 to 10) have a low rate of local-regional and distant recurrence (98.7%) and very good overall survival at 5 years (98%) with endocrine therapy alone without chemotherapy. This study has randomly assigned patients with an intermediate recurrence score (11 to 25) to endocrine therapy alone or to chemotherapy followed by endocrine therapy.

Additionally, retrospective analysis has shown that the 21-gene recurrence score can be used in postmenopausal patients with ER-positive tumors and 1 to 3 involved axillary lymph nodes to predict the benefit of chemotherapy in addition to endocrine therapy. Knowledge of the recurrence score has been shown to alter treatment recommendations by oncologists, and patients likewise change their decision to undergo treatment based on the risk of recurrence. The MammaPrint assay uses a 70-gene expression profile to assess the risk of distant metastasis. MammaPrint is FDA approved for use in stage-1 or stage-2, node negative, ER-positive or ER-negative breast cancers to identify patients with high or low risk of recurrence. Although fresh tissue was initially required to perform the assay, it has since been adapted for use in paraffin-embedded tissue samples. The prospective RASTER study reported that patients classified as low risk based on MammaPrint had a 97% distant recurrence-free interval at five years. Results of the prospective MINDACT (MicroarrayInNode negative and 1–3 positive lymph node Disease may Avoid ChemoTherapy) trial were recently reported. The study was designed to assess whether the 70-gene expression assay would help avoid chemotherapy in patients who are considered clinically high risk but categorized as low genomic risk based on the assay. A 5-year rate of distant metastasis-free survival of more than 92% was identified as the cutoff for the benefit of chemotherapy. At 5 years, the rate of survival without distant metastasis in patients with high clinical risk and low genomic risk was 94.7%, meeting the criteria for noninferiority. However, the rate of disease-free survival and overall survival was higher with chemotherapy in the intention to treat population.

**OVERVIEW OF BREAST CANCER THERAPY**

Before diagnostic biopsy, the surgeon must consider the possibility that a suspicious mass or mammographic finding may be a breast cancer. Once a diagnosis of breast cancer is made, the type of therapy offered to a breast cancer patient is determined by the stage of the disease, the biologic subtype, and the general health status of the individual. Laboratory tests and imaging studies are performed based on the initial stage as presented in Table 17-13. Before therapy is initiated, the patient and the surgeon must share a clear perspective on the planned course of treatment. Before initiating local therapy, the surgeon should determine the clinical stage, histologic characteristics, and appropriate biomarker levels.

### In Situ Breast Cancer (Stage 0)

Both LCIS and DCIS may be difficult to distinguish from atypical hyperplasia or from cancers with early invasion. Expert pathologic review is required in all cases. Bilateral mammography is performed to determine the extent of the in situ cancer and to exclude a second cancer. Because LCIS is considered a marker for increased risk rather than an inevitable precursor of invasive disease, the current treatment options for LCIS include observation, chemoprevention, and bilateral total mastectomy. The goal of treatment is to prevent or detect at an early stage the invasive cancer that subsequently develops in 25% to 35% of these women. There is no benefit to excising LCIS because the disease diffusely involves both breasts in many cases and the risk of developing invasive cancer is equal for both breasts. The use of tamoxifen as a risk-reduction strategy should be considered in women with a diagnosis of LCIS.

Women with DCIS and evidence of extensive disease (>4 cm of disease or disease in more than one quadrant) usually require mastectomy (Fig. 17-29). For women with limited disease, lumpectomy and radiation therapy are generally recommended. For nonpalpable DCIS, needle localization or other image-guided techniques are used to guide the surgical resection. Specimen mammography is performed to ensure that all visible evidence of cancer is excised. Adjuvant tamoxifen therapy is considered for DCIS patients with ER-positive
disease. The gold standard against which breast conservation therapy for DCIS is evaluated is mastectomy. Women treated with mastectomy have local recurrence and mortality rates of <2%. There is no randomized trial comparing mastectomy vs. breast conserving surgery, and none of the randomized trials of breast-conserving surgery with or without radiotherapy for DCIS were powered to show a difference in mortality. Women treated with lumpectomy and adjuvant radiation therapy in the initial clinical trials were noted to have a local recurrence rate that is increased compared to mastectomy. About 45% of these recurrences will be invasive cancer when radiation therapy is not used. The B-17 trial was conducted by the NSABP to assess the need for radiation in patients treated with breast conserving surgery for DCIS. Patients were randomly assigned to lumpectomy with radiation or lumpectomy alone, and after a mean follow-up time of 90 months rates of both ipsilateral noninvasive and invasive recurrences were significantly lower in patients who received radiation. However, in the B-17 trial the margins were not prospectively assessed, and it is estimated that up to half of the patients may have had tumor at the margin of resection. The benefit of the addition of radiation over breast-conserving surgery alone for DCIS has also been demonstrated in several other randomized trials where margins were prospectively assessed including the European Organization for Research and Treatment of Cancer (EORTC) protocol 10853; the United Kingdom, Australia, New Zealand DCIS Trial; and the Swedish Trial.

In 2016, the Society of Surgical Oncology (SSO), American Society for Radiation Oncology (ASTRO), and the American Society of Clinical Oncology (ASCO) established consensus guidelines on margins for patients with DCIS undergoing breast-conserving surgery. Based on a multidisciplinary consensus panel using a meta-analysis of margin width and ipsilateral breast tumor recurrence, a 2-mm margin was determined as adequate width for DCIS for patients undergoing breast-conserving surgery with whole-breast radiation therapy.

Despite the data from randomized trials showing a benefit in all patient subgroups with the addition of radiation in DCIS, there has been an interest in trying to define a subset where radiation could be avoided in order to minimize the cost and inconvenience associated with radiation. In addition, there have been several studies published where patients were treated with excision alone and never developed invasive breast cancer even at 25 years of follow-up. Silverstein and colleagues were proponents of avoiding radiation therapy in selected patients with DCIS who have widely negative margins after surgery. They reported that when greater than 10-mm margins were achieved, there was no additional benefit from radiation therapy. When margins were between 1 and 10 mm, there was a relative risk of local recurrence of 1.49, compared to 2.54 for those with margins less than 1 mm. These data suggested that appropriately selected patients with DCIS might not require postoperative radiation therapy.

The Eastern Cooperative Oncology Group (ECOG) initiated a prospective registry trial (ECOG 5194) to identify those patients who could safely undergo breast-conserving surgery without radiation. Eligible patients were those with low or intermediate grade DCIS measuring 2.5 cm or less who had negative margins of at least 3 mm and those with high-grade DCIS who had tumors measuring 1 cm or less with a negative margin of at least 3 mm. At a median follow-up of 6.2 years, patients with low or intermediate grade DCIS had an in-breast
recurrence rate of 6.1% while those with high-grade DCIS had a recurrence rate of 15.3%. Approximately 4% of patients developed a contralateral breast cancer during follow-up in both the low/intermediate and high-grade groups. This study identified an acceptable recurrence rate for those patients with low or intermediate grade DCIS treated with excision alone with a margin of at least 3 mm. In contrast, patients with high-grade DCIS had an unacceptably high local recurrence rate.

The Radiation Therapy Oncology Group (RTOG) initiated the 9804 trial for patients with “good risk” DCIS and randomized them to lumpectomy vs. lumpectomy with whole breast irradiation. Eligible patients were those with unicentric, low or intermediate grade DCIS measuring 2.5 cm or less with a margin of 3 mm or greater. The trial was closed early due to slow accrual; however, the results for 585 patients were recently reported with a median follow-up of 6.46 years. The local recurrence rate at 5 years was 0.4% for patients randomized to receive radiation and 3.2% for those who did not receive radiation.

Solin et al utilized samples from the ECOG 5194 trial to develop a quantitative multigene RT-PCR assay for predicting recurrence risk in patients with DCIS treated with surgery alone. They were able to define low, intermediate, and high risk groups using a DCIS Score. The DCIS Score was able to quantify the risk of recurrence in the breast for both DCIS and invasive events. This tool has recently been evaluated in another dataset and appears to be a promising tool for clinical use.

When selecting therapy for patients with DCIS, one must consider clinical and pathologic factors, including tumor size, grade, mammographic appearance, and patient preference. There is no single correct surgical treatment, and many patients will require extensive counseling in order to make a decision regarding surgical therapy. The role of axillary staging in patients with DCIS is limited. One consideration is for patients undergoing mastectomy. Since most lesions are currently diagnosed with needle core biopsy, there is about a 20% incidence of invasive breast cancer on final pathologic assessment of the primary tumor. Since it is not feasible to perform sentinel node dissection after mastectomy, most surgeons will recommend the use of sentinel node dissection at the time of mastectomy for DCIS.

Results from the NSABP B-24 trial reported a significant reduction in local recurrence after 5 years of tamoxifen in women with ER-positive DCIS. Based on this finding, some guidelines have advocated that all patients (women with ER-positive DCIS without contraindications to tamoxifen therapy) should be offered tamoxifen following surgery and radiation therapy for a duration of 5 years. The B-24 trial revealed a significant reduction in recurrence with adjuvant tamoxifen therapy for patients with DCIS; however, the results were not initially assessed based on ER status. There were 1804 women with DCIS randomized to lumpectomy and radiation with or without tamoxifen. The rate of breast cancer events was significantly lower in those who received tamoxifen at a median follow-up of 74 months (8.2% vs. 13.4%, P = 0.0009). Subsequently, Alred and colleagues evaluated 41% of patients with DCIS in the NSABP B-24 trial to determine the effect of tamoxifen based on ER status measured in the primary tumor. They found that 76% of women had DCIS that was ER-positive and these women had a greater reduction in ipsilateral breast tumor recurrence with tamoxifen than did patients with ER-negative DCIS (11% vs. 5.2%, P < 0.001). However, it should be noted that 15% of patients in B-24 had tumor at the resection margins. For these patients, tamoxifen could be viewed as treating what, by the current standard, would be viewed as inadequate local excision of the primary tumor.

Early Invasive Breast Cancer (Stage I, IIIA, or IIB)

There have been six prospective randomized trials comparing breast-conserving surgery to mastectomy in early stage breast cancer, and all have shown equivalent survival rates regardless of the surgical treatment type. One caveat, however, is that the majority of studies had a restriction of tumor size; most were either 2 cm or 2.5 cm, while the NSABP B-06 trial was 4 cm, and the NCI trial was up to 5 cm. NSABP B-06, which is the largest of all the breast conservation trials, compared total mastectomy to lumpectomy with or without radiation therapy in the treatment of women with stages I and II breast cancer. After 5- and 8-year follow-up periods, the disease-free (DFS), distant disease-free, and overall survival (OS) rates for lumpectomy with or without radiation therapy were similar to those observed after total mastectomy. However, the incidence of ipsilateral breast cancer recurrence was higher in the group not receiving radiation therapy. These findings supported the use of lumpectomy and radiation therapy in the treatment of stages I and II breast cancer and has since become the preferred method of treatment for women with early stage breast cancer who have unicentric disease and who are not known BRCA mutation carriers. Reanalysis of the B-06 study results was undertaken after 20 years of follow-up and confirmed that there was no difference in disease-free survival rates after total mastectomy or after lumpectomy with or without adjuvant radiation therapy. The in-breast recurrence rate was substantially higher in the lumpectomy alone group (39.2%) compared with the lumpectomy plus adjuvant radiation therapy group (14.3%), confirming the importance of radiation therapy in the management of patients with invasive disease. However, it should be noted that there were several criteria in the B-06 study. There was a specific lymphadenopathy exclusion criteria. Secondly, all patients randomized to breast-conserving surgery had a frozen section, and if the margins were involved, they were converted to mastectomy but were included in the analysis as having had a breast-conserving operation (on the basis of intention to treat). Finally, in the breast-conserving group recurrences in the treated breast were considered as a “nonevent.”

Data from all of the randomized trials where breast conservation was performed with or without radiation therapy have been examined by the EBCTCG. At 15 years of follow-up, the absolute reduction in mortality with the use of radiation therapy after lumpectomy was 5.1% in node-negative patients and 7.1% in node-positive patients. These data support the concept that the addition of radiation not only improves local control but also has an impact on survival. Similar to DCIS, clinicians have sought to identify subgroups of patients who may not benefit from the addition of radiation therapy, particularly older patients who may have a shorter life expectancy due to medical comorbidities. Randomized trials have shown that in selected patients with small, ER-positive, low-grade tumors, lumpectomy alone without radiation therapy may be appropriate. The Cancer and Leukemia Group B (CALGB) C9343 trial enrolled women over the age of 70 with T1N0 breast cancer and randomized them to lumpectomy with or without radiation therapy. All patients received adjuvant tamoxifen.
there were fewer local recurrences with radiation (1% vs. 4%, \(P < 0.001\)), there were no differences in DFS and OS. While long-term follow-up at 10 years showed fewer local recurrences with radiation (2% vs. 10%), there were no significant differences in time to distant metastasis, breast cancer–specific survival, or OS between the two groups. A trial similar to CALGB C9343 was conducted in Canada where they enrolled women age 50 years and older and randomized them to lumpectomy with or without radiation. Mean age was 68 years, and 80% of women had ER-positive tumors. Again, local recurrence rates were lower in women who received radiation (0.6% vs. 7.7%, \(P < 0.001\)); however, at a median follow-up of 5.6 years, there were no differences in DFS or OS. The PRIME-2 study enrolled women age 65 years or older with ER-positive, node-negative, up to 3 cm breast cancers, who had undergone breast-conserving surgery and were candidates for adjuvant endocrine treatment. They were assigned to receive whole-breast irradiation or no treatment. After a median follow-up of 5 years, ipsilateral breast tumor recurrence was 1.3% with radiation vs. 41% in those assigned to no radiotherapy. However, no differences in distant metastases, contralateral breast cancers, or overall survival were noted between the groups.\(^{234}\) These studies suggest that radiation can be avoided in select older patients with ER-positive, early-stage breast cancer.

Accelerated partial breast irradiation (APBI) is also an option for carefully selected patients with DCIS and early-stage breast cancer. Since the majority of recurrences after breast conservation occur in or adjacent to the tumor bed, there has been interest in limiting the radiation to the area of the primary tumor bed with a margin of normal tissue. APBI is delivered in an abbreviated fashion (twice daily for 5 days) and at a lower total dose compared with the standard course of 5 to 6 weeks of radiation (50 Gy with or without a boost) in the case of whole breast irradiation. Proponents have suggested that this shortened course of treatment may increase the feasibility of breast conservation for some women and may improve radiation therapy compliance. The RTOG 04-13/NSABP B-39 trial is a randomized comparison of whole breast irradiation to APBI in women with early stage breast cancer. The trial has completed accrual, and it will likely be several years before data are mature to report outcomes between the two radiation treatment strategies. TARGIT is another study that randomized 3451 patients in 33 centers in over 10 countries to intraoperative breast irradiation (IORT) or external beam radiotherapy (EBRT). The preliminary results were reported in 2012: with a median follow-up of 2.4 years, use of IORT had a recurrence rate of 3.3% vs. 1.3% with EBRT, a 2% increased recurrence risk.\(^{235,236}\) ASTRO developed guidelines for the use of APBI outside of clinical trials based on data reported from published studies.\(^{237,238}\) The ASTRO guidelines describe patients “suitable” for APBI to include women age 60 years or older with a unifocal, T1, ER-positive tumor with no lymphovascular invasion and margins of at least 2 mm. They describe a group where there is uncertainty about the appropriateness of APBI (“cautionary” group) to include patients with invasive lobular histology, a tumor size of 2.1 cm to 3 cm, ER-negative disease, focal lymphovascular invasion, or margins less than 2 mm. Finally, a group felt to be “unsuitable” for APBI includes those with T3 or T4 disease, ER-negative disease, multifocality, multicentricity, extensive LVI, or positive margins.

Currently, mastectomy with axillary staging and breast conserving surgery with axillary staging and radiation therapy are considered equivalent treatments for patients with stages I and II breast cancer. Breast conservation is considered for all patients because of the important cosmetic advantages and equivalent survival outcomes; however, this approach is not advised in women who are known BRCA mutation carriers due to the high lifetime risk for development of additional breast cancers. Relative contraindications to breast conservation therapy include (a) prior radiation therapy to the breast or chest wall, (b) persistently positive surgical margins after reexcision, (c) multicentric disease, and (d) scleroderma or lupus erythematosus.

For most patients with early-stage disease, reconstruction can be performed immediately at the time of mastectomy. Immediate reconstruction allows for skin-sparing, thus optimizing cosmetic outcomes. Skin-sparing mastectomy with immediate reconstruction has been popularized over the past decade as reports of low local-regional failure rates have been reported and reconstructive techniques have advanced. There is a growing interest in the use of nipple-areolar sparing mastectomy with reports suggesting the oncologic safety of this approach in early stage breast cancer. Patients who are planned for postmastectomy radiation therapy may not be ideal candidates for nipple-sparing mastectomy because of the effects of radiation on the preserved nipple. In addition to providing optimal cosmesis from preservation of the skin and/or the nipple-areolar complex, immediate reconstruction allows patients to wake up with a breast mound, which provides some psychological benefit for the patient. Immediate reconstruction is also more economical as both the extirpative and reconstructive surgery are combined in one operation.

Immediate reconstruction can be performed using implants or autologous tissue; tissue flaps commonly used include the transverse rectus abdominis myocutaneous flap, deep inferior epigastric perforator flap, and latissimus dorsi flap (with or without an implant). If postmastectomy radiation therapy is needed, a tissue expander can be placed at the time of mastectomy to save the shape of the breast and reduce the amount of skin replacement needed at the time of definitive reconstruction. The expander can be deflated at the initiation of radiation therapy to allow for irradiation of the chest wall and regional nodal basins. Removal of the tissue expander and definitive reconstruction, usually with autologous tissue, can proceed 6 months to 1 year after completion of radiation therapy.

Axillary lymph node status has traditionally been an important determinant in staging and prognosis for women with early stage breast cancer. Historically, axillary lymph node dissection (ALND) was utilized for axillary staging and regional control by removing involved lymph nodes. Randomized trials evaluating immediate ALND over ALND performed in a delayed fashion once clinically palpable axillary disease became evident have not shown any detriment in survival.\(^{239}\) With increased mammographic screening and detection of smaller, node-negative breast cancers, it became clear that routine use of ALND for axillary staging was not necessary in up to 75% percent of women with operable breast cancer presenting with a negative axilla at the time of screening. Lymphatic mapping and sentinel lymph node (SLN) dissection were initially developed for assessment of patients with clinically node-negative melanoma. Given the changing landscape of newly diagnosed breast cancer patients with a clinically node-negative axilla, surgeons quickly began to explore the utility of SLN dissection as a replacement for ALND in axillary staging.
In the early 1990s, David Krag at the University of Vermont began performing SLN dissection with injection of a radioisotope in the primary tumor site and localizing the SLN node with a handheld gamma probe. He was able to identify a SLN in 18 of 22 patients examined, and the SLN was positive in all 7 patients with positive lymph nodes. Giuliano and colleagues initiated a pilot study in 1991 to examine the use of SLN dissection using blue dye in patients with clinically negative nodes. They reported successful identification of a SLN in 114 (65.5%) of 174 patients, and in 109 (95.6%), the SLN accurately predicted the status of the axillary nodes. These studies along with initial work by Doug Reintgen and Charles Cox at the Moffitt Cancer Center and Umberto Veronesi and his colleagues at the European Institute of Oncology in Milan led the way toward validation of the technique in large single institution and multicenter studies.

Following validation of the technique of SLN dissection for staging of the axilla by multiple centers, randomized trials were initiated in order to determine if SLN dissection could replace ALND in the contemporary management of breast cancer patients. The ALMANAC trial randomized 1031 patients with primary operable breast cancer to SLN dissection vs. standard axillary surgery. The incidence of lymphedema and sensory loss for the SLN group was significantly lower than with the standard axillary treatment. At 12 months, drain usage, length of hospital stay, and time to resumption of normal day-to-day activities after surgery were also statistically significantly lower in the SLN group. The NSABP B-32 trial compared clinically node-negative patients undergoing SLN dissection followed by ALND with patients undergoing SLN dissection with ALND only if a SLN was positive for metastatic disease. A total of 5611 patients were randomized with a SLN identification rate of 97% and a false-negative rate of 9.7%. A total of 26% of these clinically node-negative patients had a positive SLN. Over 60% of patients with positive SLNs had no additional positive lymph nodes within the ALND specimen. The B-32 trial and other randomized trials demonstrated no difference in DFS, OS, and local-regional recurrence rates between patients with negative SLNs who had SLN dissection alone compared with those who underwent ALND. Most important, patients who had SLN dissection alone were found to have decreased morbidity (arm swelling and range of motion) and improved quality of life vs. patients who underwent ALND.

The American College of Surgeons Oncology Group (ACOSOG) initiated the Z0010 and Z0011 trials in order to evaluate the incidence and prognostic significance of occult metastases identified in the bone marrow and SLNs (Z0010) of early-stage clinically node-negative patients and to evaluate the utility of ALND in patients with clinical T1-2, N0 breast cancer with 1 or 2 positive SLNs for patients treated with breast-conserving surgery and whole breast irradiation (WBI) (Z0011). The Z0010 study enrolled 5539 patients with clinical T1-2 breast cancer planned for breast conserving surgery and WBI. Of these patients, 24% proved to have positive SLNs based on standard pathologic assessment, and of the negative SLNs subjected to immunohistochemical staining for cytokeratin, 10.5% proved to have occult metastasis. Of the patients who had bone marrow aspiration, 3.0% had immunohistochemically detected tumor cells in the bone marrow. Although the presence of disease in the bone marrow identified a population at high risk for recurrence, neither immunohistochemical detection of disease in the SLNs or the bone marrow was statistically significant on multivariable analysis with clinicopathologic and treatment factors included. The investigators concluded that routine use of immunohistochemistry to detect occult disease in SLNs is not warranted.

The Z0011 trial was a companion study to Z0010 and was designed to study the role of completion ALND on survival in women with positive SLNs. Patients were not eligible if they received neoadjuvant chemotherapy or neoadjuvant hormonal therapy or if their treatment plan included mastectomy, lumpectomy without radiation, or lumpectomy with APBI. WBI was to be administered using standard tangential fields without specific treatment of the axilla or additional fields targeting other nodal basins. Patients with 1 or 2 positive SLNs were randomized to completion ALND or no further surgery. Adjuvant systemic therapy recommendations were left to the treating clinicians. After median follow-up of 6.3 years, there was no difference between patients randomized to ALND and those randomized to no further surgery (SLN only) in terms of OS (91.9% and 92.5%, respectively; \( P = 0.25 \)) or DFS (82.2% and 83.8%, respectively; \( P = 0.14 \)). The low local regional failure rates and similar survival outcomes were recently reported with 10-year follow-up.

The morbidity of SLN dissection alone vs. SLN dissection with completion ALND has been reported by the ACOSOG investigators. Immediate effects of SLN dissection in the Z0010 trial included wound infection in 1%, axillary seroma in 7.1%, and axillary hematoma in 1.4%. At 6 months following surgery, axillary paresthesias were noted in 8.6% of patients, decreased range of motion in the upper extremity was reported in 3.8%, and 6.9% of patients had a change in the arm circumference of \( >2 \) cm on the ipsilateral side, which was reported as lymphedema. Younger patients were more likely to report paresthesias, whereas increasing age and body mass index were more predictive of lymphedema. When adverse surgical effects were examined in the Z0011 trial, patients undergoing SLN dissection with ALND had more wound infections, seromas, and paresthesias than those women undergoing SLN dissection alone. Lymphedema at 1 year after surgery was reported by 13% in the SLN plus ALND group but only 2% in the SLN dissection alone group. Arm circumference measurements were greater at 1 year in patients undergoing SLN dissection plus ALND, but the difference between study groups was not statistically significant. This supports the results published from the ALMANAC trial.

Prior to the publication of ACOSOG Z0011, completion ALND was standard of care for patients with positive SLNs. Since the reporting of ACOSOG Z0011, the National Comprehensive Cancer Network (NCCN) guidelines now state that there was no OS difference for patients with 1 or 2 positive SLNs treated with breast-conserving surgery who underwent completion ALND vs. those who had no further axillary surgery. In addition, the American Society of Breast Surgeons issued a consensus statement supporting omission of ALND for patients who meet Z0011 criteria. The results of ACOSOG Z0011 have revolutionized management of the axilla and changed practice such that selected patients with axillary metastasis can now avoid ALND if they have clinical and pathologic features similar to those patients enrolled on Z0011. However, there have been some concerns raised about the Z0011 study that include the fact that the study only recruited about half of
the intended patients and that there was no standardization of whether or not patients received irradiation to the low axilla when the radiation oncologist irradiated the breast. These issues have thus far limited the uptake of the results of Z0011 by some centers.

The International Breast Cancer Study Group (IBCSG) 23-01 trial was similar in design to Z0011 but enrolled only patients with micrometastases in the SLNs. Patients with SLN micrometastases were randomized to ALND vs. no further surgery. Unlike Z0011, the 23-01 trial did not exclude patients treated with mastectomy. Approximately 9% of patients randomized to each study arm underwent mastectomy. The investigators published the primary and secondary endpoints of the trial showing no differences in OS or local-regional recurrence between the study arms. However, as with the Z0011 trial, some concerns have been raised regarding the 23-01 study. For example, in the statistics on the primary endpoint, local recurrence included contralateral breast cancer and other tumor types as events. No hypothesis was presented as to why the difference in axillary surgery should impact on either of these events. Including these events therefore reduced the power of the study to show a statistical difference between treatment arms. There is also concern that the study appears underpowered to show a meaningful difference in overall survival.

Most pathology laboratories perform a more detailed analysis of the SLN than is routinely done for axillary nodes recovered from a levels I and II dissection. This can include examining thin sections of the node with step sectioning at multiple levels through the paraffin blocks or performing immunohistochemical staining of the SLN for cytokeratin or a combination of these techniques. The results of ACOSOG Z0010 and NSABP B-32 showed no clinically meaningful difference in survival based on detection of occult metastases in the SLNs using immunohistochemical staining and do not support the routine use in SLN processing. The type of intraoperative assessment of SLNs also varies for different clinicians and pathology laboratories. Some centers prefer to use touch preparation cytologic analysis of the SLNs, whereas others use frozen-section analysis, and the sensitivity and specificity of these assays vary considerably. The GeneSearch Breast Lymph Node Assay is a real-time reverse-transcriptase polymerase chain reaction assay that detects breast tumor cell metastasis in lymph nodes through the identification of the gene expression markers mammaglobin and cytokeratin 19. These markers are present in higher levels in breast tissue and not in nodal tissue (cell type-specific messenger RNA). The GeneSearch breast lymph node assay generates expression data for genes of interest, which are then evaluated against predetermined criteria to provide a qualitative (positive/negative) result. The assay is designed to detect foci that correspond to metastases that are seen with examination by standard hematoxylin and eosin staining and measure >0.2 mm. The GeneSearch assay results have been compared with permanent-section histologic analysis and frozen-section analysis of sentinel nodes in a prospective trial, and the assay was approved by the FDA for the intraoperative assessment of sentinel nodes. When a positive node is identified intraoperatively by touch preparation, frozen-section analysis, or GeneSearch assay, the surgeon can proceed with immediate ALND. With the findings of ACOSOG Z0011 that there is not a survival benefit to the use of ALND in selected patients, many surgeons have abandoned the intraoperative evaluation of SLNs. There are a number of nomograms and predictive models designed to determine which patients with a positive SLN are at risk for harboring additional positive non-SLNs in the axilla. These tools can be helpful in determining the likelihood of additional disease in the axilla and may be used clinically to counsel patients.

In patients who present with axillary lymphadenopathy that is confirmed to be metastatic disease on FNA or core biopsy, SLN dissection is not necessary, and patients can proceed directly to ALND or be considered for preoperative systemic therapy (see “Neoadjuvant [Preoperative] Chemotherapy” under “Nonsurgical Breast Cancer Therapies”). Initially there was controversy about the suitability of SLN dissection in women with larger primary tumors (T3) and those treated with neoadjuvant chemotherapy. The American Society of Clinical Oncology has included SLN dissection is its guidelines as appropriate for axillary staging in these patients. If an SLN cannot be identified, then ALND is generally performed for appropriate staging. However, this is not universally accepted, and there are as yet no randomized studies that have assessed how a patient with a locally advanced cancer at presentation should be treated if SLN dissection reveals no metastases or micrometastases after neoadjuvant therapy.

The ASCO guidelines suggest that adjuvant chemotherapy should be considered for patients with positive lymph nodes, ER-negative disease, HER2-positive disease, Adjuvant! Online mortality greater than 10%, grade 3 node-negative tumors >5 mm, triple-negative tumors, lymphovascular invasion, or estimated distant relapse risk of greater than 15% at 10 years based on the 21 gene recurrence score assay. Adjuvant endocrine therapy is considered for women with hormone receptor-positive cancers, and an aromatase inhibitor is recommended if the patient is postmenopausal. HER2/neu status is determined for all patients with newly diagnosed invasive breast cancer and when positive, should be used to guide systemic therapy recommendations. The FDA approved trastuzumab in November 2006 for use as part of a treatment regimen containing doxorubicin, cyclophosphamide, and paclitaxel for treatment of HER2/neu-positive, node-positive breast cancer. Subsequently, the BCIRG 006 study reported that giving trastuzumab concurrently with docetaxel and carboplatin appeared as effective as giving trastuzumab following an anthracycline containing regimen. In addition to trastuzumab, pertuzumab has also recently been FDA approved for adjuvant use in patients with HER2 amplified breast cancers with high risk of recurrence.

Advanced Local-Regional Breast Cancer (Stage IIIA or IIIB)

Women with stage IIIA and IIIB breast cancer have advanced local-regional breast cancer but have no clinically detected distant metastases (Fig. 17-30). In an effort to provide optimal local-regional disease-free survival as well as distant disease-free survival for these women, surgery is integrated with radiation therapy and chemotherapy (Fig. 17-31). However, it should be noted that these patients have an increased risk of distant metastasis that is often highlighted by radiological evidence when staging PET or CT and bone scans are performed. Thus, the paradigm for small screen detected cancers where cure can be expected in >90% of patients, often by local treatment alone, is not appropriate for patients with locally advanced disease.

Preoperative (also known as neoadjuvant) chemotherapy should be considered in the initial management of patients with
locally advanced stage III breast cancer, especially those with estrogen receptor negative tumors. Chemotherapy is used to maximize distant disease-free survival, whereas radiation therapy is used to maximize local-regional control and disease-free survival.

In selected patients with stage IIIA cancer, preoperative chemotherapy can reduce the size of the primary cancer and permit breast-conserving surgery. Investigators from the MD Anderson Cancer Center reported that low local-regional failure rates could be achieved in selected patients with stage III disease treated with preoperative chemotherapy followed by breast-conserving surgery and radiation. The 5-year actuarial ipsilateral breast tumor recurrence-free survival rates in this study were 95%. They noted that the ipsilateral breast tumor recurrence rates increased when patients had clinical N2 or N3 disease, >2 cm of residual disease in the breast at surgery, a pattern of multifocal residual disease in the breast at surgery, and lymphovascular space invasion in the primary tumor. This study demonstrated that breast-conserving surgery can be used for appropriately selected patients with locally advanced breast cancer who achieve a good response with preoperative chemotherapy. However, the Oxford overview of all randomized studies of neoadjuvant therapy (vs. adjuvant therapy) reported a hazard ratio of 1.5 (i.e., 50% increase) in local recurrence rates.

Figure 17-30. Locally advanced breast cancer. A. Mammography of the right breast reveals a large tumor with enlarged axillary lymph nodes. B. Imaging of the left breast is normal. (Used with permission from Dr. Anne Turnbull, Consultant Radiologist/Director of Breast Screening, Royal Derby Hospital, Derby, UK.)

Figure 17-31. Treatment pathways for stage IIIA and stage IIIB breast cancer.
A meta-analysis reported a hazard ratio of 1.3. These studies included some patients treated with radiation therapy alone without resection of the primary tumor bed, which results in higher local failure rates. These findings are important in view of the previous findings that the avoidance of recurrence in a conserved breast avoids about one breast cancer death over the next 15 years for every four such recurrences avoided. The German Breast Cancer Group recently reported their local recurrence rate in 5535 patients in seven studies. With a median of 46 months (range 1–127) follow-up the local recurrence rates ranged from 7.6% to 19.5% for T1-T4 tumors and from 6.4% to 17.9% for N0-N3 tumors treated with neoadjuvant therapy. For patients with stage IIIA disease who experience minimal response to chemotherapy and for patients with stage IIIB breast cancer, preoperative chemoradiation can decrease the local-regional cancer burden enough to permit subsequent modified radical mastectomy to establish local-regional control. In both stages II A and IIIB disease, surgery is followed by adjuvant radiation therapy. However there is a small percentage of age of patients who experience progression of disease during neoadjuvant therapy, and therefore the surgeon should review patients with the oncologist at regular points during the neoadjuvant regimen.

For selected clinically indolent, ER-positive, locally advanced tumors, primary endocrine therapy may be considered, especially if the patient has other comorbid conditions. A series of 195 patients with ER-positive, locally advanced breast cancer treated by endocrine therapy—median age 69 years, median tumor size 6 cm, median follow-up 61 months—reported a 5-year overall survival of 76%, a breast cancer–specific survival of 86%, and a metastasis-free survival of 77%. The median time to an alternative treatment was 48 months. Given that this was a 20-year series, the number of such patients is small but should be considered when the clinician is discussing treatment options. Results from the ACOSOG Z1031 trial suggest that neoadjuvant endocrine therapy is a good option for tumor downstaging in patients with strongly ER-positive tumors. The preoperative endocrine prognostic index (PEPI score) can be calculated based on pathologic findings from surgery following neoadjuvant endocrine therapy. This can help guide decision-making regarding the need for systemic chemotherapy in this patient population.

### Internal Mammary Lymph Nodes

Metastatic disease to internal mammary lymph nodes may be occult, may be evident on chest radiograph or CT scan, or may present as a painless parasternal mass with or without skin involvement. There is no consensus regarding the need for internal mammary lymph node radiation therapy in women who are at increased risk for occult involvement (cancers involving the medial aspect of the breast, axillary lymph node involvement) but who show no signs of internal mammary lymph node involvement. Systemic chemotherapy and radiation therapy are indicated in the treatment of grossly involved internal mammary lymph nodes.

### Distant Metastases (Stage IV)

Treatment for stage IV breast cancer is not curative but may prolong survival and enhance a woman’s quality of life. Endocrine therapies that are associated with minimal toxicity are preferred to cytotoxic chemotherapy in ER-positive disease. Appropriate candidates for initial endocrine therapy include women with hormone receptor-positive cancers who do not have immediately life threatening disease (or “visceral crisis”). This includes not only women with bone or soft tissue metastases but also women with limited visceral metastases. Symptoms per se (e.g., breathlessness) are not in themselves an indication for chemotherapy. For example, breathlessness due to a pleural effusion can be treated with percutaneous drainage, and if the breathlessness is relieved, the patient should be commenced on endocrine therapy; if the breathlessness is due to lymphangitic spread, then chemotherapy would be the treatment of choice. The same approach should be taken to other symptoms such as pain. Systemic chemotherapy is indicated for women with hormone receptor-negative cancers, “visceral crisis,” and hormone-refractory metastases. Women with stage IV breast cancer may develop anatomically localized problems that will benefit from individualized surgical or radiation treatment, such as brain metastases, pleural effusion, pericardial effusion, biliary obstruction, ureteral obstruction, impending or existing pathologic fracture of a long bone, spinal cord compression, and painful bone or soft tissue metastases. Bisphosphonates or anti-RANKL (receptor activator of nuclear factor kappa-B ligand) agent, denosumab, which may be given in addition to chemotherapy or endocrine therapy, should be considered in women with bone metastases. Whether to perform surgical resection of the local-regional disease in women with stage IV breast cancer has been debated after several reports have suggested that women who undergo resection of the primary tumor have improved survival over those who do not. Khan and associates used the National Cancer Data Base to identify patterns of treatment in women with metastatic breast cancer and found that those who had surgical resection with negative margins had a better prognosis than those women who did not have surgical therapy. Gnerlich et al reported similar findings using the SEER database, and there have been several reports subsequent to this study from single institutions that have confirmed these findings. Some have suggested that the finding of improved survival is due to selection bias and that local therapy should be reserved for palliation of symptoms. A randomized trial through ECOG (E2108) was designed to address this question. The surgical management of patients with stage IV disease should be addressed by obtaining multidisciplinary input and by considering the treatment goals of each individual patient and the patient’s treating physicians.

### Local-Regional Recurrence

Women with local-regional recurrence of breast cancer may be separated into two groups: those who have had mastectomy and those who have had lumpectomy. Women treated previously with mastectomy undergo surgical resection of the local-regional recurrence and appropriate reconstruction. Chemotherapy and antiestrogen therapy are considered, and adjuvant radiation therapy is given if the chest wall has not previously received radiation therapy or if the radiation oncologist feels that given the time from previous treatment there is scope for further radiation therapy, particularly if this is palliative. Women treated previously with a breast-conservation procedure undergo a mastectomy and appropriate reconstruction. Chemotherapy and antiestrogen therapy are considered depending of the hormone receptor status and HER2 status of the tumor.

### Breast Cancer Prognosis

Survival rates for women diagnosed with breast cancer in the United States can be obtained from the SEER Program of the
Surgical Techniques in Breast Cancer Therapy

Excisional Biopsy With Needle Localization

Excisional biopsy implies complete removal of a breast lesion with a margin of normal-appearing breast tissue. In the past, surgeons would obtain prior consent from the patient, allowing mastectomy if the initial biopsy results confirmed cancer. Today it is important to consider the options for local therapy (lumpectomy vs. mastectomy with or without reconstruction) and the need for nodal assessment with SLN dissection. Needle-core biopsy is the preferred diagnostic method, and excisional biopsy should be reserved for those cases in which the needle biopsy results are discordant with the imaging findings or clinical examination (Fig. 17-32). In general, circumareolar incisions can be used to access lesions that are subareolar or within a short distance of the nipple-areolar complex. Elsewhere in the breast, incisions can be placed along the lines of tension in the skin that are generally concentric with the nipple-areola complex. In the lower half of the breast, the use of radial incisions typically provides the best outcome. When the tumor is quite distant from the central breast, the biopsy incision can be excised separately from the primary mastectomy incision, should a mastectomy be required. Radial incisions in the upper half of the breast are not recommended because of possible scar contracture resulting in displacement of the ipsilateral nipple-areola complex. Similarly, curvilinear incisions in the lower half of the breast may displace the nipple-areolar complex downward.

After excision of a suspicious breast lesion, the specimen should be x-rayed to confirm that the lesion has been excised with appropriate margins. The biopsy tissue specimen is oriented for the pathologist using sutures, clips, or dyes. Additional margins (superior, inferior, medial, lateral, superficial, and deep) may be taken from the surgical bed if the specimen x-ray shows the lesion is close to one or more margins. Some surgeons also take additional shavings from the margins as one approach to confirm complete excision of the suspicious lesion. Electrocautery or absorbable ligatures are used to achieve wound hemostasis. Cosmesis may be facilitated by approximation of the surgical defect using 3-0 absorbable sutures. A running subcuticular closure of the skin using 4-0 or 5-0 absorbable monofilament sutures is performed. Wound drainage is usually not required.

Excisional biopsy with needle or seed localization requires a preoperative visit to the mammography suite for placement of a localization wire or a radioactive or magnetic seed that can be detected intraoperatively with a handheld probe. The lesion can also be targeted by sonography in the imaging suite or in the operating room. The lesion to be excised is accurately localized by mammography, and the tip of a thin wire hook or a seed is positioned close to the lesion (Fig. 17-33). Using the wire hook as a guide, or detection of the seed with a handheld probe, the surgeon subsequently excises the suspicious breast lesion while removing a margin of normal-appearing breast tissue. Before the patient leaves the operating room, specimen radiography is performed to confirm complete excision of the suspicious lesion (Fig. 17-34).

Sentinel Lymph Node Dissection

Sentinel lymph node (SLN) dissection is primarily used to assess the regional lymph nodes in women with early breast cancers who are clinically node-negative by physical examination and imaging studies.²⁷¹-²⁷⁹ This method also is accurate in women with larger tumors (T3 N0), but nearly 75% of these women will prove to have axillary lymph node metastases on histologic examination, and wherever possible it is better to identify them preoperatively as this will allow a definitive procedure for known axillary disease. SLN dissection has also been reported to be accurate for staging of the axilla after chemotherapy in women with clinically node-negative disease at initial presentation.²⁸⁰,²⁸¹ Tan et al in a review and meta-analysis of 449 cases of SLN biopsy in clinically lymph node-negative disease reported a sensitivity of 93%, giving a false negative rate of 7% with a negative predictive value of 94% and an overall accuracy of 95%.²⁸² Clinical situations where SLN dissection is not recommended include patients with inflammatory breast cancers, those with biopsy proven metastasis, DCIS without mastectomy, or prior axillary surgery. Although limited data are available, SLN dissection appears to be safe in pregnancy when performed with radioisotope alone.

Evidence from large prospective studies suggests that the combination of intraoperative gamma probe detection of radioactive colloid and intraoperative visualization of blue dye (isosulfan blue dye or methylene blue) is more accurate for identification of SLNs than the use of either agent alone. Some surgeons use preoperative lymphoscintigraphy, although it is not required for identification of the SLNs. On the day before surgery, or the day of surgery, the radioactive colloid is injected either in the breast parenchyma around the primary tumor or prior biopsy site, into the subareolar region, or subdermally in proximity to the primary tumor site. With a 25-gauge needle, 0.5 mCi of 0.2-μm technetium 99m-labeled sulfur colloid is injected for same-day surgery, or a higher dose of 2.5 mCi of technetium-labeled sulfur colloid is administered when the isotope is to be injected on the day before surgery. Subdermal injections are given in proximity to the cancer site or in the subareolar location. Later, in the operating room, 3 to 5 mL of blue dye is injected either in the breast parenchyma or in the subareolar location. It is not recommended that the blue dye be used in a subdermal injection because this can result in tattooing of the skin (isosulfan blue dye) or skin necrosis (methylene blue). For nonpalpable cancers, the injection of the technetium-labeled sulfur colloid solution can be guided by ultrasound or by mammographic guidance. In women who have undergone previous excisional biopsy, the injections are made in the breast parenchyma around the biopsy cavity but not into the cavity itself. Women are told preoperatively that the isosulfan blue dye injection will cause a change in the color of their urine and that there is a very small risk of allergic reaction to the dye (1 in 10,000). Anaphylactic reactions have been documented, and some groups administer a regimen of antihistamine, steroids, and a histamine H-2 receptor antagonist preoperatively as a prophylactic regimen to prevent allergic reactions. The use of radioactive colloid is safe, and radiation exposure is very low. Sentinel node dissection can be performed in pregnancy with the radioactive colloid without the use of blue dye.

A hand-held gamma counter is used to transcutaneously identify the location of the SLN. This can help to guide placement of the incision. A 3- to 4-cm incision is made in line with that used for an axillary dissection, which is a curved transverse incision in the lower axilla just below the hairline. After dissecting through the subcutaneous tissue, the surgeon dissects through the axillary fascia, being mindful to identify blue lymphatic channels. Following these channels can lead directly to the SLN and limit the amount of dissection through the axillary tissues. The gamma probe is used to facilitate the dissection and to pinpoint the location of the SLN. As the dissection continues, the signal from the probe increases in intensity as the SLN is approached. The SLN also is identified by visualization of blue dye in the afferent lymph vessel and in the lymph node itself.

Before the SLN is removed, a 10-second in vivo radioactivity count is obtained. After removal of the SLN, a 10-second ex vivo radioactive count is obtained, and the node is then sent to the pathology laboratory for either permanent- or frozen-section analysis. The lowest false-negative rates for SLN dissection have been obtained when all blue lymph nodes and all lymph nodes with counts >10% of the 10-second ex vivo count of the SLN are harvested (“10% rule”). Based on this, the gamma counter is used before closing the axillary wound to measure residual radioactivity in the surgical bed. A search is made for additional SLNs if the counts remain high. This procedure is repeated until residual radioactivity in the surgical bed is less than 10% of the 10-second ex vivo count of the most radioactive SLN and all blue nodes have been removed. Studies have demonstrated that 98% of all positive SLNs will be recovered with the removal of four SLNs; therefore, it is not necessary to remove greater than four SLNs for accurate staging of the axilla.

Results from the NSABP B-32 trial showed that the false-negative rate for SLN dissection is influenced by tumor location, type of diagnostic biopsy, and number of SLNs removed at surgery.²⁴³ The authors reported that tumors located in the lateral breast were more likely to have a false-negative SLN. This may be explained by difficulty in discriminating the hot spot in the axilla when the radioisotope has been injected at the primary tumor site in the lateral breast. Those patients who had undergone an excisional biopsy before the SLN procedure were significantly more likely to have a false-negative SLN. This report further confirms that surgeons should use needle biopsy for diagnosis whenever possible and reserve excisional biopsy for the rare situations in which needle biopsy findings are non-diagnostic or discordant. Finally, removal of a larger number of SLNs at surgery appears to reduce the false-negative rate. In B-32, the false-negative rate was reduced from 17.7% to 10% when two SLNs were recovered and to 6.9% when three SLNs were removed. Yi and associates reported that the number of SLNs that need to be removed for accurate staging is influenced by individual patient and primary tumor factors.²⁸³

In the B-32 trial, SLNs were identified outside the levels I and II axillary nodes in 1.4% of cases. This was significantly influenced by the site of radioisotope injection. When a subareolar or periareolar injection site was used, there were no instances of SLNs identified outside the level I or II axilla, compared with a rate of 20% when a peritumoral injection was used. This supports the overall concept that the SLN is the first site of drainage from the lymphatic vessels of the primary tumor. Although many patients will have similar drainage patterns from injections given at the primary tumor site and at the subareolar plexus, some patients will have extra-axillary drainage, either alone or in combination with axillary node drainage, and this is best assessed with a peritumoral injection of the radioisotope. Kong et al reported that internal mammary node drainage on preoperative lymphoscintigraphy was associated with
worse distant disease-free survival in early-stage breast cancer patients.284

Breast Conservation

Breast conservation involves resection of the primary breast cancer with a margin of normal-appearing breast tissue, adjuvant radiation therapy, and assessment of regional lymph node status.285,286 Resection of the primary breast cancer is alternatively called segmental mastectomy, lumpectomy, partial mastectomy, wide local excision, and takedown. For many women with stage I or II breast cancer, breast-conserving therapy (BCT) is preferable to total mastectomy because BCT produces survival rates equivalent to those after total mastectomy while preserving the breast.287 Six prospective randomized trials have shown that overall and disease-free survival rates are similar with BCT and mastectomy; however, three of the studies showed higher local-regional failure rates in patients undergoing BCT. In two of these studies, there were no clear criteria for histologically negative margins.285,287 Data from the EBCTCG meta-analysis revealed that the addition of radiation reduces recurrence by half and improves survival at year 15 by about a sixth.288 When all of this information is taken together, BCT is considered to be oncologically equivalent to mastectomy.

In addition to being equivalent to mastectomy in terms of oncologic safety, BCT appears to offer advantages over mastectomy with regard to quality of life and aesthetic outcomes. BCT allows for preservation of breast shape and skin as well as preservation of sensation, and it provides an overall psychologic advantage associated with breast preservation.

Breast conservation surgery is currently the standard treatment for women with stage 0, I, or II invasive breast cancer. Women with DCIS require only resection of the primary cancer and adjuvant radiation therapy without assessment of regional lymph nodes. When a lumpectomy is performed, a curvilinear incision lying concentric to the nipple-areola complex is made in the skin overlying the breast cancer when the tumor is in the upper aspect of the breast. Radial incisions are preferred when the tumor is in the lower aspect of the breast. Skin excision is not necessary unless there is direct involvement of the overlying skin by the primary tumor. The breast cancer is removed with an envelope of normal-appearing breast tissue that is adequate to achieve a cancer-free margin. Significant controversy has existed on the appropriate margin width for BCT.267 However, recently the SSO and ASTRO developed a consensus statement, supported by data from a systematic review data, encouraging “no tumor on ink” to be the standard definition of a negative margin for invasive stages I and II breast cancer in patients who undergo breast conserving surgery with whole-breast irradiation. The meta-analysis found that increasing the margin width does not affect local recurrence rates as long as the inked or transected margin is microscopically negative.267,268 Specimen X-ray should routinely be performed to confirm the lesion has been excised. Specimen orientation is performed by the surgeon. Additional margins from the surgical bed are taken as needed to provide a histologically negative margin. Requests for determination of ER, PR, and HER2 status are conveyed to the pathologist.

It is the surgeon’s responsibility to ensure complete removal of cancer in the breast. Ensuring surgical margins that are free of breast cancer will minimize the chances of local recurrence and will enhance cure rates. If negative margins are not obtainable with reexcision, mastectomy is required. SLN is performed before removal of the primary breast tumor. When indicated, intraoperative assessment of the sentinel node can proceed while the segmental mastectomy is being performed.

The use of oncoplastic surgery can be entertained at the time of segmental mastectomy or at a later time to improve the overall aesthetic outcome. The use of oncoplastic techniques range from a simple reshaping of breast tissue to local tissue rearrangement to the use of pedicled flaps or breast reduction techniques. The overall goal is to achieve the best possible aesthetic result. In determining which patients are candidates for oncoplastic breast surgery, several factors should be considered, including the extent of the resection of breast tissue necessary to achieve negative margins, the location of the primary tumor within the breast, and the size of the patient’s breast and body habitus. Oncoplastic techniques are of prime consideration when (a) a significant area of breast skin will need to be resected with the specimen to achieve negative margins; (b) a large volume of breast parenchyma will be resected resulting in a significant defect; (c) the tumor is located between the nipple and the inframammary fold, an area often associated with unfavorable cosmetic outcomes; or (d) excision of the tumor and closure of the breast may result in malpositioning of the nipple.

Mastectomy and Axillary Dissection

A skin-sparing mastectomy removes all breast tissue, the nipple-areola complex, and scars from any prior biopsy procedures.293,294 There is a recurrence rate of less than 6% to 8%, comparable to the long-term recurrence rates reported with standard mastectomy, when skin-sparing mastectomy is used for patients with Tis to T3 cancers. A total (simple) mastectomy without skin sparing removes all breast tissue, the nipple-areola complex, and skin. An extended simple mastectomy removes all breast tissue, the nipple-areola complex, skin, and the level I axillary lymph nodes. A modified radical (“Patey”) mastectomy removes all breast tissue, the nipple-areola complex, skin, and the levels I, II, and III axillary lymph nodes; the pectoralis major that was divided and removed by Patey may be simply divided, giving improved access to level III nodes, and then left in situ, or occasionally the axillary clearance can be performed without dividing pectoralis minor. The Halsted radical mastectomy removes all breast tissue and skin, the nipple-areola complex, the pectoralis major and pectoralis minor muscles, and the levels I, II, and III axillary lymph nodes. The use of systemic chemotherapy and hormonal therapy as well as adjuvant radiation therapy for breast cancer have nearly eliminated the need for the radical mastectomy.

Nipple-areolar sparing mastectomy has been popularized over the last decade especially for risk-reducing mastectomy in high risk women. For those patients with a cancer diagnosis, many consider the following factors for eligibility: tumor located more than 2 to 3 cm from the border of the areola, smaller breast size, minimal ptosis, no prior breast surgeries with periareolar incisions, body mass index less than 40 kg/m², no active tobacco use, no prior breast irradiation, and no evidence of collagen vascular disease.

For a variety of biologic, economic, and psychosocial reasons, some women desire mastectomy rather than breast conservation. Women who are less concerned about cosmesis may view mastectomy as the most expeditious and desirable therapeutic option because it avoids the cost and inconvenience of radiation therapy. Some women whose primary breast cancers cannot be excised with a reasonable cosmetic result or those who have extensive microcalcifications are best treated with
mastectomy. Similarly, women with large cancers that occupy the subareolar and central portions of the breast and women with multicentric primary cancers also undergo mastectomy.

**Modified Radical Mastectomy**

A modified radical mastectomy preserves the pectoralis major muscle with removal of levels I, II, and III (apical) axillary lymph nodes. The operation was first described by David Patey, a surgeon at St Bartholomew’s Hospital London, who reported a series of cases where he had removed the pectoralis minor muscle allowing complete dissection of the level III axillary lymph nodes while preserving the pectoralis major and the lateral pectoral nerve. A modified radical mastectomy permits preservation of the medial (anterior thoracic) pectoral nerve, which courses in the lateral neurovascular bundle of the axilla and usually penetrates the pectoralis minor to supply the lateral border of the pectoralis major. Anatomic boundaries of the modified radical mastectomy are the anterior margin of the latissimus dorsi muscle laterally, the midline of the sternum medially, the subclavius muscle superiorly, and the caudal extension of the breast 2 to 3 cm inferior to the inframammary fold inferiorly. Skin-flap thickness varies with body habitus but ideally is 7 to 8 mm inclusive of skin and telasubcutanea (Fig. 17-35). Once the skin flaps are fully developed, the fascia of the pectoralis major muscle and the overlying breast tissue are elevated off the underlying musculature, which allows for the complete removal of the breast (Fig. 17-36).

Subsequently, an axillary lymph node dissection is performed. The most lateral extent of the axillary vein is identified, and the areolar tissue of the lateral axillary space is elevated as the vein is cleared on its anterior and inferior surfaces. The areolar tissues at the junction of the axillary vein and the anterior edge of the latissimus dorsi muscle, which include the lateral and subscapular lymph node groups (level I), are cleared. Care is taken to preserve the thoracodorsal neurovascular bundle. The dissection then continues medially with clearance of the central axillary lymph node group (level II). The long thoracic nerve of Bell is identified and preserved as it travels in the investing fascia of the serratus anterior muscle. Every effort is made to preserve this nerve because permanent disability with a winged scapula and shoulder weakness will follow denervation of the serratus anterior muscle. Patey divided the pectoralis minor and removed it to allow access right up to the apex of the axilla. The pectoralis minor muscle is usually divided at the tendinous portion near its insertion onto the coracoid process (Fig. 17-37 inset), which allows dissection of the axillary vein medially to the costoclavicular (Halsted’s) ligament. Finally, the breast and axillary contents are removed from the surgical bed and are sent for pathologic assessment. In his modified radical mastectomy, Patey removed the pectoralis minor muscle. Many surgeons now divide only the tendon of the pectoralis minor muscle at its insertion onto the coracoid process while leaving the rest of the muscle intact, which still provides good access to the apex of the axilla.

![Figure 17-36. Modified radical mastectomy after resection of breast tissue. The pectoralis major muscle is cleared of its fascia as the overlying breast is elevated. The latissimus dorsi muscle is the lateral boundary of the dissection. (Visual Art: © 2013. The University of Texas MD Anderson Cancer Center.)](image)
Seromas beneath the skin flaps or in the axilla represent the most frequent complication of mastectomy and axillary lymph node dissection, reportedly occurring in as many as 30% of cases. The use of closed-system suction drainage reduces the incidence of this complication. Catheters are retained in the wound until drainage diminishes to <30 mL per day. Wound infections occur infrequently after a mastectomy, and the majority are a result of skin-flap necrosis. Cultures of specimens taken from the infected wound for aerobic and anaerobic organisms, debridement, and antibiotic therapy are effective management. Moderate or severe hemorrhage in the postoperative period is rare and is best managed with early wound exploration for control of hemorrhage and reestablishment of closed-system suction drainage. The incidence of functionally significant lymphedema after a modified radical mastectomy is approximately 20% but can be as high as 50% to 60% when postoperative radiation is employed. Extensive axillary lymph node dissection, the delivery of radiation therapy, the presence of pathologic lymph nodes, and obesity are predisposing factors. Patients should be referred to physical therapy at the earliest signs of lymphedema to prevent progression to the later stages. The use of individually fitted compressive sleeves and complex decongestive therapy may be necessary.

Reconstruction of the Breast and Chest Wall

The goals of reconstructive surgery after a mastectomy for breast cancer are wound closure and breast reconstruction, which is either immediate or delayed. In most cases, wound closure after mastectomy is accomplished with simple approximation of the wound edges. However, if a more radical removal of skin and subcutaneous tissue is necessary, a pedicled myocutaneous flap from the latissimus dorsi muscle is generally the best approach for wound coverage. A skin graft provides functional coverage that will tolerate adjuvant radiation therapy; however, this is not preferred because poor graft adherence may delay delivery of radiation therapy. Breast reconstruction after risk-reducing mastectomy or after mastectomy for early-stage breast cancer may be performed at the same time as the mastectomy. This allows for a skin-sparing mastectomy to be performed, which offers the best overall cosmetic outcomes. Reconstruction can proceed with an expander/implant reconstruction or with autologous tissue such as a pedicled myocutaneous flap or a free flap using microvascular techniques. In patients with locally advanced breast cancer, reconstruction is often delayed until after completion of adjuvant radiation therapy to ensure that local-regional control of disease is obtained. The expected use of postmastectomy radiotherapy should also be considered as a reason for delayed reconstruction as radiotherapy to a reconstructed breast has been reported to result in inferior cosmetic outcomes. Consideration can be made for placement of a tissue expander to allow for skin-sparing, but this should be discussed with the radiation oncologist and other members of the treatment team. If chest wall coverage is needed to replace a large skin or soft tissue defect, many different types of myocutaneous flaps are employed, but the latissimus dorsi and the rectus abdominis myocutaneous flaps are most frequently used. The latissimus dorsi myocutaneous flap consists of a skin paddle based on the underlying latissimus dorsi muscle, which
is supplied by the thoracodorsal artery with contributions from the posterior intercostal arteries. A transverse rectus abdominis myocutaneous (TRAM) flap consists of a skin paddle based on the underlying rectus abdominis muscle, which is supplied by vessels from the deep inferior epigastric artery. The free TRAM flap uses microvascular anastomoses to establish blood supply to the flap. When the bony chest wall is involved with cancer, resection of a portion of the bony chest wall is indicated. If only one or two ribs are resected and soft tissue coverage is provided, reconstruction of the bony defect is usually not necessary because scar tissue will stabilize the chest wall. If more than two ribs are sacrificed, it is advisable to stabilize the chest wall with prosthetic material, which is then covered with soft tissue by using a latissimus dorsi or TRAM flap.

NONSURGICAL BREAST CANCER THERAPIES

Radiation Therapy

Radiation therapy is used for all stages of breast cancer depending on whether the patient is undergoing BCT or mastectomy. Adjunct radiation for patients with DCIS and early-stage breast cancer have been described previously in this chapter. Those women treated with mastectomy who have cancer at the surgical margins are at sufficiently high risk for local recurrence to warrant the use of adjuvant radiation therapy to the chest wall postoperatively. Women with metastatic disease involving four or more axillary lymph nodes and premenopausal women with metastatic disease involving one to three lymph nodes also are at increased risk for recurrence and are candidates for the use of chest wall and supraclavicular lymph node radiation therapy. In advanced local-regional breast cancer (stage IIIA or IIIB), women are at high risk for recurrent disease after surgical therapy, and adjuvant radiation therapy is used to reduce the risk of recurrence. Current recommendations for stages IIIA and IIIB breast cancer are (a) adjuvant radiation therapy to the breast and supraclavicular lymph nodes after neoadjuvant chemotherapy and segmental mastectomy with or without axillary lymph node dissection, (b) adjuvant radiation therapy to the chest wall and supraclavicular lymph nodes after neoadjuvant chemotherapy and mastectomy with or without axillary lymph node dissection, and (c) adjuvant radiation therapy to the chest wall and supraclavicular lymph nodes after segmental mastectomy or mastectomy with axillary lymph node dissection and adjuvant chemotherapy. Data from the EBCCTCG has shown improvements in local-regional control and survival in patients treated with mastectomy and postmastectomy radiation therapy for one to three positive axillary lymph nodes. This data is based on clinical trials from the era of axillary lymph node dissection for staging prior to the routine use of sentinel lymph node dissection. It is likely that the volume of disease in the earlier trials was greater overall than what is currently seen in patients who have small volume metastases detected at sentinel node dissection. It is important to include all multidisciplinary team members (medical oncology, plastic surgery, radiation oncology, and surgical oncology) regarding the risks and benefits of postmastectomy radiation therapy in patients with one to three positive nodes.

The use of partial breast irradiation (APBI) for patients treated with breast-conserving surgery has also been previously described. APBI can be delivered via brachytherapy, external beam radiation therapy using 3D conformal radiation, or intensity-modulated radiation therapy. Although initial results are promising in highly selected low-risk populations, use of APBI should be based on current guidelines or offered in the setting of a prospective trial.

Chemotherapy Adjuvant

Chemotherapy. The Early Breast Cancer Trialists’ Collaborative Group overview analysis of adjuvant chemotherapy demonstrated reductions in the odds of recurrence and death in women ≤70 years of age with stage I, IIA, or IIB breast cancer. For those ≥70 years of age, the lack of definitive clinical trial data regarding adjuvant chemotherapy prevented definitive recommendations. Adjuvant chemotherapy is of minimal benefit to women with negative nodes and cancers ≥0.5 cm in size and is not recommended. Women with negative nodes and cancers 0.6 to 1.0 cm are divided into those with a low risk of recurrence and those with unfavorable prognostic features that portend a higher risk of recurrence and a need for adjuvant chemotherapy. Adverse prognostic factors include blood vessel or lymph vessel invasion, high nuclear grade, high histologic grade, HER2/neu overexpression, and negative hormone receptor status. American Society of Clinical Oncology guidelines suggest that adjuvant chemotherapy should be considered for patients with positive lymph nodes, HER2-positive disease, Adjuvant! Online mortality greater than 10%, grade 3 lymph node negative tumors >5 mm, triple-negative tumors, lympho-vascular invasion, or estimated distant relapse risk of greater than 15% at 10 years based on 21 gene recurrence score. Adjuvant chemotherapy is recommended by the NCCN for women with unfavorable prognostic features. Table 17-14 lists the frequently used chemotherapy regimens for breast cancer. For women with hormone receptor-negative cancers that are >1 cm in size, adjuvant chemotherapy is appropriate.

However, women with node-negative hormone receptor–positive cancers and T1 tumors are candidates for antiestrogen therapy with or without chemotherapy. Assessment of overall risk using known prognostic factors or additional testing such as the 21-gene recurrence score assay can help to guide decision making regarding chemotherapy in patients with node-negative, ER-positive breast cancer. For special-type cancers (tubular, mucinous, medullary, etc), which are usually strongly estrogen receptor positive, adjuvant antiestrogen therapy should be advised for cancers >1 cm. For women with node-positive tumors or with a special-type cancer that is >3 cm, the use of chemotherapy is appropriate; those with hormone receptor–positive tumors should receive antiestrogen therapy.

For stage IIIA breast cancer, preoperative chemotherapy with an anthracycline and taxane-containing regimen followed by either a modified radical mastectomy or segmental mastectomy with axillary dissection followed by adjuvant radiation therapy should be considered, especially for estrogen receptor negative disease. While the same regimen may be considered for estrogen receptor positive disease, it is known that these tumors respond less well to chemotherapy with <10% pCR rate overall and <3% pCR rate for lobular cancers. Other options such as neoadjuvant endocrine therapy followed by local-regional treatment or in some cases primary endocrine therapy may be considered depending on other tumor characteristics and the patient’s comorbid conditions and preference.

Neoadjuvant (Preoperative) Chemotherapy. In the early 1970s, the National Cancer Institute in Milan, Italy, initiated two prospective randomized multimodality clinical trials for women with T3 or T4 breast cancer.310 The best results were achieved when surgery was interposed between chemotherapy courses, with 82% local-regional control and 25% having a 5-year disease-free survival. The NSABP B-18 trial evaluated the role of neoadjuvant chemotherapy in women with operable stages II and III breast cancer.296 Women entered into this study were randomly assigned to receive either surgery followed by chemotherapy or neoadjuvant chemotherapy followed by surgery. There was no difference in the 5-year disease-free survival rates for the two groups, but after neoadjuvant chemotherapy there was an increase in the number of lumpectomies performed and a decreased incidence of node positivity. It was suggested that neoadjuvant chemotherapy be considered for the initial management of breast cancers judged too large for initial lumpectomy.

Several prospective clinical trials have evaluated the neoadjuvant approach, and two meta-analyses have been performed, each showing that neoadjuvant vs. adjuvant chemotherapy are equivalent in terms of OS.262,311 These analyses also evaluated local-regional recurrence (LRR) and found that there was an increase in LRR rates for patients receiving neoadjuvant chemotherapy when radiation therapy was used alone without surgery after completion of chemotherapy. Mittendorf and colleagues evaluated a contemporary series of almost 3000 patients treated with breast conserving surgery and radiation therapy who received either neoadjuvant or adjuvant chemotherapy for breast cancer.312 They found that the risk of LRR was driven by biologic factors and disease stage and was not impacted by the timing of chemotherapy delivery. These data highlight the importance of the multidisciplinary management of patients with breast cancer in achieving the best outcomes.

The use of neoadjuvant chemotherapy offers the opportunity to observe the response of the intact primary tumor and any regional nodal metastases to a specific chemotherapy regimen.279 For patients whose tumors remain stable in size or even progress with the initial neoadjuvant chemotherapy regimen, a new regimen may be considered that uses another class of agents, although there is no randomized data confirming this will improve outcome.

After treatment with neoadjuvant chemotherapy, patients are assessed for clinical and pathologic response to the regimen. Patients whose tumors achieve a pathologic complete response to neoadjuvant chemotherapy have been shown to have statistically improved survival outcomes to those of patients whose tumors demonstrate only a partial response, remain stable, or progress on treatment. Researchers at MD Anderson Cancer Center have shown that residual cancer burden (RCB)—categorized into four classes, RCB-0 or pathologic complete response, RCB-1, RCB-2, and RCB-3—is predictive of 10-year relapse-free survival with neoadjuvant chemotherapy in triple negative, ER-positive, and HER2-positive tumors.313 Patients who experience progression of disease during neoadjuvant chemotherapy have the poorest survival.314,315 This means that while patients who achieve a pCR will have a better prognosis based on their response to neoadjuvant chemotherapy. Equally other patients will have a poorer prognosis compared to when they started neoadjuvant therapy based on the nonresponse to treatment. Consequently, the FDA has supported the use of the neoadjuvant platform and pathologic response rates as an endpoint for mechanism of accelerated approval for new agents in high risk early stage breast cancer, though the short-term endpoints (i.e., pCR) have not been shown to correlate with long-term outcomes (i.e., disease free survival and overall survival).

Current NCCN recommendations for treatment of operable advanced local-regional breast cancer are neoadjuvant chemotherapy with an anthracycline-containing or taxane-containing regimen or both, followed by mastectomy or lumpectomy with axillary lymph node dissection if necessary, followed by adjuvant radiation therapy. For patients with HER2-positive breast cancer, trastuzumab and pertuzumab can be combined with chemotherapy in the preoperative setting to increase pathologic complete response rates. For inoperable stage IIIA and for stage IIIB breast cancer, neoadjuvant chemotherapy is used to decrease the local-regional cancer burden. This may then permit subsequent modified radical or radical mastectomy, which is followed by adjuvant radiation therapy.

Nodal Evaluation in Patients Receiving Neoadjuvant Chemotherapy. The management of the axilla after neoadjuvant chemotherapy has not been specifically addressed in randomized trials. Standard practice has been to perform an axillary lymph node dissection after chemotherapy or to perform a sentinel lymph node dissection before chemotherapy for nodal staging before chemotherapy is initiated. A number of small single-institution studies, one multicenter study, and a recent meta-analysis have explored the use of SLN dissection at the completion of chemotherapy. The published results from these studies have demonstrated the feasibility of SLN dissection in breast cancer patients after neoadjuvant chemotherapy. A review of 14 studies with 818 patients showed a false negative rate of 11% with an overall accuracy of 94%.280,281,316 While SLN dissection has been accepted for assessment of the axilla in the clinically node-negative axilla after neoadjuvant chemotherapy, clinicians have been slower to adopt this approach for axillary staging after chemotherapy in patients who started with initial node-positive disease. Several clinical
trials have been performed to evaluate the accuracy of SLN dissection in patients with documented axillary metastases at initial presentation, including ACOSOG Z1071, SENTINA, and SN FNAC. ACOSOG Z1071 (Alliance) analyzed women with clinical T0–T4, N1–N2, M0 breast cancer who underwent both SLN surgery and axillary lymph node dissection (ALND).317 The primary endpoint was the false-negative rate (FNR) of SLN surgery after chemotherapy with clinically node-positive disease with a prespecified endpoint of 10% considered to be an acceptable rate. However, the FNR was found to be 12.6%, though it was lower when dual-agent mapping technique was used and at least three or more SLNs removed.317 The SENTINA and SN FNAC trials had findings similar to Z1071. The results from Z1071 were further analyzed to determine if a clip was placed in the positive node at initial diagnosis and if the clipped node location at surgery (SLN or ALND) was evaluated. Indeed, this showed that identification of the clipped node during the surgical procedure further decreased the FNR.318 The results from the ACOSOG Z1071 (Alliance) trial, in cases presenting with cN1 disease and at least two SLN resections and clipped node was within the SLN specimen, showed that the FNR was 6.8%.318 Caudle et al at MD Anderson Cancer Center performed a prospective study of patients with biopsy-confirmed nodal metastases with a clip placed in the biopsy-proven lymph node, who were treated with neoadjuvant chemotherapy; at the time of surgery these patients underwent SLN dissection with targeting and removal of the clipped node (targeted axillary dissection [TAD]).319 TAD includes SLN surgery and selective localization and removal of the clipped node, with the goal to determine if pathologic changes in the clipped node accurately reflect the status of the nodal basin, and proposing that TAD improves the FNR compared to SLN surgery alone.319 In patients undergoing SLN surgery and ALND (n = 118), the FNR was 10.1% (95% CI, 4.2–19.8), and adding evaluation of the clipped node reduced the FNR to 1.4% (95% CI, 0.03–7.3; P = 0.3). TAD followed by ALND was performed in 85 patients, with an FNR of 2.0% (1 of 50; 95% CI, 0.05–10.7).319 Although the use of dual tracer technique, retrieval of three or more SLNs, and TAD improve axillary staging after neoadjuvant chemotherapy, there is no long-term data about the oncologic safety of omitting ALND in patients who convert from cN1 to cN0 disease at this time.

Neoadjuvant Endocrine Therapy. While initially used in elderly women who were deemed poor candidates for surgery or cytotoxic chemotherapy, neoadjuvant endocrine therapy is being increasingly evaluated in clinical trials. As clinicians have gained experience with neoadjuvant treatment strategies, it is now clear from examination of predictors of complete pathologic response that ER-positive tumors do not shrink in response to chemotherapy as readily as ER-negative tumors.320 Indeed, the pCR rate in ER-negative tumors is approximately three times that of ER-positive tumors. Fisher et al examined the results of the NSABP B-14 and B-20 trials and found that, as age increased, women obtained less benefit from chemotherapy. They recommended that factors including tumor estrogen receptor concentration, nuclear grade, histologic grade, tumor type, and markers of proliferation should be considered in these patients before choosing between the use of chemotherapy and hormonal therapy. If in fact the tumor is estrogen-receptor rich, these patients may benefit more from endocrine therapy in the neoadjuvant setting than they might if they received standard chemotherapy. Neoadjuvant endocrine therapy has been shown to shrink tumors, enabling breast-conserving surgery in women with hormone receptor-positive disease who otherwise would have to be treated with mastectomy, although long-term recurrence rates have not been reported.265 The IMPACT trial evaluated neoadjuvant use of tamoxifen or anastrozole or both in combination in postmenopausal women with ER-positive operable or locally advanced breast cancer.313 While there were no significant differences in objective tumor response among tamoxifen, anastrozole, or a combination of the two, in patients who were initially deemed as mastectomy candidates, only 31% had breast-conserving surgery with tamoxifen, whereas 44% underwent breast-conserving surgery with anastrozole. invasive lobular cancers in particular have been shown to respond poorly to neoadjuvant chemotherapy and may have better response to neoadjuvant endocrine therapy.322-324 A meta-analysis evaluating the response rate and rate of breast conservation surgery with the use of neoadjuvant endocrine therapy compared to combination chemotherapy was recently reported. This meta-analysis included nearly 3500 patients across 20 studies.325 Interestingly, aromatase inhibitors had a similar response, and breast conservation rates in comparison with combination chemotherapy albeit with lower toxicity suggest that neoadjuvant endocrine therapy is an appropriate alternative in ER-positive breast cancers. However, the incidence of complete pathological response was low (<10%) with both approaches. Also, aromatase inhibitors were associated with significantly higher response and breast conservation rates compared with tamoxifen. The ALTER-NATE (Alternate Approaches for Clinical Stage II or III Estrogen Receptor Positive Breast Cancer Neoadjuvant Treatment in Postmenopausal Women) trial is currently evaluating neoadjuvant endocrine therapy with fulvestrant or anastrozole or in combination.

Increasing knowledge of secondary resistance mechanisms to endocrine therapy and cross talk between ER and the PI3K/Akt/mTOR pathway have led to the evaluation of PI3K pathway inhibitors in combination with endocrine therapy. Postmenopausal women with ER-positive early breast cancers were treated with letrozole or letrozole in combination with everolimus, a mTOR inhibitor, in a randomized, phase 2 clinical trial. Clinical response and antiproliferative response, characterized by reduction in Ki67, was superior in the combination arm, suggesting that everolimus can increase efficacy of neoadjuvant letrozole.326 The LORLEI study is evaluating the use of taselisib, a PI3K inhibitor in combination with letrozole compared with letrozole alone. With the approval of CDK 4/6 inhibitors in the metastatic setting, clinical trials are evaluating the use of CDK inhibitors in combination with neoadjuvant endocrine therapy. Neoadjuvant anastrozole in combination with palbociclib, a CDK4/6 inhibitor, has been shown to significantly reduce Ki67, suggesting that CDK4/6 inhibition can increase the efficacy of neoadjuvant endocrine therapy.

With the use of neoadjuvant chemotherapy or endocrine therapy, observation of the response of the intact tumor and/or nodal metastases to a specific regimen could ultimately help to define which patients will benefit from specific therapies in the adjuvant setting. In adjuvant trials the primary endpoint is typically survival, whereas in neoadjuvant trials the endpoints have more often been clinical or pathologic response rates. There are a number of clinical trials underway comparing neoadjuvant chemotherapy and endocrine therapy regimens with pretreatment and posttreatment biopsy samples obtained from the primary tumors in all of the participants. These samples are being subjected to intensive genomic and proteomic analyses that may
help to define a more personalized or individualized approach to breast cancer treatment in the future.

**Antiestrogen Therapy**

**Tamoxifen.** Within the cytosol of breast cancer cells are specific proteins (receptors) that bind and transfer steroid moieties into the cell nucleus to exert specific hormonal effects. The most widely studied hormone receptors are the estrogen receptor and progesterone receptor. Hormone receptors are detectable in >90% of well-differentiated ductal and lobular invasive cancers. Although the receptor status may remain the same between the primary cancer and metastatic disease in the same patient in the majority of cases, there are instances where the status is changed in the metastatic focus; therefore, biopsy of newly diagnosed metastatic disease should be considered for assessment of hormone receptor and HER2 status.

After binding to estrogen receptors in the cytosol, tamoxifen blocks the uptake of estrogen by breast tissue. Clinical responses to antiestrogen and >60% of women with hormone receptor-positive breast cancers but in <10% of women with hormone receptor-negative breast cancers. A meta-analysis by the Early Breast Cancer Trialists’ Collaborative Group showed that adjuvant therapy with tamoxifen for 5 years reduced breast cancer mortality by about a third through the first 15 years of follow-up. This mortality benefit continues to be statistically significant in the second and third 5-year periods (i.e., years 5–9 and 10–15) when the patients are no longer receiving endocrine treatment—the so-called carry-over effect. The analysis also showed a 39% reduction in the risk of cancer in the contralateral breast. The antiestrogens do have defined toxicity, including bone pain, hot flashes, nausea, vomiting, and fluid retention. Thrombotic events occur in <3% of treated women. Cataract surgery is more frequently performed in patients receiving tamoxifen. The Stockholm trial showed that 5 years of tamoxifen was associated with a significant reduction in locoregional recurrences and distant metastasis in postmenopausal women with ER-positive breast cancer. However, an increase in endometrial cancers was observed with long-term tamoxifen use. The NSABP B14 trial evaluated 10 years of tamoxifen compared to 5 years. However, the study was terminated based on interim analyses indicating no additional benefit from tamoxifen beyond 5 years. The ATLAS trial also evaluated the use of tamoxifen for 5 years vs. 10 years in nearly 13,900 women across the world. This study showed that continuing tamoxifen for 10 years vs. 5 years produced a significant reduction in recurrence and mortality. Interestingly, the benefit was not seen in the second 5 years (i.e., years 5–9) while the patients were on treatment, but it was seen from years 10 to 15. One reason the NSABP B14 study was led to conclude that 10 years of tamoxifen was not beneficial was that the follow-up time was shorter. Results of the ATLAS study were also corroborated by the ATtom study. Similarly, extended adjuvant therapy with letrozole after 5 years of tamoxifen was shown to improve disease-free survival without improvement in overall survival except in node-positive patients.

Tamoxifen therapy is also considered for women with DCIS that is found to be ER-positive. The goals of such therapy are to decrease the risk of an ipsilateral recurrence after breast conservation therapy for DCIS and to decrease the risk of a primary invasive breast cancer or a contralateral breast cancer event. Consequently, tamoxifen is not recommended for patients who have had bilateral mastectomies with ER-positive DCIS. With the use of aromatase inhibitors in postmenopausal women, use of adjuvant tamoxifen has increasingly been limited to premenopausal women.

**Aromatase Inhibitors.** In postmenopausal women, aromatase inhibitors are now considered first-line therapy in the adjuvant setting. Currently, three third-generation aromatase inhibitors are approved for clinical use: the reversible nonsteroidal inhibitors anastrozole and letrozole and the irreversible steroidal inhibitor exemestane. While all the aromatase inhibitors have been shown to have similar efficacy with a similar spectrum of adverse effects, the Early Breast Cancer Trialists’ Collaborative Group meta-analyses of 31,920 postmenopausal women with ER-positive early breast cancers treated with tamoxifen or aromatase inhibitors demonstrated that 5 years of aromatase inhibitors reduced the rate of recurrence by 30% and 10-year breast cancer mortality by about 15% compared to 5 years of tamoxifen. The NSABP B42 study evaluated whether an additional 5 years of letrozole improved disease-free survival in postmenopausal women who have completed 5 years of tamoxifen or an aromatase inhibitor. After a median follow-up of 6.9 years, while extended letrozole significantly improved breast cancer-free interval, no improvement in disease-free survival, the primary endpoint, was observed. Recently, the results of the MA-17R study, designed to assess the efficacy of adjuvant letrozole for 10 years, were reported. Similar to NSABP B42, extended letrozole improved disease-free survival without significant improvement in overall survival. Patients who are node-positive, have received adjuvant chemotherapy, with prior receipt of tamoxifen are likely to benefit from long-term use of an aromatase inhibitor.

The aromatase inhibitors are less likely than tamoxifen to cause endometrial cancer but do lead to changes in bone mineral density that may result in osteoporosis and an increased rate of fractures in postmenopausal women. The risk of osteoporosis can be averted by treatment with bisphosphonates. Joint pains are a side effect that affects a significant number of patients. Node-negative and node-positive breast cancer patients whose tumors express hormone receptors should be considered for endocrine therapy in the adjuvant setting. Women with hormone receptor–positive cancers achieve significant reduction in risk of recurrence of breast cancer and mortality from breast cancer through the use of endocrine therapies.

For postmenopausal women with ER-positive, HER2-negative, metastatic breast cancer, available endocrine therapies include nonsteroidal aromatase inhibitors (anastrozole and letrozole); steroidal aromatase inhibitors (exemestane); serum ER modulators (tamoxifen or toremifene); ER down-regulators (fulvestrant); progestin (megestrol acetate); androgens (fluoxymesterone); and high-dose estrogen (ethinyl estradiol). A third generation nonsteroidal aromatase inhibitor or palbociclib, the CDK 4/6 inhibitor, in combination with letrozole may be considered as a treatment option for first-line therapy. Activation of CDK4/CDK6 cell cycle signaling axis has been implicated in mediating endocrine resistance. Consequently, PALOMA-1 evaluated the safety and efficacy of palbociclib in combination with letrozole vs. letrozole alone as first-line treatment for patients with ER-positive, HER2-negative advanced breast cancer. Median progression-free survival (PFS) was doubled with the combination compared to letrozole alone (20.2 months vs. 10.2 months for the letrozole). Based on this, the FDA approved palbociclib in combination with letrozole for the treatment of postmenopausal women with ER-positive, HER2-negative advanced breast cancer as initial treatment. The
benefit of palbociclib in combination with letrozole was subsequently confirmed in a phase 3 trial (PFS 24.8 months vs. 14.5 months for letrozole). Two additional CDK4/6 inhibitors, ribociclib and abemaciclib, have been approved for use in combination with endocrine therapy for patients with hormone receptor–positive advanced breast cancer.

On the other hand, PALOMA-3 compared the combination of palbociclib and fulvestrant to fulvestrant alone in pre- or postmenopausal ER-positive, HER2-negative metastatic breast cancer patients, whose disease progressed on prior endocrine therapy. Premenopausal women also received the GnRH agonist, goserelin. The median PFS was 9.2 months for the combination compared to 3.8 months with fulvestrant alone. Thus, fulvestrant with palbociclib is a potential option for women with metastatic breast cancer who have progressed on prior endocrine therapy. Additionally, abemaciclib in combination with fulvestrant or as single agent is approved for use in ER-positive advanced breast cancers previously treated with endocrine therapy.

In premenopausal women with stage IV ER-positive breast cancer without previous exposure to endocrine therapy, initial treatment with tamoxifen or ovarian suppression/ablation plus aromatase inhibitor with or without CDK4/6 inhibitors are reasonable options.

Activation of the PI3K/mammalian target of rapamycin (mTOR) signal transduction pathway has also been implicated in secondary resistance to estrogen targeting. BOLEbLERO-2 evaluated the use of exemestane in combination with everolimus in postmenopausal women with ER-positive tumors who had progressed or recurred on a nonsteroidal aromatase inhibitor. An improvement in PFS was observed with combination compared to exemestane alone (11 vs. 4.1 months) leading to FDA approval. Similar improvement in PFS was observed with a combination of tamoxifen and everolimus. However, a phase 3 trial of letrozole in combination with temsirolimus, an mTOR inhibitor, did not show any improvement in PFS in aromatase inhibitor–naive metastatic postmenopausal women. Trials evaluating the adjuvant use of mTOR inhibitors and CDK 4/6 inhibitors are currently in progress.

Women whose tumors respond to an endocrine therapy with either shrinkage of their breast cancer (objective response) or long-term stabilization of disease (stable disease) are considered to represent “clinical benefit” and should receive additional endocrine therapy at the time of progression because their chances of a further response remain high. Patients whose tumors progress de novo on an endocrine agent have a low rate of clinical benefit (<20%) to subsequent endocrine therapy; the choice of endocrine or chemotherapy should be considered based on the disease site and extent as well as the patient’s general condition and treatment preference.

The adjuvant use of aromatase inhibitors and recent advances in tumor genome sequencing technologies have enabled the identification of secondary ESR1 mutations. These mutations, typically present in the ligand binding domains, lead to ligand-independent activation of the receptor, mediate resistance to aromatase inhibitors, and are associated with shorter survival. Reported incidence of these mutations is variable (20%–30%) based on prior exposure to aromatase inhibitors and are uncommon in primary breast cancers. Clinical trials evaluating novel selective estrogen receptor degraders with potential activity against these mutations are in progress.

Ablative Endocrine Therapy

In the past, adrenalectomy and/or hypophysectomy were the primary endocrine modalities used to treat metastatic breast cancer, but today these approaches are seldom used. In women who are premenopausal at diagnosis, ovarian ablation can be accomplished by oophorectomy or ovarian radiation. Ovarian suppression can be accomplished by the use of gonadotrophin-hormone releasing hormone agonists, such as goserelin or leuprolide. Evaluation of the combination of goserelin with tamoxifen vs. cyclophosphamide/methotrexate/fluorouracil chemotherapy in premenopausal ER-positive early-stage breast cancers showed that relapse-free survival was superior with endocrine therapy combination, with a similar trend in overall survival. Data from the SOFT and TEXT trials on adjuvant endocrine therapy show that exemestane plus ovarian suppression significantly reduces recurrences as compared with tamoxifen plus ovarian suppression. In these trials, ovarian suppression was achieved with the use of the gonadotropin-releasing hormone agonist triptorelin, oophorectomy, or ovarian irradiation. The disease-free survival was 89% in the tamoxifen plus ovarian suppression group, while it was 93% in exemestane plus ovarian suppression group; however, there was no significant differences in overall survival. In the SOFT trial, while tamoxifen plus ovarian suppression was not superior to tamoxifen alone in terms of disease-free survival, improved outcomes were observed in ovarian suppression in women with a high risk of recurrence. In women who received no adjuvant chemotherapy, no meaningful benefit was obtained with ovarian suppression. Thus, ovarian suppression in combination with an aromatase inhibitor can be considered in select premenopausal women with high-risk features (age <40 years, positive lymph nodes) who warranted adjuvant chemotherapy.

Anti-HER2 Therapy

The determination of tumor HER-2 expression or gene amplification for all newly diagnosed patients with breast cancer is now recommended. It is used to assist in the selection of adjuvant chemotherapy in both node-negative and node-positive patients. Trastuzumab was initially approved for the treatment of HER2/neu-positive breast cancer in patients with metastatic disease. Once efficacy was demonstrated for patients with metastatic disease, the NSABP and the North Central Cancer Treatment Group conducted phase 3 trials that evaluated the impact of adjuvant trastuzumab therapy in patients with early-stage breast cancer. After approval from the FDA, these groups amended their adjuvant trastuzumab trials (B-31 and N9831, respectively), to provide for a joint efficacy analysis. The first joint interim efficacy analysis demonstrated an improvement in 3-year disease-free survival from 75% in the control arm to 87% in the trastuzumab arm (hazard ratio = 0.48, P < .0001). There was an accompanying 33% reduction in mortality in the patients who received trastuzumab (hazard ratio = 0.67, P = 0.015). The magnitude of reduction in hazard for disease-free survival events crossed prespecified early reporting boundaries, so the data-monitoring committees for both groups recommended that randomized accrual to the trials be ended, and the results were subsequently published.

While anthracycline-based adjuvant chemotherapy was considered preferable in HER2-positive breast cancer, the BCIRG 006 compared the use of anthracycline with taxane and trastuzumab (AC-TH) versus taxane, carboplatin chemotherapy with trastuzumab (TCH). With 10 years of follow-up, no statistical significance with regard to disease-free and overall survival was observed. However, there was a similar trend in overall survival.
survival was observed for anthracycline-based chemotherapy. While anthracycline chemotherapy was numerically superior, this was accompanied by an increase in the incidence of leukemia and congestive heart failure. A year of adjuvant trastuzumab is considered standard of care. Two years of adjuvant trastuzumab has been shown to be more effective, although it is associated with more toxicity than 1 year of trastuzumab.\textsuperscript{357} On the other hand, the PHARE trial examined 6 months vs. standard 12 months of trastuzumab. After 3.5 years of follow-up, the study failed to demonstrate that 6 months was noninferior compared to the standard therapy.\textsuperscript{358} Patients with HER2-positive tumors benefit if trastuzumab is added to taxane chemotherapy. Because of overlapping cardiotoxicities, trastuzumab is not usually given concurrently with anthracyclines.

Buzdar and colleagues reported the results of a randomized neoadjuvant trial of trastuzumab in combination with sequential paclitaxel followed by FEC-75 (5-fluorouracil, epirubicin, cyclophosphamide) vs. the same chemotherapy regimen without trastuzumab in 42 women with early-stage operable breast cancer. The pathologic complete response rates in this trial increased from 25% to 66.7% when chemotherapy was given concurrently with trastuzumab.\textsuperscript{301} A subsequent report that included additional patients treated with concurrent chemotherapy and trastuzumab further confirmed the high pathologic complete response rates and continued to show that cardiac function was preserved.\textsuperscript{302}

While novel agents have been approved for the treatment of women with metastatic HER2-positive breast cancers, currently trastuzumab is the only HER2-targeted agent approved for use in the adjuvant setting. Lapatinib is a dual tyrosine kinase inhibitor that targets both HER2 and EGFR. It was approved for use with capecitabine in patients with HER2-positive metastatic disease. Adjuvant lapatinib was shown to be inferior to trastuzumab, and the combination of lapatinib with trastuzumab did yield a significant improvement in disease-free survival compared to trastuzumab alone. Ado-trastuzumab emtansine (T-DM1) is approved for HER2-positive metastatic breast cancer patients who have previously received trastuzumab and a taxane either separately or in combination. T-DM1 is an antibody drug conjugate that incorporates the HER2 targeted activity of trastuzumab with the cytotoxic activity of DM1, a microtubule inhibitory agent leading to apoptosis.\textsuperscript{359}

Pertuzumab is a humanized monoclonal antibody that binds at a different epitope of the HER2 extracellular domain (subdomain II) and prevents dimerization of HER2 with other members of the family, primarily HER3. In the metastatic setting, it is approved in combination with trastuzumab and docetaxel for patients with metastatic HER2-positive breast cancer who have not received prior HER2-targeted therapy or chemotherapy for metastatic disease.\textsuperscript{360} In the neoadjuvant setting, pertuzumab is approved in combination with trastuzumab and docetaxel in HER2-positive, early stage breast cancers that are greater than 2 cm or node-positive. However, this approval is based on improvement in pathologic complete response rate, and not data based on improvement in event free or overall survival.\textsuperscript{361,362} In the NeoSphere trial, neoadjuvant use of pertuzumab with trastuzumab and docetaxel led to nearly a 17% increase in pathologic complete response in the breast ($P = .0141$).\textsuperscript{361} While in the TRYPHAENA study, pathologic complete responses ranging from 57% to 66% were observed with neoadjuvant pertuzumab and trastuzumab combination given with anthracycline-containing or nonanthracycline-containing chemotherapy.\textsuperscript{362} With the use of dual antibody therapy, currently there is significant interest in identifying patients who can avoid chemotherapy and potentially be treated with HER2-targeted agents alone. The NeoSphere study showed 27% pathologic complete response in HER2-positive, ER-negative, breast cancer patients treated with pertuzumab and trastuzumab alone. Pertuzumab was recently FDA approved in combination with trastuzumab and chemotherapy in the adjuvant setting in HER2 amplified breast cancers with high risk of recurrence. Approval is based on APHINITY trial showing that the addition of pertuzumab improved invasive disease free survival (7.1%) compared to placebo (8.7%) (HR 0.82, 95% CI: 0.67, 1.00; $p = 0.047$). Overall survival data is not mature.

The ExteNET study evaluated the use of neratinib, an irreversible inhibitor of EGFR, HER2, and HER4, in HER2-positive early stage patients who have completed adjuvant trastuzumab. A year of neratinib after completion of chemotherapy and trastuzumab-based adjuvant therapy significantly improved 2-year disease-free survival, the primary endpoint.\textsuperscript{363} After two years, invasive disease free survival was 94.2% in patients treated with neratinib compared with 91.9% in those receiving placebo (HR 0.66; 95% CI: 0.49, 0.90, $p = 0.008$) leading to FDA approval for HER2 amplified breast cancers following a year of adjuvant trastuzumab.

In addition to amplifications or copy number alterations, activating mutations or single nucleotide variants in HER2 have been described (2%).\textsuperscript{364} Typically observed in ER-positive breast cancers, a higher prevalence of HER2 mutations have been reported in invasive lobular carcinomas, particularly in the pleomorphic subtype.\textsuperscript{365} These mutations, usually exclusive with HER2 amplification, are observed in kinase or extracellular domains and predict for responses or resistance to HER2-targeting agents.\textsuperscript{366,367} A phase 2 trial of neratinib in HER2-mutated metastatic breast cancers showed a clinical benefit rate of 36% with one complete response and one partial response in a heavily pretreated population. A clinical trial evaluating the combination of neratinib with fulvestrant, in HER2-mutated, ER-positive breast cancers, is in progress.

### SPECIAL CLINICAL SITUATIONS

#### Nipple Discharge

**Unilateral Nipple Discharge.** Nipple discharge is a finding that can be seen in a number of clinical situations. It may be suggestive of cancer if it is spontaneous, unilateral, localized to a single duct, present in women $\geq 40$ years of age, bloody, or associated with a mass. A trigger point on the breast may be present so that pressure around the nipple-areolar complex induces discharge from a single duct. In this circumstance, mammography and ultrasound are indicated for further evaluation. A ductogram also can be useful and is performed by cannulating a single discharging duct with a small nylon catheter or needle and injecting 1.0 mL of water-soluble contrast solution. Nipple discharge associated with a cancer may be clear, bloody, or serous. Testing for the presence of hemoglobin is helpful, but hemoglobin may also be detected when nipple discharge is secondary to an intraductal papilloma or duct ectasia. Definitive diagnosis depends on excisional biopsy of the offending duct and any associated mass lesion. A 3.0 lacrimal duct probe can be used to identify the duct that requires excision. Another approach is to inject methylene blue dye within
the duct after ductography. The nipple must be sealed with collodion or a similar material so that the blue dye does not discharge through the nipple but remains within the distended duct facilitating its localization. Localization with a wire or seed is performed when there is an associated mass that lies >2.0 to 3.0 cm from the nipple.

**Bilateral Nipple Discharge.** Nipple discharge is suggestive of a benign condition if it is bilateral and multiduct in origin, occurs in women ≤39 years of age, or is milky or blue-green. Prolactin-secreting pituitary adenomas are responsible for bilateral nipple discharge in <2% of cases. If serum prolactin levels are repeatedly elevated, plain radiographs of the sellar turcica are indicated, and thin section CT scan is required. Optical nerve compression, visual field loss, and infertility are associated with large pituitary adenomas.

**Axillary Lymph Node Metastases in the Setting of an Unknown Primary Cancer**

A woman who presents with an axillary lymph node metastasis is consistent with a breast cancer metastasis has a 90% probability of harboring an occult breast cancer. However, axillary lymphadenopathy is the initial presenting sign in only 1% of breast cancer patients. Fine-needle aspiration biopsy or core-needle biopsy can be used to establish the diagnosis when an enlarged axillary lymph node is identified. When metastatic cancer is found, immunohistochemical analysis may classify the cancer as epithelial, melanocytic, or lymphoid in origin. The presence of hormone receptors (estrogen or progesterone receptors) suggests metastasis from a breast cancer but is not diagnostic. The search for a primary cancer includes careful examination of the thyroid, breast, and pelvis, including the rectum. The breast should be examined with diagnostic mammography, ultrasonography, and MRI to evaluate for an occult primary lesion. Further radiologic and laboratory studies should include chest radiography and liver function studies. Additional imaging of the chest, abdomen, and skeleton may be indicated if the extent of nodal involvement is consistent with stage III breast cancer. Suspicious findings on mammography, ultrasonography, or MRI necessitate breast biopsy. When a breast cancer is found, treatment consists of an axillary lymph node dissection with a mastectomy or preservation of the breast followed by whole-breast radiation therapy. Chemotherapy and endocrine therapy should be considered.

**Breast Cancer During Pregnancy**

Breast cancer occurs in 1 of every 3000 pregnant women, and axillary lymph node metastases are present in up to 75% of these women. The average age of the pregnant woman with breast cancer is 34 years. Fewer than 25% of the breast nodules developing during pregnancy and lactation will be cancerous. Ultrasonography and needle biopsy specimens are used in the diagnosis of these nodules. Mammography is rarely indicated because of its decreased sensitivity during pregnancy and lactation; however, the fetus can be shielded if mammography is needed. Approximately 30% of the benign conditions encountered will be unique to pregnancy and lactation (galactoceles, lobular hyperplasia, lactating adenoma, and mastitis or abscess). Once a breast cancer is diagnosed, complete blood count, chest radiography (with shielding of the abdomen), and liver function studies are performed.

Because of the potential deleterious effects of radiation therapy on the fetus, radiation cannot be considered until the fetus is delivered. A modified radical mastectomy can be performed during the first and second trimesters of pregnancy, even though there is an increased risk of spontaneous abortion after first-trimester anesthesia. During the third trimester, lumpectomy with axillary node dissection can be considered if adjuvant radiation therapy is deferred until after delivery. Lactation is suppressed. Chemotherapy administered during the first trimester carries a risk of spontaneous abortion and a 12% risk of birth defects. There is no evidence of teratogenicity resulting from administration of chemotherapeutic agents in the second and third trimesters. For this reason, many clinicians now consider the optimal strategy to be delivery of chemotherapy in the second and third trimesters as a neoadjuvant approach, which allows local therapy decisions to be made after the delivery of the baby. Pregnant women with breast cancer often present at a later stage of disease because breast tissue changes that occur in the hormone-rich environment of pregnancy obscure early cancers. However, pregnant women with breast cancer have a prognosis, stage by stage, that is similar to that of nonpregnant women with breast cancer.

**Male Breast Cancer**

Fewer than 1% of all breast cancers occur in men. The incidence appears to be highest among North Americans and the British, in whom breast cancer constitutes as much as 1.5% of all male cancers. Jewish and African-American men have the highest incidence. Male breast cancer is preceded by gynecomastia in 20% of men. It is associated with radiation exposure, estrogen therapy, testicular feminizing syndromes, and Klinefelter’s syndrome (XXY). Breast cancer is rarely seen in young males and has a peak incidence in the sixth decade of life. A firm, nontender mass in the male breast requires investigation. Skin or chest wall fixation is particularly worrisome.

DCIS makes up <15% of male breast cancer, whereas infiltrating duct carcinoma makes up >85%. Special-type cancers, including infiltrating lobular carcinoma, have occasionally been reported. Male breast cancer is staged in the same way as female breast cancer, and stage by stage, men with breast cancer have the same survival rate as women. Overall, men do worse because of the more advanced stage of their cancer (stage II, III or IV) at the time of diagnosis. The treatment of male breast cancer is surgical, with the most common procedure being a modified radical mastectomy. SLN dissection has been shown to be feasible and accurate for nodal assessment in men presenting with a clinically node-negative axilla. Adjuvant radiation therapy is appropriate in cases in which there is a high risk for local-regional recurrence. Approximately 80% of male breast cancers are hormone receptor–positive, and adjuvant tamoxifen is considered. Systemic chemotherapy is considered for men with hormone receptor-negative cancers and for men with large primary tumors, multiple positive nodes, and locally advanced disease.

**Phyllodes Tumors**

The nomenclature, presentation, and diagnosis of phyllodes tumors (including cystosarcoma phylloides) have posed many problems for surgeons. These tumors are classified as benign, borderline, or malignant. Borderline tumors have a greater potential for local recurrence.

Mammographic evidence of calcifications and morphologic evidence of necrosis do not distinguish between benign, borderline, and malignant phyllodes tumors. Consequently, it is difficult to differentiate benign phyllodes tumors from the
malignant variant and from fibroadenomas. Phyllodes tumors are usually sharply demarcated from the surrounding breast tissue, which is compressed and distorted. Connective tissue composes the bulk of these tumors, which have mixed gelatinous, solid, and cystic areas. Cystic areas represent sites of infarction and necrosis. These gross alterations give the gross cut tumor surface its classical leaf-like (phyllodes) appearance. The stroma of a phyllodes tumor generally has greater cellular activity than that of a fibroadenoma. After microdissection to harvest clusters of stromal cells from fibroadenomas and from phyllodes tumors, molecular biology techniques have shown the stromal cells of fibroadenomas to be either polyclonal or monoclonal (derived from a single progenitor cell), whereas those of phyllodes tumors are always monoclonal.

Most malignant phyllodes tumors (Fig. 17-38) contain liposarcomatous or rhabdomyosarcomatous elements rather than fibrosarcomatous elements. Evaluation of the number of mitoses and the presence or absence of invasive foci at the tumor margins may help to identify a malignant tumor. Small phyllodes tumors are excised with a margin of normal-appearing breast tissue. When the diagnosis of a phyllodes tumor with suspicious malignant elements is made, reexcision of the biopsy specimen site to ensure complete excision of the tumor with a 1-cm margin of normal-appearing breast tissue is indicated. Large phyllodes tumors may require mastectomy. Axillary dissection is not recommended because axillary lymph node metastases rarely occur.

**Inflammatory Breast Carcinoma**

Inflammatory breast carcinoma (stage IIIB) accounts for <3% of breast cancers. This cancer is characterized by the skin changes of brawny induration, erythema with a raised edge, and edema (peau d’orange). Permeation of the dermal lymph vessels by cancer cells is seen in skin biopsy specimens. There may be an associated breast mass (Fig. 17-39). The clinical differentiation of inflammatory breast cancer may be extremely difficult, especially when a locally advanced scirrhous carcinoma invades dermal lymph vessels in the skin to produce peau d’orange and lymphangitis (Table 17-15). Inflammatory breast cancer also may be mistaken for a bacterial infection of the breast. More than 75% of women who have inflammatory breast cancer present with palpable axillary lymphadenopathy, and distant metastases also are frequently present. A PET-CT scan should be considered at the time of diagnosis to rule out concurrent metastatic disease. A report of the SEER program described distant metastases at diagnosis in 25% of white women with inflammatory breast carcinoma.

Surgery alone and surgery with adjuvant radiation therapy have produced disappointing results in women with inflammatory breast cancer. However, neoadjuvant chemotherapy with an anthracycline-containing regimen may affect dramatic regressions in up to 75% of cases. Tumors should be assessed for HER2 and hormone receptors with treatment dictated based on receptor status. Modified radical mastectomy is performed after demonstrated response to systemic therapy to remove residual cancer from the chest wall and axilla. Adjuvant chemotherapy may be indicated depending on final pathologic assessment of the breast and regional nodes. Finally, the chest wall and the

supraclavicular, internal mammary, and axillary lymph node basins receive adjuvant radiation therapy. This multimodal approach results in 5-year survival rates that approach 30%. Patients with inflammatory breast cancer should be encouraged to participate in clinical trials.

Rare Breast Cancers

Squamous Cell (Epidermoid) Carcinoma. Squamous cell (epidermoid) carcinoma is a rare cancer that arises from metaplasia within the duct system and generally is devoid of distinctive clinical or radiographic characteristics. Regional metastases occur in 25% of patients, whereas distant metastases are rare.

Adenoid Cystic Carcinoma. Adenoid cystic carcinoma is very rare, accounting for <0.1% of all breast cancers. It is typically indistinguishable from adenoid cystic carcinoma arising in salivary tissues. These cancers are generally 1 to 3 cm in diameter at presentation and are well circumscribed. Axillary lymph node metastases are rare, but deaths from pulmonary metastases have been reported.

Apocrine Carcinomas. Apocrine carcinomas are well-differentiated cancers that have rounded vesicular nuclei and prominent nucleoli. There is a very low mitotic rate and little variation in cellular features. However, apocrine carcinomas may display an aggressive growth pattern.

Sarcomas. Sarcomas of the breast are histologically similar to soft tissue sarcomas at other anatomic sites. This diverse group includes fibrosarcoma, malignant fibrous histiocytoma, liposarcoma, leiomyosarcoma, malignant schwannoma, rhabdomyosarcoma, osteogenic sarcoma, and chondrosarcoma. The clinical presentation is typically that of a large, painless breast mass with rapid growth. Diagnosis is by core-needle biopsy or by open incisional biopsy. Sarcomas are graded based on cellularity, degree of differentiation, nuclear atypia, and mitotic activity. Primary treatment is wide local excision, which may necessitate mastectomy. Axillary dissection is not indicated unless there is biopsy proven lymph node involvement. Angiosarcomas are classified as de novo, as postradiation, or as arising in association with postmastectomy lymphedema. In 1948, Stewart and Treves described lymphangiosarcoma of the upper extremity in women with ipsilateral lymphedema after radical mastectomy. Angiosarcoma is now the preferred name. The average interval between modified radical or radical mastectomy and the development of an angiosarcoma is 7 to 10 years. Sixty percent of women developing this cancer have a history of adjuvant radiation therapy. Forequarter amputation may be necessary to palliate the ulcerative complications and advanced lymphedema.

Lymphomas. Primary lymphomas of the breast are rare, and there are two distinct clinicopathologic variants. One type occurs in women ≤39 years of age, is frequently bilateral, and has the histologic features of Burkitt’s lymphoma. The second type is seen in women ≥40 years of age and is usually of the B-cell type. Breast involvement by Hodgkin’s lymphoma has been reported. An occult breast lymphoma may be diagnosed after detection of palpable axillary lymphadenopathy. Treatment depends on the stage of disease. Lumpectomy or mastectomy may be required. Axillary dissection for clearance of disease may be necessary. Recurrent or progressive local-regional disease is best managed by chemotherapy and radiation therapy. The prognosis is favorable, with 5- and 10-year survival rates of 74% and 51%, respectively. More recently anaplastic large cell lymphoma has been described in association with breast implants for cosmetic or reconstructive purposes. This disease is treated with complete excision of the implant capsule with any associated soft tissue mass. More advanced cases may require systemic therapy and radiation treatment.

SPECIFIC CONSIDERATIONS

Disorders of the Head and Neck
Antoine Eskander, Stephen Y. Kang, Michael S. Harris, Bradley A. Otto, Oliver Adunka, Randal S. Weber, and Theodoros N. Teknos

Infectious processes of the ear may be considered by their location (external, middle, or inner ear), their time course (acute or chronic), and the presence of complications. The external ear or pinna consists of a cartilaginous framework, perichondrium, and a relatively thin layer of skin. Erysipelas (St Anthony’s Fire) or impetigo are causes of external ear infection affecting the dermis or hypodermis of the auricle, typically caused by Streptococcus pyogenes or Staphylococcus aureus, respectively, that may be encountered posttraumatically or related to ear piercing. Treatment is oral antibiotic therapy targeting these organisms. History and clinical features such as presence of bullae and golden crusting distinguish erysipelas and impetigo from other benign entities causing erythema and edema of the auricle, such as relapsing polychondritis, which is typically diffuse, lobule-sparing, and steroid-responsive.

**Acute otitis externa**, often referred to as “swimmer’s ear,” denotes infection of the skin of the external auditory canal. Typically, the pathology is incited by moisture within the canal leading to skin maceration and pruritus. Subsequent trauma to the canal skin by scratching (i.e., instrumentation with a cotton swab or fingernail), erodes the normally protective skin/cerumen barrier. Hearing aid use and comorbid dermatologic conditions such as eczema or other forms of dermatitis may similarly serve as predisposing factors. The milieu of the external ear canal—dark, warm, humid—is ideal for rapid microbial proliferation. The most common offending organism is Pseudomonas aeruginosa, although other bacteria and fungi may also be involved. Symptoms and signs of otitis externa include itching during the initial phases and pain with marked swelling of the canal soft tissues as the infection progresses. Treatment involves removal of debris under otomicroscopy and application of appropriate ototopical antimicrobials, such as neomycin/polymyxin or quinolone-containing eardrops. The topical steroid component of these drops (e.g., hydrocortisone or dexamethasone) addresses swelling and, as a result, decreases the intense pain associated with this infection. In cases of marked ear canal edema, the use of an otowick is required to facilitate delivery of ototopical medication medially into the ear canal. Fungal infections may call for the addition of 2% acetic acid to reestablish the premorbid pH balance. Patients with otitis externa should also be instructed to keep the ear dry. Systemic antibiotics are reserved for those with severe infections, diabetics, and immunosuppression.
Malignant otitis externa, a fulminant necrotizing infection of the soft tissues of the external ear canal combined with osteomyelitis of the temporal bone, is a potentially life-threatening form of otitis externa seen most commonly among elderly patients with insulin-dependent diabetes mellitus or immunodeficiency. The classic physical finding is granulation tissue along the floor of the external auditory canal near the bony cartilaginous junction. Symptoms include persistent otalgia for longer than one month and purulent otorrhea. Biopsy is called for in order to exclude malignancy. Computed tomography (CT) and magnetic resonance imaging (MRI) define the extension of disease. Technetium 99-m scans are useful in gauging extend of bony involvement in early disease. Gallium-67 scans are valuable for monitoring disease during the course of treatment and for determining duration of antibiotic therapy. These patients require aggressive medical therapy including ototopical and IV antibiotics targeting Pseudomonas. Other gram-negative bacteria and fungi are occasionally implicated, necessitating culture-directed therapy. Patients who do not respond to medical management require surgical debridement. This condition may progress to involvement of the adjacent skull base and soft tissues, meningitis, brain abscess, and death.

Acute otitis media (AOM) typically implies a bacterial infection of the middle ear. This diagnosis accounts for 25% of pediatric antibiotic prescriptions and is the most common bacterial infection of childhood. Most cases occur before 2 years of age and are secondary to immaturity of the Eustachian tube. Well-recognized contributing factors include upper respiratory viral infection and daycare attendance, as well as craniofacial conditions affecting Eustachian tube function, such as cleft palate.

It is important to distinguish between acute otitis media and otitis media with effusion (OME). The later denotes uninfected serous fluid accumulation within the middle ear space. In children not already considered “at risk” for developmental difficulties, OME is generally observed for resolution for a period of 3 months. Age-appropriate hearing testing should be performed when OME persists for ≥3 months or at any time when language delay, learning problems, or a significant hearing loss is suspected. In the absence of these factors, the child with OME should be reexamined at 3- to 6-month intervals until the effusion is no longer present or until significant hearing loss is identified or structural abnormalities of the eardrum or middle ear are suspected. When hearing, speech, or structural concerns exist, myringotomy with tympanostomy tube placement is indicated.

Signs and symptoms of infectious otitis media occurring for <3 weeks denote AOM. In this phase, otalgia and fever are the most common symptoms and physical exam reveals a bulging, opaque tympanic membrane (Fig. 18-1). If the process lasts 3 to 8 weeks, it is deemed subacute. Chronic otitis media, lasting more than 8 weeks, usually results from an unresolved acute otitis media. The most common organisms responsible are Streptococcus pneumoniae, Haemophilus influenzae, and Moraxella catarrhalis.

In order to minimize antibiotic resistance and obviate complications of antimicrobial therapy such as allergic reaction and diarrhea, guidelines have been established for the treatment of AOM. Pain associated with AOM should be recognized and treated with oral analgesics. In children older than 6 months who are not otherwise considered “high risk” for complications (e.g., immunocompromised, previous cochlear implantation, developmental anomalies of the inner ear) with symptoms consistent with unilateral AOM without otorrhea, an initial period of observation is offered. If initial observation is selected by the physician and family, a mechanism for reexamination in 48 to 72 hours to evaluate for clinical improvement must be in place. When these criteria are not met, or clinical improvement is not observed within 48 to 72 hours, oral antibiotics are begun. First-line therapy is high-dose amoxicillin or amoxicillin-clavulanate, for β-lactamase coverage. Chronic otitis media is frequently...
treated with myringotomy and tube placement (Fig. 18-2). This treatment is indicated for frequent acute episodes and in the setting of COME as discussed previously. The purpose of this procedure is to remove the effusion and provide a route for middle ear ventilation. Episodes of AOM following tube placement are still possible. Myringotomy tubes, however, allow for prevention of painful tympanic membrane distension, risk of perforation and other complications, and permit delivery of ototopicals into the middle ear space, in most cases obviating the need for systemic antibiotic therapy.

Spontaneous tympanic membrane perforation during acute otitis media provides for drainage of purulent fluid and middle ear ventilation and frequently results in immediate resolution of severe pain. In the majority of cases, these perforations will heal spontaneously after the infection has resolved. Chronic otitis media, however, may be associated with nonhealing tympanic membrane perforations. Patients may have persistent otorrhea, which is treated with topical drops. Preparations containing aminoglycoside are avoided because this class of drugs is toxic to the inner ear. Solutions containing alcohol or acetic acid may be irritating or caustic to the middle ear and are also avoided in the setting of a perforation. Nonhealing perforation requires surgical closure (tympanoplasty) after medical treatment of any residual acute infection.

Chronic inflammatory changes from otitis media intersect with and share common etiological factors with cholesteatoma. Cholesteatoma is an epidermoid cyst of the middle ear and/or mastoid cavity that develops as result of Eustachian tube dysfunction. While several theories exist regarding causes of cholesteatoma, most cholesteatoma arises from squamous epithelium drawn into the middle ear via retraction pockets, most commonly in the pars flaccida. Squamous epithelium may also migrate into the middle ear via a perforation. Chronic mastoiditis that fails medical management or is associated with cholesteatoma is treated by mastoidectomy. Chronic inflammation and destruction of middle ear structures by osteolytic enzymes of cholesteatoma matrix may also be associated with erosion of the ossicular chain, which can be reconstructed with various prostheses or autologous ossicular replacement techniques.

Complications of otitis media with or without cholesteatoma may be grouped into two categories: intratemporal (otologic) and intracranial. Fortunately, complications are rare in the antibiotic era, but mounting antibiotic resistance necessitates an increased awareness of these conditions. Intratemporal complications include acute coalescent mastoiditis, petrositis, facial nerve paralysis, and labyrinthitis. In acute coalescing mastoiditis, destruction of the bony lamellae by an acute purulent process results in severe pain, fever, and fluctuance behind the ear. The mastoid air cells coalesce into one common space filled with pus. Mastoid infection may also spread to the petrous apex, causing retro-orbital pain and sixth-nerve palsy. These diagnoses are confirmed by computed tomographic scan. Facial nerve paralysis may also occur secondary to an acute inflammatory process in the middle ear or mastoid.

Intratemporal complications of otitis media are managed by myringotomy tube placement in addition to appropriate IV antibiotics. In acute coalescent mastoiditis and petrositis, mastoidectomy is also performed as necessary to drain purulent foci. Labyrinthitis refers to inflammation of the inner ear. Most cases are idiopathic or are secondary to viral infections of the endolympathic space. The patient experiences vertigo together with sensorineural hearing loss, and symptoms may smolder over several weeks. Labyrinthitis associated with middle ear infection may be serous or suppurative. In the former case, bacterial products and/or inflammatory mediators transudate into the inner ear via the round window membrane, establishing an inflammatory process therein. Total recovery is eventually possible after the middle ear is adequately treated.

Suppurative labyrinthitis, however, is a much more toxic condition in which the acute purulent bacterial infection extends into the inner ear and causes marked destruction of the sensory hair cells and neurons of the eighth-nerve ganglion. This condition may be a harbinger for meningitis and must be treated rapidly. The goal of management of inner ear infection, which occurs secondary to middle ear infection, is to “sterilize” the middle ear space with antibiotics and the placement of a myringotomy tube.

The most common intracranial complication of otitis media is meningitis. Otologic meningitis in children is most commonly associated with an H. influenzae type B infection. Other intracranial complications include epidural abscess, subdural abscess, brain abscess, otitic hydrocephalus, and sigmoid sinus thrombophlebitis. In these cases, the otogenic source must be urgently treated with antibiotics and myringotomy tube placement. Mastoidectomy and neurosurgical consultation may be necessary.

**Facial Nerve Disorders.** Bell’s palsy is the most common etiology of facial nerve weakness/paralysis and is clinically distinct from that occurring as a complication of otitis media in that the otologic exam is normal. Bell’s palsy is rapid, unilateral and, historically, considered idiopathic. It is now accepted, however, that the majority of these cases represent a viral neuropathy caused by herpes simplex. It is critical that clinicians distinguish Bell’s palsy from other causes of facial weakness/palsy. Alternative diagnoses are suggested by weakness/paralysis that arise gradually (rather than <72 hours), is bilateral, is accompanied by other neurological deficits, or does not show some recovery within 2 to 3 weeks and complete recovery at 3 to 4 months. Treatment includes oral steroids plus antiviral therapy (i.e., valacyclovir). Complete recovery is the norm, but it does not occur universally, and selected cases may benefit from surgical decompression of the nerve via exposure in the mastoid and middle cranial fossa.
Varicella zoster virus may also cause facial nerve paralysis when the virus reactivates from dormancy in the nerve. This condition, known as Ramsay Hunt syndrome, is characterized by severe otalgia followed by the eruption of vesicles of the external ear and the soft palate. Treatment is similar to Bell’s palsy, but full recovery is only seen in approximately two-thirds of cases.

Traumatic facial nerve injuries may occur secondary to accidental trauma or surgical injury. Iatrogenic facial nerve trauma most often occurs during mastoidectomy, most commonly to the vertical segment of the nerve. Detailed knowledge of facial nerve anatomy and adjunctive use of nerve integrity monitoring systems are imperative in this context. When the facial nerve is injured during an operative procedure, it is explored. Injury to >50% of the neural diameter of the facial nerve is addressed either with primary reanastomosis or reconstructed with the use a nerve graft. Complete recovery of nerve function is uncommon in these cases.

Lesions of the Internal Auditory Canal and Cerebellopontine Angle. The most common lesion affecting the internal auditory canal (IAC) and the cerebellopontine angle (CPA) is vestibular schwannoma (formerly referred to as “acoustic neuroma”). Less commonly encountered lesions of the IAC and CPA include meningioma and epidermoid tumors. Vestibular schwannomas are benign tumors that comprise 60% to 92% of all CPA lesions and 6% to 10% of intracranial tumors. They demonstrate an average growth rate of 1 to 2 mm per year. Vestibular schwannomas are most commonly unilateral and sporadic; bilateral tumors are the hallmark of neurofibromatosis type 2 (NF2), an autosomal dominant condition linked to mutation of a tumor suppressor gene mapped to chromosome 22. The most common presenting symptoms of vestibular schwannoma are asymmetric sensorineural hearing loss and speech perception deficits often out of proportion to degree of hearing loss indicated by audiometry. Unilateral tinnitus is also frequently reported. Disequilibrium or, less commonly, episodic vertigo may be present. Facial nerve weakness or paralysis is rare. Larger tumors may feature facial numbness and loss of the cornea reflex from compression of the trigeminal nerve. Very large lesions can lead to brainstem compression, obstructive hydrocephalus, and death.

Gadolinium-enhancement on T1-weighted MRI is the gold standard for diagnosis and detects even very small tumors (Fig. 18-3). The conventional armamentarium for vestibular...

Figure 18-3. A. Axial T1 magnetic resonance imaging (MRI) post-contrast showing left cerebellopontine angle tumor with avid gadolinium enhancement. Minimal internal auditory canal involvement is noted. B. Axial T2 MRI showing left cerebellopontine angle tumor with thin cerebrospinal fluid cleft between tumor and brainstem/cerebellum. C. Axial T1 MRI post-contrast showing left cerebellopontine angle tumor with avid gadolinium enhancement. The lesion is confined to the internal auditory canal with minimal cerebellopontine angle involvement. D. Intraoperative phono during microsurgical resection via translabyrinthine approach. Black arrow indicates cochlear nerve.
schwannoma includes observation, microsurgical resection, and stereotactic radiation. Management of patients with vestibular schwannomas involves weighing a multitude of variables particular to the tumor (location, size, growth pattern), the patient (age, overall health, individual wishes), and the interaction between tumor and patient (symptoms currently experienced, symptoms likely to develop with lesion progression, degree of residual hearing). For patients who have hearing that may still benefit from acoustic amplification using a hearing aid, either a retrosigmoid or a middle fossa approach may be offered, depending on tumor location, size, patient preference, and provider experience. For patients without serviceable hearing preoperatively, a translabyrinthine approach is most commonly offered.

Sinonasal Inflammatory Disease

Rhinosisinusitis. Rhinosinusitis is defined as symptomatic inflammation of the nasal cavity and paranasal sinuses. Rhinosinusitis is preferred over sinusitis because sinusitis almost always is accompanied by inflammation of the contiguous nasal mucosa. Rhinosinusitis is a significant health burden, affecting nearly 12% of the population. Rhinosinusitis is the fifth most common diagnosis responsible for antibiotic prescription and accounts for more than 20% of all antibiotics prescribed to adults. Rhinosinusitis may be broadly classified based on duration of symptomatology. Symptoms lasting <4 weeks may be classified as acute rhinosinusitis (ARS), while symptoms lasting >12 weeks may be classified as chronic rhinosinusitis (CRS). Rhinosinusitis lasting between 4 and 12 weeks has historically been defined as “subacute,” although the current clinical practice guideline published by the American Academy of Otolaryngology—Head and Neck Surgery does not distinguish rhinosinusitis in this time frame, noting that this group likely represents crossover symptoms from one of the other two subclasses. Hence, the decision on how to manage this group of patients must be individualized.

Acute Rhinosinusitis. Acute rhinosinusitis most commonly occurs in the setting of a viral upper respiratory tract infection (URI). Although it is believed that acute bacterial rhinosinusitis (ABRS) typically follows a viral URI, it has been estimated that only up to 2% of viral URIs lead to ABRS. The most common viruses involved in ARS include rhinovirus, influenza virus, and parainfluenza virus. It is not known whether the viral URI preceedes or only occurs along with ABRS. Regardless, viral infection leads to mucosal edema with sinus ostium obstruction, mucus stasis, tissue hypoxia, ciliary dysfunction, and epithelial damage, which may enhance bacterial adherence. Other conditions that may contribute to ABRS should be investigated, especially in the setting of recurrent ABRS. Such conditions include foreign body, sinus fungal ball (with bacterial secondary infection), and periapical dental disease (Figs. 18-4 and 18-5).

The symptomatic criteria used to define ABRS include up to 4 weeks of purulent nasal drainage accompanied by nasal obstruction, facial pain with pressure and fullness, or both.
Other historical factors that may predict the development of ABRS include persistence of symptoms beyond 10 days, or worsening of symptoms, following initial improvement, within 10 days (“double worsening”). Although routine head and neck examination may identify anteriorly or posteriorly draining purulent secretions, the utilization of a rigid endoscope may improve diagnostic sensitivity and may also facilitate culture acquisition (Fig. 18-6).

The management of ABRS is heavily dependent on antibiotics, either culture-directed or empirically chosen to cover the most common isolates of ABRS, including S. pneumoniae, H. influenzae, and M. catarrhalis. Nosocomial ABRS more commonly involves P. aeruginosa or S. aureus. Methicillin-resistant S. aureus (MRSA) has been isolated with increasing frequency. Other treatments include topical and systemic decongestants, nasal saline spray, topical nasal steroids, and oral steroids in selected cases. In the acute setting, surgery is reserved for complications or pending complications, which may include extension to the eye (orbital cellulitis or abscess) or the intracranial space (meningitis or intracranial abscess).

Chronic Rhinosinusitis. Chronic rhinosinusitis (CRS) is characterized by symptomatic inflammation of the nose and paranasal sinuses lasting over 12 weeks. CRS has been clinically classified into two main groups: those with CRS with nasal polyps (CRSsNP) tend to exhibit a Th2-biased inflammatory profile, and those with CRS without nasal polyps (CRSsNP) tend to exhibit a Th1-biased profile. Although the etiology of CRS is unclear and the development of the clinical subtypes may be distinct, there exists significant overlap not only in physiologic manifestations but also in symptomatology. Hence, the sinonasal cavities of patients with both subtypes of CRS tend to exhibit mucosal edema, ostial obstruction, ciliary dysfunction, and an abhorrent inflammatory milieu.

Two of the following symptomatic criteria must be present to diagnose CRS: purulent nasal drainage, nasal obstruction, facial pain-pressure-fullness, and decreased sense of smell. These patients may also experience acute exacerbation, generally signified by an escalation of symptoms. Frequently, this is due to bacterial infection. However, patients with acute exacerbation of CRS may be distinguished from patients with recurrent acute bacterial rhinosinusitis (four or more episodes of ABRS per year) through baseline comparison: patients with CRS are symptomatic, even while at baseline, while patients with recurrent acute bacterial sinusitis are normal at baseline. As with ARS, the diagnosis of CRS requires objective confirmation utilizing either nasal endoscopy, CT scans, or, less commonly, MRI.

Nasal endoscopy is a critical element of the diagnosis of CRS. Abnormalities that may confirm the diagnosis of CRS include

- Purulent mucus in the middle meatus or anterior ethmoid region
- Edema in the middle meatus or ethmoid region
- Polyps in nasal cavity or the middle meatus

In addition to establishing the diagnosis, nasal endoscopy can be valuable in antibiotic selection by facilitating specific culture acquisition. Furthermore, simple polypectomy or steroid injection can be performed under topical anesthesia in the appropriate clinical setting.

Imaging is also an important clinical tool in the diagnosis of CRS. In general, CT is the modality of choice for diagnosis and management of CRS. Usual diagnostic criteria include mucosal thickening, sinus opacification, and bony remodeling (erosion or hyperostosis). It should be underscored, however, that CT scan is not the positive gold standard because many asymptomatic patients will demonstrate findings on a sinus CT scan, and many patients with presumed sinusitis will have negative findings. CT scan has excellent negative predictive value when performed in the setting of active symptoms. Thus, if a patient complains of rhinosinusitis-like symptoms but has no specific physical (endoscopic) findings, and the scan
is negative, other diagnoses (e.g., allergic rhinitis, migraine headache, tension headaches, and laryngopharyngeal reflux) should be sought. This has led to the utility of point-of-care CT (POC-CT) scan that can be performed in the physician’s office. POC-CT utilizes cone beam technology, which acquires the equivalent of >100 axial slices in approximately 1 minute at an effective resolution of 0.3 mm or less. The equipment occupies a room of 8’ × 10’ and can thus be accommodated in almost any office setting (Fig. 18-7). Perhaps most important, the radiation dosing for even the most sophisticated protocol is 0.17 mSv, which is <10% the dose of a conventional head CT and equivalent to approximately 20 days of background radiation. One theoretical shortcoming of this technology is that it does not permit soft tissue imaging. This is seldom a concern in sinonasal evaluation, as this is typically undertaken in bone windows. The acquired data are immediately formatted into triplanar (axial, sagittal, coronal) reconstructions and is also compatible with devices used for intraoperative stereotactic navigation, which can be used to confirm relationships between the disease process, medial orbital wall, and skull base during surgery (Figs. 18-8 and 18-9).

Medical management of CRS is heavily dependent on topical intranasal therapy. The reasons for this lie not only in established effectiveness but also in tolerability and safety—the chronic nature of CRS generally lends to requisite long-term medication administration despite other measures such as surgery. Nasal irrigation and topical nasal steroids are commonplace in the management of CRSwNP and CRSsNP. Oral steroids have demonstrated effectiveness in patients with CRSwNP, although the role in CRSsNP is less clear. Although otolaryngologists commonly utilize antibiotics in the management of CRS, indications and administration practices are not uniform. Oral antibiotic therapy given for short duration (<4 weeks) is generally useful in the management of acute exacerbation related to bacterial infection. Long-term utilization of antibiotics may be necessary in the setting of chronic infection or osteomyelitis. Additionally, long-term macrolide administration may be utilized for anti-inflammatory effects in the appropriate clinical setting.

In most cases, patients considering endoscopic sinus surgery (ESS) for CRS should have significant residual
symptomatology despite medical therapy. However, there currently exists no consensus regarding what constitutes a “maximum” course of medical therapy. It should be noted that unless there is suspicion of neoplasm or pending complication of rhinosinusitis, the decision to proceed with surgery is highly individualized. This is because surgery for uncomplicated CRS is elective, and patients who “fail” medical management will exhibit significant variability in symptoms, physical signs, and CT findings. Furthermore, ESS is not necessarily curative—the intent of ESS is to remove the symptoms related to CRS rather than cure the underlying condition itself.

Surgery is typically preformed endoscopically where the goals are to remove polyps, enlarge or remove obstructing tissue surrounding the natural sinus ostia (Fig. 18-10), and remove chronically infected bone and mucosa to promote both ventilation and drainage of the sinus cavities. Inspissated mucin or pus is drained and cultured. Eventual resolution of the chronic inflammatory process can be attained with a combination of meticulous surgery and directed medical therapy, although the patient must understand that surgery may not alter the underlying immunologic pathophysiology. In cases where resection of inflammatory tissue and polyps are not required, recent trends have also included use of angioplasty-type balloons to dilate sinus ostia. The exact role for this technology is unclear, but it appears to have promise in outpatient office management of patients with focal or limited obstructive pathology.

**Endoscopic Skull Base Surgery.** Over the past three decades, the development and expansion of multidisciplinary skull base teams has become somewhat commonplace at large academic institutions. Facilitated mainly by growing cooperation between otolaryngologists and neurosurgeons, a variety of approaches that utilize the sinonasal corridor to treat a plethora of pathologic processes of the anterior skull base have been developed.

Technological advances in endoscopy, instrumentation, and imaging have also facilitated the development of endoscopic endonasal approaches (EEAs), allowing team members to work simultaneously while maintaining optimal visualization of the relevant anatomy and freedom of movement within the corridor. Although historically the sphenoid sinus has been the common access route in the management of sellar pathology, a series of modular approaches of varied complexity have been developed that have broadened the reach of EEAs to address lesions at virtually all comportments of the ventral skull base, from the crista galli to the anterior arch of C2.22

One of the key tenets of the EEA is that the sinonasal corridor presents the most prudent and safest path to the lesion of interest. Accordingly, the EEA is generally chosen for lesions adjacent to the skull base, without intervening brain parenchyma, cranial nerves, major vessels, or other important anatomical structures. Currently, EEAs are utilized to treat a significant number of pathologic process involving the skull base, including: cerebrospinal fluid leaks, encephaloceles, meningoceles, pseudomeningoceles, benign intracranial tumors (Fig. 18-11), benign sinonasal tumors, malignant sinonasal tumors, and inflammatory or traumatic conditions leading to compression at the craniovertebral junction. Although EEAs tend to be considered “minimally invasive,” the corridor created in the sinonasal cavity is nonetheless comprehensive enough to
Figure 18-10. A. Endoscopic view of the right nasal cavity demonstrating the uncinate process (U), ethmoid bulla (EB), middle turbinate (MT), inferior turbinate (IT), and nasal septum (S). B. Endoscopic view of a microdebrider being used to widen the right maxillary sinus ostium.

Figure 18-11. Preoperative coronal (A) and sagittal (B) magnetic resonance images of a large olfactory groove meningioma removed using endoscopic endonasal approach. Postoperative coronal (C) and sagittal (D) images demonstrating removal of the tumor. The skull base can be reconstructed using local flaps (most commonly a nasoseptal flap pedicled on the posterior nasal artery).
provide maximal freedom of movement for the critical component of the case (i.e., tumor resection near vital structures). Once the corridor is created by the otolaryngologist, the neurosurgeon joins, and a two-person, three- to four-hand technique is utilized to address the lesion of interest and reconstruct the skull base (Fig. 18-12).

Despite the relatively confined aperture provided by the nostrils, even large tumors can be removed using EEAs, albeit via piecemeal removal. For malignant tumors, this has required a philosophical shift whereby en bloc resection of the entire tumor is replaced by piecemeal removal of the bulk of the tumor followed by complete resection of the pedicle with sufficient margins. Outcomes utilizing EEAs for resection of malignant tumors, when chosen appropriately, parallel those of traditional open approaches. However, EEAs are not favored over traditional approaches when oncological principles would otherwise need to be violated.

**Pharyngeal and Adenotonsillar Disease**

Waldeyer’s ring consists of the palatine tonsils between the anterior and posterior tonsillar pillars, the lingual tonsils (lymphoid tissue in the base of tongue), and the adenoid located in the nasopharynx. These four main sites of Waldeyer’s ring are connected by other minor lymphoid tissue along the posterior and lateral pharyngeal wall completing the ring. These are all considered mucosa-associated lymphoid tissue (MALT). These tissues react to inflammatory disease, infection, trauma, acid reflux, and radiotherapy. Even the vibratory effects of chronic snoring have been implicated in the development of adenotonsillar disease. Inflammation of these tissues can lead to referred pain through cranial nerves IX and X to the throat and ear. Adenotonsillar tissue does not have any afferent lymphatics and receives antigen presentation directly, with appropriate production of memory cells. However, there is no clear immune compromise after removal.

**Microbiology and Complications.** Adenotonsillar infections present with three temporal patterns: acute, recurrent acute, and chronic. Acute infection is typically viral in origin but secondary bacterial invasion may initiate chronic disease. Viruses do not cause chronic infections; however, Epstein-Barr Virus (EBV) can cause significant hypertrophy. Systemic EBV infection, also known as mononucleosis, can mimic bacterial pharyngitis, but the progression of signs and symptoms demonstrates lymphadenopathy, splenomegaly, and hepatitis. This can be diagnosed on bloodwork (heterophile antibody or atypical lymphocytes). The most common bacterial causes of acute tonsillitis are group A β-hemolytic streptococcus species (GABHS) and *S. pneumoniae.* If GABHS is confirmed, then antibiotic therapy is warranted in the pediatric population to decrease the risk (3%) of developing rheumatic fever. A positive test for GABHS historically meant a throat swab with culture and sensitivity; however, rapid antigen assays have been demonstrated to be reasonably sensitive and specific (85% and 95%, respectively), thus largely replacing cultures. If the rapid assay is negative, then a culture is warranted. The remainder of the bacteriology for adenotonsillar disease is similar to otitis media and sinusitis, which includes *H. influenzae* and *M. catarrhalis.* Atypical infections include *Corynebacterium diphtheria,* *Neisseria gonorrhoeae,* and *Chlamydia trachomatis.*

Complications of GABHS pharyngitis, typically from *S. pyogenes,* can be systematic and include poststreptococcal glomerulonephritis, scarlet fever, and rheumatic fever. Antibiotic therapy does not decrease the incidence of glomerulonephritis. Scarlet fever, caused by blood-borne streptococcal toxins, causes a strawberry tongue and a punctate rash on the trunk that spreads distally while sparing the palms and soles. Peritonsillar abscess is also a common complication that is treated in an ambulatory setting through a transoral approach after appropriate topicalization and local anesthetic. Deep neck space infections are rare from pharyngitis but can occur from odontogenic and salivary gland infections. These typically require a transcervical approach for incision and drainage.

**Adenoids and Adenoidectomy.** Acute adenoiditis typically presents with purulent rhinorrhea, nasal obstruction, and fever and can be associated with otitis media, particularly in the pediatric population. Recurrent acute adenoiditis is defined as four or more acute infections in a 6-month period, but in an adult, this may be difficult to distinguish from recurrent acute sinusitis, and endoscopy with or without imaging of the sinuses may be warranted to distinguish between the two diagnoses. Chronic adenoiditis presents with persistent nasal discharge, halitosis, chronic congestion, and postnasal drip. In children, obstructive adenoid hyperplasia often requires surgical intervention to help relieve obstructive symptoms such as snoring, obligate mouth breathing, and hyponasal voice.

The management of adenoid disease is slightly different than that for tonsillar disease. Chronic infection can be treated with antibiotics, although this often does not lead to a full resolution of symptoms. If the adenoid bed appears hyperplastic on lateral X-ray imaging or endoscopy, a 2-month trial of nasal steroids may be helpful. Adenoidectomy is indicated for recurrent and chronic infections that have failed conservative management. These infections are not limited to the adenoid bed but also involve the sinuses and the middle ear. Adenoidectomy with a myringotomy and ventilation tube placement is beneficial for recurrent or chronic otitis media in children because the

**Figure 18-12.** Two-surgeon, three- to four-hand technique utilized in endoscopic endonasal surgery.
Adenoid functions as a reservoir for bacteria that can enter the middle ear through the Eustachian tube.\textsuperscript{25}

Adenoidectomy is also the first line of surgical management for children with chronic sinusitis because the adenoid can obstruct mucociliary clearance from the sinonasal tract into the choana and ultimately into the pharynx. Patients with obstructive systems attributable to the adenoids and suspected benign or malignant neoplasms of the adenoid bed are also candidates. However, the procedure is contraindicated in patients with velopalatine insufficiency (VPI) and in patients with a cleft palate. Prior to adenoidectomy, patients should be examined for a submucous cleft, a lack of midline muscular tissue of the soft palate. Clinical signs of this include a bifid uvula, a translucent portion of the muscular diastasis of the soft palate (zona pellicuda), and a palpable notched hard palate.\textsuperscript{26} A number of different methods can be used to perform an adenoidectomy: cold steel, suction coagulator, microdebrider, and coblation. Adenoid regrowth and bleeding rates are both low, and no study has been able to demonstrate the superiority of one technique over the other for either outcome.\textsuperscript{27,28} Adenoidectomy is not without complications though, beyond VPI and bleeding, halitosis and adenoid bed regrowth (\textminus1\%) are common complications. Rare complications include torticollis secondary to inflammation of the prevertebral fascia, nasopharyngeal stenosis, and cervical spine subluxation, which is more common in patients with Down syndrome.

**Tonsils and Tonsillectomy** Patients with acute tonsillitis present with sore throat, fever, dysphagia, and tender cervical nodes with erythematous or exudative tonsils. The Centor Criteria is used to identify the likelihood of bacterial infection in adult patients complaining of sore throat in the emergency department or walk-in clinic, a point is given for each of the following: fever, tonsillar exudate, lymphadenopathy, and lack of cough.\textsuperscript{29-31} A score of 0 to 1 warrants no treatment, a score of 2 to 3 warrants GABHS testing, and a score of 4 warrants initiation of antibiotic therapy. First-line treatment is with penicillin or a cephalosporin; however, in those with an allergy, a macrolide can be considered. Documentation of recurrent acute infections should include a temperature ($>38.3^\circ$C), cervical adenopathy, tonsillar exudate, and a positive test for GABHS.

According to the American Academy of Otolaryngology—Head and Neck Surgery (AAO-HNS) clinical practice guideline on tonsillectomy in children, tonsillectomy is indicated when children have more than 7 documented episodes per year, 5 episodes per year in the past 2 years, or 3 episodes per year in the past 3 years.\textsuperscript{32} Tonsillectomy can still be considered in children who do not meet these criteria if they have multiple antibiotic allergies or intolerances, have a history of peritonsillar abscess after the acute inflammation has resolved, or have PFAPA (periodic fever, apthous stomatitis, pharyngitis, and adenitis). A peritonsillar abscess is an infection of the peritonsillar salivary gland (Weber’s gland), located between the tonsil capsule and the muscles of the tonsillar fossa. In selected cases of active peritonsillar abscess, tonsillectomy is required in the acute setting to treat systemic toxicity or impending airway compromise. Multiple techniques have been described, including electrocautery, sharp dissection, laser, and radiofrequency ablation. There is no consensus as to the best method.

**Sleep Disordered Breathing and Adenotonsillar Disease.** Patients with sleep-disordered breathing (SDB) and tonsillar hypertrophy may also benefit from tonsillectomy if they have growth retardation, poor school performance, enuresis, or behavioral problems. The benefits may be accentuated in children with abnormal polysomnography; however, DB may require further treatment after tonsillectomy when it is multifactorial. Clinical documentation of tonsillar grade/size is based on the percentage of the transverse oropharyngeal space measured between the anterior tonsillar pillars: grade 1 $<25\%$; grade 2+ 25\% to 49\%; grade 3+ 50\% to 74\%; grade 4+ $\geq75\%$ or more sometimes referred to as “kissing tonsils.”\textsuperscript{33} Tonsillectomy is effective for control of SDB in 60\% to 70\% of patients with tonsillar hypertrophy, although this much lower (10\%–25\%) in obese children, and it is therefore not curative in obese children but may improve some of their symptoms nonetheless. In patients with Down syndrome, obesity, craniofacial abnormalities, neuromuscular disorders, sickle cell disease, or mucopolysaccharidoses, polysomnography (PSG) should be performed prior to tonsillectomy.\textsuperscript{33} When the need for surgery is uncertain or when there is a discordance between tonsillar size on physical examination and the reported severity of SDB, physicians should advocate for PSG prior to tonsillectomy. Tonsillectomy, usually with adenoídectomy if the adenoids are enlarged, is often performed on an outpatient basis unless the patient has documented or strongly suspected obstructive sleep apnea (OSA), is $<3$ years of age, or has severe OSA (in children, an apnea-hypopnea index $\geq10$ or more, oxygen saturation $<80\%$, or both). Other reasons for admission include a home $>1$ hour from a hospital, patients with craniofacial abnormalities, or any other medical issue. There is strong evidence to suggest the routine administration of a single intraoperative dose of IV dexamethasone in children undergoing tonsillectomy, though antibiotics should not be administered or prescribed perioperatively in children. The complications from tonsillectomy include perioperative bleeding (3\%–5\%), airway obstruction, death, and readmission from postoperative dysphagia leading to dehydration.\textsuperscript{34} It is recommended that surgeons calculate and quote their own primary and secondary posttonsillectomy hemorrhage rates yearly.\textsuperscript{35} A rare but serious complication in patients with obstructive adenotonsillar disease post adenotonsillectomy is postobstructive pulmonary edema syndrome, which presents with decreased oxygen saturation and frothy, blood-tinged oral secretions. Patients usually recover with reintubation, positive pressure, diuresis, and supportive care.

**Multilevel Sleep Surgery.** SDB surgery is often multilevel and is not limited to adenotonsillar disease. Patients with nasal obstruction may benefit from septoplasty and tracheotomy reduction, although in the adult population this is most commonly used to allow patients to tolerate their OSA appliances. Similarly, patients with significant lingual tonsillar hypertrophy and a large base of tongue may benefit from a base of tongue reduction, tongue base advancement, or geniohyoidopexy. A base of tongue reduction alone does not often provide enough apnea-hypopnea index reduction (30\%–60\%) for resolution of symptoms and is fraught with a high morbidity rate.\textsuperscript{35} Rarely, maxillomandibular advance is required to open up the retrolingual space. In patients with life threatening symptoms (right heart failure/cor pulmonale, oxygen saturation $<70\%$, comorbid cardiopulmonary disease) who have failed other measures, the only “cure” for OSA is a tracheotomy.

**Other Tonsillar Pathology.** Unilateral tonsillar hypertrophy is mostly benign but can also be the result of *Mycobacterium tuberculosis*, atypical mycobacterium, fungi, or Actinomyces. With the epidemic rise in incidence of oropharyngeal
cancers, neoplasms (squamous cell carcinoma and lymphoma) have increasingly also presented as tonsillar asymmetry.\(^{36}\) Management of these lesions is dependent on the pretest probability of malignancy and the type of malignancy. If squamous cell carcinoma is suspected, then a biopsy alone is sufficient so as to not impact the possibility of other future surgical interventions such as transoral robotic surgery. If lymphoma or a nonmalignant pathology is suspected, tonsillectomy is often recommended for diagnostic and therapeutic reasons, and the specimen should be sent fresh to pathology for a lymphoma protocol workup, bacterial and fungal culture, and gram stain. Pharyngitis may also be seen in immune-mediated conditions such as erythema multiforme, bullous pemphigoid, and pemphigus vulgaris.

### Benign Conditions of the Larynx

Hoarseness is the most common presenting symptom for patients with a voice complaint. Other complaints include breathiness, weakness/hypophonia, aphonia, and pitch breaks. Voice disorders affect a large range of patient ages, occupations, and socioeconomic statuses and affect both genders equally. They can be associated with dysphagia, globus sensation, laryngopharyngeal reflux (LPR) disease and, rarely, airway obstruction.\(^{37}\) Smoking can both cause and aggravate preexisting benign laryngeal conditions and raises the suspicion of malignancy often requiring a biopsy to exclude this diagnosis.

Any discussion of laryngeal disorders should start with a review of the anatomy of the vocal cords (Fig. 18-13). The true vocal cords are formed from stratified squamous epithelium, beneath which is the superficial lamina propria (in Reinke’s space). Beneath this is the ligament that includes the middle and deep lamina propria. Beneath this ligament is the muscular layer that includes the thyroarytenoid muscle or vocalis. The cover-body theory describes the freely mobile cover (mucosa and Reinke’s space) over the more rigid body (vocalis and vocalis).\(^{38}\)

Membranous vocal cord lesions have been notoriously difficult to classify reliably; however, increased availability of videoendoscopic examination and standardized definitions have improved the classification of these lesions.\(^{39}\) These lesions are usually mid cord because that is the site of maximal lateral displacement and amplitude. Vocal fold nodules are typically bilateral, fairly symmetric, and with normal or mild impairment of the mucosal wave, and they almost always resolve with voice therapy. A vocal fold polyp is more often unilateral than bilateral, is exophytic, and is associated with unorganized gelatinous debris in the subepithelial space. These can be hemorrhagic as is often seen in males secondary to capillary rupture within the mucosa by shearing forces during voice abuse. Hemorrhagic polyps are seen more often in patients on anticoagulants. These lesions usually fail conservative measures (voice rest, voice therapy, smoking cessation, and reflux management) usually requiring microlaryngeal surgery to remove the lesion while preserving normal mucosa. Vocal fold cyst is an encapsulated lesion within the subepithelial or ligamentous space and is associated with reduced mucosal wave. It typically does not resolve with voice therapy. These lesions require microlaryngeal surgery for complete removal of the cyst while preserving the overlying mucosa, and this surgery can be performed with cold steel or carbon dioxide (CO2) laser. A fibrous mass of the vocal fold is amorphous fibrous material within the subepithelial space or

---

**Figure 18-13.** Coronal view of the larynx demonstrate the supraglottic, glottic and subglottis (LEFT) and the layers of the true vocal cord (RIGHT).
ligament often associated with reduced mucosal wave, and it also does not resolve with voice therapy.

Reinke’s edema is characterized by edema in the superficial lamina propria of the vocal cord. Edema is thought to arise from injury to the capillaries that exist in this layer, with subsequent extravasation of fluid. The etiology is multifactorial: smoking, LPR, hypothyroidism, and vocal misuse. This pathology is more common in women (because they present early due to a deep vocal pitch change in their voice) and heavy smokers. The physical examination findings are typically bilateral. Surgery typically involves microlaryngoscopy with removal of the gelatinous debris in Reinke’s space with trimming of the excess mucosa. However, smoking cessation and surgery do not fully reverse the structural abnormalities due to the presence of possible structure alterations in fibroblasts caused by the toxicity of cigarette components, resulting in uncontrolled production of fibrous matrix in the lamina propria, thus preventing complete vocal recovery.

Laryngeal granulomas typically occur in the posterior larynx on the arytenoid mucosa (Fig. 18-14). These lesions are typically multifactorial: chronic throat clearing, phonotrauma, endotracheal intubation, compensatory supraglottic squeeze from vocal fold paralysis, and LPR. The majority of these lesions (82%) disappear within 48 weeks with conservative measures such as voice therapy, vocal rest, oral steroids, inhaled steroids, and proton pump inhibitors. Botulinum toxin of thyroarytenoid and lateral cricoarytenoid muscles can be used as first-line treatment in patients who prefer a chemically activated voice rest regimen. LPR appears to be the most important contributing factor, and when aggressive conservative and medical therapy has failed, a Nissen fundoplication may be indicated. Surgery is rarely required for patients with laryngeal granulomas because it does not address the underlying etiology and is frequently associated with recurrence. Nonetheless, excision is sometimes required in patients with airway obstruction or the suspicion of malignancy. Careful preservation of the arytenoid perichondrium intraoperatively is required to assist with reepithelialization and to decrease the risk of recurrence postoperatively.

Recurrent respiratory papillomatosis (RRP) is pathophysiologically associated with human papillomavirus (HPV) within the mucosa of the upper aerodigestive tract. The glottis and supraglottis are the two most common involved subsites. HPV 6 and 11 are the most often implicated types; however, LPR and herpes simplex virus (HSV) type-2 are risk factors of adult-onset RRP. The disorder typically presents in early childhood (juvenile-onset RR; JoRRP) secondary to HPV acquisition during vaginal delivery; however, children born by caesarean section are also at risk for the disease. JoRRP usually resolves around puberty but can progress into adulthood. Adult-onset RRP is less severe and is more likely to involve extralaryngeal subsites. There is no cure for RRP. Surgery excision is used to improve voice and airway symptoms in a palliative fashion. Surgical excision in the operating room involves microlaryngoscopy with the use of the laser (CO2 for bulky disease or KTP for more superficial disease) or the use of a microdebrider. The microdebrider has been demonstrated to have superior voice outcomes in JoRRP; however, CO2 laser is the most commonly used operative ablative technique used in adults. Recent advances have made it possible to treat a select group of adult RRP patients in the office using the KTP laser, typically for those with a lower disease burden. Several adjuvant treatments are used to increase the intersurgical interval, including intralesional cidofovir injection, oral indole-3-carbinol, oral methotrexate, and retinoic acid. In addition to preventing RRP in some patients, the HPV vaccine has also been demonstrated to increase the intersurgical interval in the most aggressive JoRRP patients.

Leukoplakia is a white patch seen on mucosa that can be wiped off on physical examination. This can be seen anywhere in the upper aerodigestive tract. In the larynx, this is typically seen on the superior surface of the true vocal cords and may represent squamous hyperplasia, dysplasia, and/or carcinoma with an associated risk of malignant transformation of 1% to 3% in hyperplastic lesions and 10% to 30% in dysplastic lesions. Lesions that are not overtly suspicious for malignancy, particularly in patients without a strong smoking or alcohol history, can be managed conservatively (increased hydration, elimination of poor vocal habits, phonotrauma, and management of LPR) for 1 month before reevaluation with fiberoptic laryngoscopy. Any lesions that progress, persist, or recur could have microlaryngoscopy with complete excision. Similarly, because erythroplasia and ulceration are more suggestive of malignancy, these lesions also require an excisional biopsy in the operating room.

The most common cause of unilateral vocal cord paresis is iatrogenic in origin, following surgery to the thyroid, parathyroid, carotid, spine through an anterior approach, or cardiothoracic structures. It is therefore very important that all patients undergoing thyroid surgery receive preoperative visualization of the larynx, usually in the form of fiberoptic nasolaryngoscopy, although an indirect mirror exam can be used if adequate visualization is possible. Postthyroidectomy visualization may also be required to document normal vocal cord movement. Less common causes include malignancy of structures near the recurrent laryngeal nerve (RLN) from the skull base jugular foramen to the mediastinum. In the pediatric population, there can be neurologic causes, the most common of which is the Arnold-Chiari malformation. Overall, the left vocal cord is more commonly involved secondary to the longer course of the RLN on that side. Other rare etiologies include trauma, intubation injury, atypical infections, and neurotoxic medications. Patients typically present with a weak breathy voice and may have aspiration secondary to diminished supraglottic sensation if the proximal vagal nerve or superior laryngeal nerve is involved. RLN injury is also associated with delayed relaxation.

Figure 18-14. Laryngeal granuloma.
of the cricopharyngeus muscle that can lead to dysphagia and decreased sensation in the hypopharynx, which can cause pooling of secretions. In children, stridor, weak cry, and airway compromise may be presenting symptoms, whereas in adults this is rarely the case unless there is bilateral vocal cord paralysis. When an obvious cause is not identified after a thorough history and physical examination including fiberoptic nasolaryngoscopy, then a more comprehensive workup is required. A workup should not include autoimmune serology as a screen because this is low yield, but this can be included if there is a suspicion of autoimmune disorders. Imaging, in the form of a CT scan, is the mainstay of the workup and should include the skull base to the mediastinum. Repeat imaging is beneficial in this population within a 2-year period because many patients have undiagnosed small malignancies as the primary cause of their paralysis that are too small to detect on initial imaging. Laryngeal electromyography can assist with identifying whether the paresis is a result of a paralysis or cricoarytenoid joint fixation/dislocation. It can also help prognosticate a paralysis. This is, however, rarely used in practice. Despite an extensive workup, 20% to 35% of cases are idiopathic.

The management of bilateral vocal cord paralysis almost always requires a tracheotomy because the cords are left in a paramedian position leaving a slit light glottic aperture. If the paralysis is permanent, then a cordectomy with or without arytenoidectomy can be used to open up the airway in an attempt to eventually decannulate the patient. However, this has obvious implications for voice with a weak and breathing voice. Many patients with a unilateral paralysis compensate when the cord is in the paramedian position using supraglottic structure and the contralateral cord on their own or with speech therapy. However, in patients with a less than adequate voice-related quality of life, four techniques have been used to surgically manage patients with a unilateral vocal cord paralysis: injection laryngoplasty, medialization thyroplasty, arytenoid addition, and laryngeal reinnervation. Injection laryngoplasty involves injecting a temporary filler medial to the vocalis into the ligament at the posterior and midmembranous vocal cord. This can be performed in the office or in the operating room, depending on the comfort of the surgeon and patient characteristics. Materials used include autologous (fat, collagen) or alloplastic (hydroxyapatite, hyaluronic acid, micronized cadaveric human collagen) compounds. Early medialization is recommended in patients with mediastinal and thoracic malignancies because it is safe and has been shown to improve quality of life in a palliative setting. Teflon is historic and is no longer used because of its granulomatous side effects on the larynx. A more permanent medialization can be performed using a medialization thyroplasty, during which a small window is created in the inferolateral aspect of the thyroid cartilage and a submucosal-carved silastic block is placed in the operating room with the patient under neurolept anesthetic so that vocalization and flexible laryngoscopic visualization of the larynx can be improved (Fig. 18-15). In some cases, this is not enough of a medialization due to a large posterior glottic chink, and an arytenoid adduction is required to provide better closure of the posterior glottis and supraglottis with ensuing improved vocal outcomes. This is a technically challenging procedure that is rarely required, but in select patients it is associated with significant improvements in voice. Lastly, laryngeal reinnervation, typically with the ansa cervicalis that supplies motor function to the strap muscles, can also be performed. This is the best approach in patients who have had a recurrent laryngeal nerve severed during a central or upper mediastinal neck procedure because it is in the field. Multiple studies demonstrate favorable outcomes; however, no significant differences between treatment arms has been demonstrated based on perceptual, acoustic, quality of life, and laryngoscopic outcomes.

Vascular Lesions

Vascular lesions can be broadly classified into two groups: hemangiomas and vascular malformations.

Hemangiomas. Hemangiomas are the most common vascular lesion present in infancy and early childhood. Infantile hemangiomas present largely within the first few weeks of life. Initially they proliferate (2 weeks to 1 year), and then they begin to involute (1–7 years) until they have fully involuted, leaving the child with redundant skin, scar, or a fatty lesion. Children with large facial infantile hemangiomas benefit from regular neurological examinations and brain MRI to rule out PHACES syndrome (Posterior fossa malformations, Hemangiomas, Arterial lesions, Cardiac abnormalities/aortic coarctation, Eye abnormalities). Only 10% of these lesions require early intervention because of impairment of vision or swallowing, or airway compromise. Early intervention can include medical management, such as systemic steroids, intraleisional steroids, intraleisional interferon α-2a, or photocoagulation therapy, and surgical management, including excision with CO₂ laser/microdebrider and tracheotomy. Systemic steroids assist with rapidly proliferating lesions until the child reaches approximately one year of age; however, it is associated with growth retardation and immune suppression. Intraleisional interferon α-2a has been largely abandoned because it is a daily subcutaneous injection and is associated
with significant neurological side effects, including spastic diplegia. Photocoagulation therapy with either the flashlamp-pumped pulsed-dye laser (FPDL), the potassium titanyl phosphate (KTP) laser, or the neodymium yttrium-aluminum garnet (Nd:YAG) laser, is repeated every 4 to 6 weeks until the lesion disappears. A randomized trial recently demonstrated that propranolol was effective at a dose of 3mg/kg per day for 5 months in the treatment of infantile hemangioma with a very acceptable and low side-effect profile.57 Other groups have had success at discontinuing propranolol at 1 year of age with excellent outcomes.58 For patients who do not require early intervention, the lesion is observed every 3 months for involution after the proliferative phase has ended. Surgery is considered if regression has not occurred by 5 years of age because the cosmetic result is less likely to be satisfactory.

**Congenital hemangiomas** differ from infantile hemangiomas in that they reach their maximal size at birth and do not have a proliferative phase. There are two subtypes: rapidly involuting (RICH), which typically disappears by 1 of age with minimal fatty appearance upon resolution, and noninvoluting (NICM). The management is similar to infantile hemangiomas with the exception that medical management is not typically necessary.

**Vascular Malformations.** Vascular malformations, in contrast to infantile hemangioma, are always present at birth, although they may not be apparent for a few months. Although they do not have a proliferative phase, they grow with the patient, have hormonal growth spurts and do not involute.59 Vascular malformations can be classified as low flow (capillary, venous, lymphatic, and mixed), which comprise approximately two-thirds of all vascular malformations, or high flow (arteria and arteriovenous).

Capillary malformations arise from the cutaneous superficial plexus and are made up of capillary and postcapillary venules with a pink, red, or purple macular-papular appearance. Venous malformations arise from dilated vascular channels lined by normal endothelium; therefore, they are soft, compressible, and nonpalpable. If they are superficial, they will increase in size with Valsalva or dependent positioning. They can grow suddenly with trauma or in association with hormonal changes. Lymphatic malformations typically present at birth with the majority (90%) being identified by 2 years of age. They can be macrocystic (>2 cm), microcystic (<2 cm), or a combination. They are most commonly found in the head and neck, particularly on the neck, and on physical examination they are soft and doughy with normal overlying skin. Infrayoid lesions tend to be macrocystic, well circumscribed, and discrete and can be totally excised, whereas suprayoid lesions are typically microcystic, infiltrative, and excision is usually incomplete. On MRI, the best imaging modality for this malformation, a septated mass with low-intensity signal on T1 and high-intensity signal on T2 is noted. They grow slowly with the patient but can have a sudden increase in size with hemorrhage or infection. Rarely, they cause airway compromise, feeding difficulties, and failure to thrive.

Treatment of vascular malformations is based on depth, size, and growth pattern. Capillary malformations are typically treated with the pulsed dye laser (585 nm). Venous lesions can be treated with the KTP laser (532 nm) or the Nd:YAG laser (1064 nm), sclerotherapy, and, in select cases, complete surgical excision is possible. Arteriovenous malformations are rare but typically require surgical excision with negative margins often after embolization. Lymphatic malformations are typically treated at least in part with surgical excision, although this is less successful for microcystic lesions. OK-432 is lyophilized low virulence *S pyogenes* cultured in penicillin. It is used as a sclerotherapy agent for lymphatic malformations and has a 94% response rate in macrocystic lesions, a 63% response rate in mixed macromicrocystic lesions, and no response in microcystic lesions.60

**TRAUMA OF THE HEAD AND NECK**

**Soft Tissue**

Soft tissue trauma of the head and neck is managed with the same general surgical principles as any other body subsite with a few particularities. Most lacerations can be closed primarily if there is not soft tissue loss; even some devitalized soft tissue should be preserved because of the excellent blood supply to head and neck tissue that allows it to recover at a higher rate. Thus, minimal debridement is usually required. Thorough irrigation to remove foreign bodies and clean the tissue is required. This is followed by a careful layered closure. On the face, the deep layers are usually closed with a 3-0 or 4-0 Vicryl/Polysorb after a minimal amount of undermining, and interrupted 5-0 or 6-0 Prolene or Nylon is used for the skin. These sutures are removed at 5 days on the face. Antibiotics are reserved for through-and-through mucosal lacerations, contaminated wounds, bite injuries, and when delayed closure is performed (>72 hours). The chosen antibiotic should cover *S aureus*. Patients are instructed to avoid sunlight because this can cause pigmentary abnormalities in the suture line as it heals and matures over the first year.

Eyelid lacerations are closed in layers with careful reaproximation of the orbicularis oculi as a separate layer. Another important layer to reaproximate separately is the gray line (conjunctival margin) so as to avoid height mismatch or lid notching. Lip injuries follow the same principle with a three-layer closure involving the orbicularis oris, which is the strength layer, followed by careful reaproximation of the vermilion border to avoid a step-deformity (Fig. 18-16). Of course, a mucosal layer closure may also be required for through-and-through defects. Rarely, locoregional flaps or grafts are required for closure when greater than one-fourth of the eyelid width or one-third of the lip width is missing. Auricular hematoma is managed with prompt incision and drainage followed by bolstering technique; anteriorly and posteriorly placed dental pledgets secured with through-and-through sutures. These are to remain in place for at least 4 days to prevent reaccumulation of the hematoma and to prevent a cauliflower ear deformity. Auricular lacerations are typically closed primarily with perichondrial sutures to preserve the precarious cartilage blood supply followed by a primary closure of the skin, making sure to cover the cartilage to prevent chondritis. Given the rich vascular supply to the face and neck, many soft-tissue components that appear devitalized will indeed survive, and therefore minimal debridement of devitalized tissue is required.

Facial lacerations resulting in facial nerve injury are not explored if they are anterior to a vertical line dropped from the lateral canthus as there is excellent collateral innervation in the anterior midface. Posterior to this line, the nerve should be repaired, primarily if possible, using 8-0 to 10-0 monofilament suture to approximate the epineurium under the operative
microscope. If primary reapproximation is not possible due to a missing segment, cable nerve grafts can be performed using the sural nerve or the greater auricular nerve. If the buccal branch is injured, this raises suspicion regarding injury to the parotid duct, which lies along an imaginary line drawn from the tragus to the midline upper lip. The duct should be repaired over a 22-gauge stent or marsupialized into the oral cavity.

**Facial Fractures**

The most common facial fracture involves the mandible. Fig. 18-17 demonstrates the most common sites of fracture, which include the condyle (36%), body (35%), and angle (20%). In most cases, more than one site is involved due to reciprocating forces. The vector forces from the muscles of mastication, vertical from the masseter and horizontal from the pterygoid muscles, can cause a fracture to be favorable or unfavorable depending on the angle of the fracture line. After taking a history and performing a physical examination, imaging is performed in the form of a Panorex or a CT scan. Where closed reduction can be achieved, patients are placed in maxillomandibular fixation (MMF) with arch bars applied via circumdental wiring, and these are left in place for 4 to 6 weeks depending on patient factors and the fracture location. In elderly patients, this is kept in for 6 to 8 weeks. In children and patients with condylar fractures only 2 to 3 weeks is required, and this is important to prevent condylar ankylosis. During this time, patients are placed on a liquid diet and are provided with wire cutters in case of aspiration or airway emergency. Open reduction and fixation is indicated in patients with open, comminuted, displaced, or unfavorable fractures. In these patients, MMF is usually only temporary with a soft diet starting almost immediately in the postoperative setting. Because the MMF is temporary with rigid fixation, it is performed usually using the 4-point fixation technique, where the maxilla and mandible are held in occlusion by wires attached to intraoral cortical bone screws, with two screws above and below the occlusal line anteriorly. This is a benefit of open reduction and internal fixation because prolonged MMF is associated with gingival and dental disease, as well as with significant weight loss and malnutrition, during the fixation period. After fixation, the fracture is exposed, more commonly from a transcervical compared to a transoral approach. Care is made not to injure the marginal mandibular branch of the facial nerve during this exposure. A rigid, locking, load-bearing mandibular plate is used. In edentulous patients, determining the baseline occlusion is of less significance because dentures may be refashioned once healing is complete.

Midface fractures are rarely isolated and include multiple subsites. However, isolated zygoma fractures are typically displaced inferior inferiorly and medially with disruption of the suture lines between the temporal, frontal, and maxillary bones and the zygoma. If multiple zygoma fractures are present or if the zygomatic arch is significantly displaced, a coronal incision is required to perform the reduction and fixation. However, if it is an isolated depressed fracture, a Gilles reduction can be achieved inferiorly (transorally) or superiorly (along temporalis muscle). The pathophysiology of orbital blow-out fractures is (a) hydraulic from increased intraocular pressure or (b) buckling from direct bone conduction. This requires surgical intervention if there is a defect of $\geq 2 \text{ cm}^2$ or $>50\%$ of the floor with herniation. A forced duction test, where the musculature attachment of the inferior oblique is grasped with forceps and manipulated to determine passive ocular mobility, is performed to ensure that there is no inferior rectus entrapment. If there is entrapment, this would also result in diplopia with upward gaze. Blowout fractures demonstrating significant entrapment or enopthalmos are treated by orbital exploration and reinforcement of the floor with titanium mesh, hydroxyapatite, or split calvarial bone grafts. Sometimes, the anterior maxillary bone that has been fractured and is accessed in the process of repairing other fractures can also be used.

There are three classic patterns of more extensive midface fractures: Le Fort I, II, and III. However, fractures rarely follow this exact pattern, and the two sides of the face may have different Le Fort fractures. Nonetheless, a full understanding of midface buttresses is central in understanding these fractures (Fig. 18-18). There are three vertical buttresses: the nasofrontal-maxillary, the frontozygomaticomaxillary, and
DISORDERS OF THE HEAD AND NECK

CHAPTER 18

There are five horizontal buttresses: the frontal bone, nasal bones, upper alveolus, zygomatic arches, and the infraorbital region. Signs of midface fractures include subconjunctival hemorrhage, ocular signs/symptoms, malocclusion, facial asymmetry, midface hypoesthesia (V2), hematoma, and a mobile maxillary complex. Transverse maxillary alveolus fractures above the teeth are Le Fort I fractures, which may result in a mobile hard palate. When this fracture extends superiorly to include the nasofrontal buttress, medial orbital wall, and even as high as the infraorbital rim and zygomaticomaxillary articulation laterally, it is considered a Le Fort II. Mobility includes the palate, nasal dorsum, which is separated from the upper face, and the inferomedial aspect of the orbital rim. When the fracture disrupts the frontozygomaticomaxillary, frontomaxillary, and frontonasal suture line, craniofacial disjunction, a Le Fort III fracture. Of note, all of the Le Fort fractures involve the pterygoid plates posteriorly (Fig. 18-19).

Temporal Bone Fractures

Temporal bone fractures occur in approximately one fifth of skull fractures. Temporal bone fractures were previously classified as longitudinal or transverse describing the path along the temporal bone of the fracture line, but this has been largely replaced by the more relevant otic capsule sparing or involving classification given that most fractures are oblique. Otic capsule sparing fractures present with conductive hearing loss, ossicular injury, bloody otorrhea, and labyrinthine concussion. The facial nerve is rarely injured nor cerebrospinal fluid (CSF) leak common with this fracture pattern. However, in patients with otic capsule involving temporal bone fractures, typically caused by occipitomastoid impact, sensorineural hearing loss, vestibular dysfunction, facial nerve paralysis, and CSF leak are far more common. Regardless of the fracture pattern, when CSF leak is suspected, it usually resolves with conservative measures including bed rest, elevation of the head of the bed, stool softeners, and avoiding sneezing or straining. In some cases, a CSF drain can be placed if there is a delay in spontaneous resolution. Rarely will surgical repair be required. Unlike CSF leaks with temporal bone fractures, the facial nerve needs to be assessed and managed urgently. An incomplete or delayed facial nerve paralysis almost always resolves spontaneously with conservative measures, including oral steroids. An immediate complete paralysis that does not recover within 1 week should be prognosticated to consider nerve decompression. Electroneurography (ENoG), EMG, and nerve stimulation tests have been used to help determine which patients with delayed-onset complete paralysis will benefit from surgical decompression. The finding of >90% degeneration more than 72 hours after the onset of complete paralysis is considered an indication for surgery. A nerve excitability test, where thresholds are increased to elicit visible muscle contraction on each side, can indicate advanced degeneration when there is a difference of >3.0 to 3.5 mA between sides. Whether surgical intervention is indicated or not for facial nerve paresis, it is crucial to protect the eye because a corneal drying and abrasion can lead to blindness in the absence of eye closure and a blink reflex. This requires application of ocular lubricant at night with the eye taped shut, frequent artificial tears application while awake, and a humidity chapter.

TUMORS OF THE HEAD AND NECK

Squamous cell carcinoma (SCC) comprises >90% of all of the malignant pathology of the mucosal lining of the upper aerodigestive tract. Naturally, a discussion of tumors of the head and neck typically focuses on this pathology presenting from the lips and oral cavity to the larynx and hypopharynx. Management of these tumors requires a systematic approach. The ideal treatment protocol varies by subsite, stage, patient comorbidity, and center preference/experience. Given the relative rarity of these tumors, multidisciplinary management is of the utmost importance to provide the patient with a balanced perspective. This can be performed in the form of a multidisciplinary clinic where radiation and surgical oncologists simultaneously see the patient or through a tumor board where a new patient’s history, physical examination findings, imaging, and prior pathology
specimens are reviewed. This encourages discussion from multiple points of view concerning the most appropriate treatment options available. In addition to radiation and surgical oncology, medical oncology, dentistry, speech language pathologists, radiologists, and pathologists contribute to the decision-making in this patient population. Some of the greatest advances in head and neck oncology over the last several decades include the development of standardized organ preservation protocols, advances in free flap reconstruction with microvascular techniques, and vaccinations. The future of head and neck oncology is bright with advances in molecular biology, immunotherapy, and preventative methods with vaccination. These have the potential of significantly decreasing incidence rates and improving survival and quality of life for those with the disease.

Etiology and Epidemiology
The main etiological factors associated with head and neck cancers are tobacco products and alcohol. Overall, there has been a decline in incidence of head and neck cancers of the oral cavity and larynx/hypopharynx subsites, likely related to public health campaigns and government taxation policies as it relates to cigarette consumption. Similarly, the incidence of head and neck cancer between countries varies widely and is strongly associated with the incidence of cigarette smoking. Cigarette smoking triples the likelihood of developing an oral cavity cancer, while the addition of alcohol synergistically increases the likelihood by 10- to 15-fold. The risk increases as the number of years smoking and number of cigarettes smoked per day increases. Individuals who both smoke (two packs per day) and drink (four units of alcohol per day) had a 35-fold increased risk for the development of a carcinoma compared to controls.

The preoperative and perioperative periods are excellent opportunities for head and neck oncologists to pursue a smoking cessation intervention. Continued smoking after completion of treatment is associated with a 3- to 4-fold increased risk of developing a second primary or recurrent tumor. A study assessing patients diagnosed with a new head and neck cancer demonstrated that of the patients that were smoking at diagnosis, only 54% were able to quit, highlighting the difficulty this population has with smoking cessation.

Betel nut/quid chewing, which is a product of the areca catechu tree, is endemic to some parts of Asia and India, and in these regions oral cavity cancer is one of the most common cancers. Betel nut when chewed acts as a mild stimulant similar to that of coffee but can be associated with submucous fibrosis that adds an additional challenge in the management of patients who present with a concurrent oral cavity cancer. These products are associated with particular subsites secondary to direct contact (e.g., buccal mucosa) as well as subsites with dependent saliva drainage (e.g., floor of mouth, mandibular alveolus, and wet lip). Reverse smoking, where the lighted portion of the tobacco product is placed within the mouth during inhalation is also associated with oral cavity cancer, specifically hard palate carcinoma. The risk for this cancer is 47 times greater in patients that exhibit this behavior compared to nonsmokers.

In Europe and North America there has been an increasing interest in decriminalizing marijuana smoking. There is a strong correlation between this activity and head and neck cancers, particularly those who have received solid organ and bone marrow transplants are at an increased risk of head and neck cancers. Similarly, HIV-infected patients have a higher incidence of head and neck cancers, and despite aggressive treatment have poorer results compared to HIV-negative patients. Other conditions associated with oral cancer include Plummer-Vinson syndrome (iron-deficiency anemia, dysphagia, glossitis, cheilitis, and esophageal webs), dyskeratosis congenita, Bloom’s syndrome, and Fanconi anemia.

HPV is a double stranded DNA virus that is transmitted through sexual contact. Over the last two decades, this virus, specifically the 16 and 18 subtypes, has been associated with an epidemic rise in oropharyngeal squamous cell carcinoma. The p16 protein is a surrogate for HPV positivity. HPV status in oropharynx cancer has prognostic and therefore treatment-related implications.

Anatomy and Histopathology
The upper aerodigestive tract is divided into several distinct sites that include the oral cavity, pharynx, larynx, and nasal cavity/paranasal sinuses. Each of these sites has separate subsites as alluded to earlier with specific etiological, pathological, prognostic, and treatment-related peculiarities. Locoregional tumor spread is determined by weaknesses in the framework, fascial planes, and the course of neurovascular and lymphatic channels.

The oral cavity extends from the vermillion border of the lip to the hard-palate/skin-palate junction superiorly, to circumvallate papillae inferiorly, and to the anterior tonsillar pillars laterally. It is divided into eight subsites including the (a) mucosal lip, (b) the mandibular alveolus, (c) floor of mouth, (d) tongue (anterior two-thirds), (e) buccal mucosa, (f) retromolar trigone, (g) maxillary alveolus, and (h) hard palate (Fig. 18-20). Advanced oral cavity cancer can present with mandibular and/or maxillary invasion requiring resection, at least in part, of these structures. Oral cavity cancers typically metastasize to the submental, submandibular, and upper jugular lymph nodes (levels I-III).

Figure 18-20. Oral cavity landmarks.
The pharynx is divided into three regions: nasopharynx, oropharynx, and hypopharynx (Fig. 18-21). The nasopharynx extends from the posterior nasal septum and choana to the skull base and includes the fossa of Rosenmüller and torus tubarius of the Eustachian tubes laterally. The inferior margin of the nasopharynx is the superior surface of the soft palate. In adults, the adenoids are typically absent secondary to involution during late adolescence, but these can be seen in some adults in the posterior aspect of this subsite. Isolated posterior triangle (level V) lymphadenopathy in an adult should be considered nasopharyngeal carcinoma (NPC) until proven otherwise. Due to its midline location, bilateral regional metastatic spread is common in nasopharyngeal carcinoma. Given the epidemic rise of oropharyngeal cancers, isolated level V adenopathy in an adult may also represent oropharyngeal cancer, although cancers at this site typically drain to the upper and lower cervical nodes (levels II–IV) as well as the retropharyngeal nodes. The oropharynx has a number of subsites including the tonsillar region, base of tongue, soft palate, and posterolateral pharyngeal walls. The hypopharynx extends from the vallecula to the lower border of the cricoid posterior and lateral the larynx. It includes several subsites as well including the pyriform fossa, the postcricoid space, and the posterior pharyngeal wall. Lymphatic drainage is to the mid and lower cervical nodes (levels III–IV); however, usually the upper cervical nodes (level II) are addressed at the same time for tumors at this site.

The larynx is divided into three regions: the supraglottis, glottis, and subglottis (Fig. 18-22). The supraglottis includes several subsites: the epiglottis, false vocal cords, medial surface of the aryepiglottic folds, and the upper half of the laryngeal ventricles. The glottic larynx includes the true vocal cords, the anterior and posterior commissure, and the lower half of the laryngeal ventricles. The subglottis extends from below the true vocal cords to the superior cricoid border from within. The supraglottis has a high rate of bilateral metastatic spread secondary to its rich lymphatic drainage, whereas isolated glottic cancers rarely have lymphatic spread. Laryngeal cancers, in addition to having the propensity for lymphatic spread, particularly in advanced cases, can have preepiglottic and paraglottic invasion as well as invasion of the laryngeal framework (thyroid and cricoid cartilage). Furthermore, glottic and subglottic lesions, in addition to potential spread to the upper and lower cervical nodes (levels II–IV), have the propensity for spread to the central neck (level VI) in the paralaryngeal and paratracheal region.

Second Primary Tumors in the Head and Neck
Patients with head and neck squamous cell carcinoma (HNSCC) are at increased risk for the development of a second primary malignancy (SPM), which is defined as a second malignancy that presents either simultaneously or after the diagnosis of an index tumor. A synchronous SPM is diagnosed simultaneously or within 6 months of the index tumor, while a metachronous SPM is diagnosed >6 months after the index tumor. SPMs need to be distinguished from local recurrences or metastasis of the primary tumor. The incidence of SPM ranges from 2% to 7% per year, and this risk remains constant from the time of initial diagnosis throughout the lifetime of the patient. Secondary primary malignancies represent the second leading cause of death in patients with HNSCC. One-quarter to one-third of deaths in these patients are attributable to SPM, highlighting the importance of SPM in the successful management of HNSCC.

The classic criteria for defining second primary malignancy (SPM) were proposed by Warren and Gates and are: (a) histologic confirmation of malignancy in both the index and secondary tumors; (b) two malignancies that are anatomically...
separated by normal mucosa; and (c) the possibility of the SPM being a metastasis from the index tumor must be excluded. Most investigators use these criteria to define an SPM. However, disagreement exists regarding the application of the second and third criteria. For example, when both tumors appear in the same anatomic subsite, there is no agreement on the distance that should exist between the tumors, with some investigators favoring 1.5 cm and others requiring 2 cm. Furthermore, when the tumors occur in the same anatomic subsite, some investigators add that the SPM must present at least three years after the diagnosis of the index tumor, while others require that the SPM present at least five years after the index tumor. Others suggest that molecular analysis is required to classify a tumor as an SPM.

Treatment of SPMs of the upper aerodigestive tract is site specific. In general, the SPM should be treated as a separate entity, in the same manner as a primary index tumor at the anatomic subsite. In many cases, particularly in metachronous SPMs, patients have already received a full complement of treatment, including primary or adjuvant radiation and/or chemoradiation treatment. In these cases, surgical treatment of the SPM is often indicated when feasible. Reirradiation is an option in carefully selected cases when salvage surgery is not possible. Proper patient selection for reirradiation is critical, and only patients with minimal comorbidity and toxicity of previous radiation treatment should be considered. Patients at high risk for local recurrence after salvage surgery may benefit from increased locoregional control from adjuvant reirradiation, although there is no survival advantage compared with salvage surgery alone. Survival in patients with SPM depends upon the stage and location of the primary site of the SPM. Patients with SPM arising in the head and neck have significantly improved survival when compared with patients with SPM arising in the lung and esophagus.

Staging
Staging for upper aerodigestive tract malignancies is defined by the American Joint Committee on Cancer and follows the TNM (primary tumor, regional nodal metastases, distant metastasis) staging format which was recently updated in the 8th edition in 2017. The T stage for each subsite incorporates relevant anatomy; for instance, T3 lesions of the glottis are associated with vocal cord immobility. Recent changes have incorporated HPV/P16 status for oropharynx cancer (Tables 18-1 and 18-2) and depth of invasion for oral cavity cancers (Table 18-3).

The N classification for head and neck sites is nearly uniform for all sites (Tables 18-4 and 18-5) except for the nasopharynx and for HPV-associated (p16-positive) oropharynx cancer. Recent changes have also incorporated extracapsular extension into this nodal staging to improve the discrimination and prognostication of the classification.

Upper Aerodigestive Tract
There are similarities in the initial assessment and management of all patients with a newly diagnosed upper aerodigestive tract malignancy. The frequently reviewed clinical practice guidelines (National Comprehensive Cancer Network; NCCN) provide valuable information by site and stage with regard to workup and management and should be used to direct care.

After a thorough history that should include assessment of the previously discussed risk factors, a comprehensive physical examination should follow. A full head and neck examination including inspection and palpation is critical for nearly all head and neck cancers. Oral cavity and oropharyngeal cancers should be palpated when possible to provide additional tactile information regarding depth of invasion, mobility, and invasion into adjacent structures. A cranial nerve (CN) examination with a focus on the assessment of trigeminal (V2/V3) parasthesia/paresthesia.

| Table 18-1 | Clinical and pathologic T category for HPV-associated (p16-positive) oropharyngeal cancer |
| T CATEGORY | T CRITERIA |
| T0 | No primary identified |
| T1 | Tumor 2 cm or smaller in greatest dimension |
| T2 | Tumor larger than 2 cm but not larger than 4 cm in greatest dimension |
| T3 | Tumor larger than 4 cm in greatest dimension or extension to lingual surface of epiglottis |
| T4 | Moderately advanced local disease |

"Mucosal extension to lingual surface of epiglottis from primary tumors of the base of the tongue and vallecula does not constitute invasion of the larynx."

T CATEGORY | T CRITERIA
--- | ---
TX | Primary tumor cannot be assessed
Tis | Carcinoma in situ
T1 | Tumor ≤2 cm, ≤5 mm depth of invasion (DOI). DOI is depth of invasion and not tumor thickness.
T2 | Tumor ≤2 cm, DOI >5 mm and ≤10 mm or tumor >2 cm but ≤4 cm, and DOI ≤10 mm
T3 | Tumor >4 cm or any tumor with DOI >10 mm but ≤20 mm
T4 | Moderately advanced or very advanced local disease
T4a | Moderately advanced local disease
Tumor invades adjacent structures only (e.g., through cortical bone of the mandible or maxilla, or involves the maxillary sinus or skin of the face) or extensive tumor with bilateral tongue involvement and/or DOI >20 mm.
Note: Superficial erosion of bone/tooth socket (alone) by a gingival primary is not sufficient to classify a tumor as T4.
T4b | Very advanced local disease
Tumor invades masticator space, pterygoid plates, or skull base and/or encases the internal carotid artery

Table 18-4
Clinical N category for non–HPV-associated (p16-negative) oropharyngeal cancer

N CATEGORY | N CRITERIA
--- | ---
NX | Regional lymph nodes cannot be assessed
N0 | No regional lymph node metastasis
N1 | Metastasis in a single ipsilateral lymph node, 3 cm or smaller in greatest dimension and ENE(−)
N2 | Metastasis in a single ipsilateral node larger than 3 cm but not larger than 6 cm in greatest dimension and ENE(−); or metastases in multiple ipsilateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(−); or in bilateral or contralateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(−)
N2a | Metastasis in a single ipsilateral node larger than 3 cm but not larger than 6 cm in greatest dimension and ENE(−)
N2b | Metastasis in multiple ipsilateral nodes, none larger than 6 cm in greatest dimension and ENE(−)
N2c | Metastasis in bilateral or contralateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(−)
N3 | Metastasis in a lymph node larger than 6 cm in greatest dimension and ENE(−); or metastasis in any node(s) and clinically overt ENE(+)
N3a | Metastasis in a lymph node larger than 6 cm in greatest dimension and ENE(−)
N3b | Metastasis in any node(s) and clinically overt ENE(+)

ENE = extranodal extension.

Lip. The lips starting at the vermillion border represent a transition between external skin to internal mucosa. The sphincter function of the lip is created by activation of the circumferential musculature of the orbicularis oris, a critical structure in lip form and function. Lip cancers are most common in men and are often seen in those with fairer complexions. In addition to tobacco use and immunosuppression, UV exposure is an additional important risk factor unique to this head and neck subsite. The majority (>90%) of lip cancers present on the lower lip due to its increased protrusion and increased sun exposure.

Although the vast majority of lip cancers are SCC, other cutaneous malignancies such as basal cell carcinoma and malignant melanoma are not uncommon at this subsite.

Basal cell carcinoma presents more frequently on the upper lip than lower.

Negative prognostic factors for lip cancers include perineural invasion, invasion into bone (maxilla or mandible), upper
lip or oral commissure involvement, positive regional metastasis, and young age at diagnosis.

The primary management of lip cancer is a surgical resection of the primary site with an adequate margin (1 cm). This provides margin analysis and additional pathologic information that can help stratify which patients may benefit from adjuvant treatment. The primary regional nodal drainage basin for lip cancers is the submandibular, submental, and perifacial nodes (level I), and metastases occur in <10% of patients with a higher incidence in those with upper lip cancers.\(^\text{108}\) When there are clinical evident notes, a neck dissection is indicated. Otherwise, in the clinically and radiographically negative neck involvement, a neck dissection is indicated.

ENE = extranodal extension.

The preferred approach to management of these tumors is a surgical resection with adequate (1 cm) surgical margins with management of the regional nodal basin. In general, tumors of the oral cavity metastasize to the submandibular, submental, and upper cervical nodes and are almost always treated with a suprathyroid neck dissection at the time of primary resection with a few rare exceptions (T1 oral tongue lesions that have less than 4 mm depth of invasion). In the “Neck” section of this chapter, we will discuss this in more detail. Adjuvant radiotherapy is indicated in patients with close margins, regional lymphadenopathy, advanced stage tumors (T3/T4), perineural invasion, and lymphovascular invasion, while adjuvant chemoradiotherapy is reserved for those with positive margins or extracapsular invasion.\(^\text{115,114}\)

### Oral Tongue

The oral tongue is a muscular structure composed of intrinsic (longitudinal, vertical, and transverse muscle fibers) and extrinsic (genioglossus, hyoglossus, styloglossus, and palatoglossus) muscles separated by a midline raphe and has overlying nonkeratinizing squamous epithelium. The posterior limit of the oral tongue is the circumvallate papillae beyond which the oropharynx begins while the ventral portion is contiguous with the anterior floor of mouth.
Tumors of the tongue typically start along the epithelial surface and can be endophytic or exophytic with or without ulceration (Fig. 18-26) and are typically seen on the lateral and ventral surfaces of the tongue. Lesions on the dorsal aspect of the tongue, particularly along the midline, are less likely to be malignant. What is seen on the surface is typically the tip of the iceberg, and palpation can provide further information regarding the depth of invasion of the tumor. These tumors can be extensive, and when they cross the midline and start to involve the base of tongue an extensive surgical resection including a total glossectomy may be required. However, most tumors present at an early stage due to significant pain, otalgia, voice change secondary to difficulties with articulation, and dysphagia, which may lead to weight loss. On history and physical examination, ipsilateral paresthesias and deviation of the tongue protrusion with fasciculations or atrophy may indicate lingual nerve and hypoglossal nerve tumor invasion respectively (Fig. 18-27).

Early lesions (T1–T2) can be closed primarily, allowed to heal by secondary intention, or reconstructed with a split thickness flap. Figure 18-23. Estlander flap. A. Intra-operative image of lower lip squamous cell carcinoma with buccal and cutaneous extension pre-excision; B. Intra-operative defect and Estlander flap design. C. Immediate post-operative flap. D. One year post-operative image.

Figure 18-24. A-C. Karapandzic labiaplasty for lower lip carcinoma.
skin graft after partial glossectomy. This procedure allows reasonable speech and swallowing function as long as there is not significant tethering in the floor of the mouth if this has been resected. Articulation is determined by premaxillary contact of the tongue, and dental appliances can be used in the postoperative setting to improve this. Tongue protrusion and lateral movement predicts a patient’s ability to swallow, and this is less difficult to repair secondarily. Therefore, many patients, even with small tongue cancers that require significant floor of mouth resection, receive soft pliable fasciocutaneous free flap reconstruction to improve these functional outcomes. Advanced lesions that require a more radical resection require free flaps, which obliterate the oral cavity dead space while creating bulk in the posterior oropharynx to improve the pharyngeal swallowing phase.

**Figure 18-25.** Bernard burrow flap reconstruction for a total lower lip defect involving upper and lip advancement rotation flap and cheek advancement.

**Figure 18-26.** Oral tongue squamous cell carcinoma.

**Figure 18-27.** A and B. Anatomy of the floor of mouth and submandibular space. a. = artery; m. = muscle; n. = nerve.
Floor of Mouth The floor of mouth is a mucosal-covered semilunar area that extends from the anterior tonsillar pillar posteriorly to the frenulum anteriorly, and from the inner surface of the mandible to the ventral surface of the oral tongue. The ostia of the submaxillary and sublingual glands are contained in the anterior floor of mouth. The muscular floor of mouth is composed of the sling-like genioglossus, mylohyoid, and hyoglossus muscles, which serve as a barrier to the spread of disease. Invasion into these muscles can result in decreased tongue mobility and poor articulation.

The floor of mouth begins just below the lingual surface of the mandibular alveolus and ends at the ventral tongue where the frenulum connects the floor of mouth to the tongue along the midline and at the anterior tonsillar pillars posteriorly. Just deep to the floor of mouth mucosa is the submandibular (Wharton’s) duct and sublingual minor salivary glands followed by the genioglossus, hyoglossus, and mylohyoid muscles. Direct invasion of these structures is not uncommon and can result in direct spread to the sublingual and submandibular spaces as well as decreased tongue mobility, leading to articulation complaints. The lingual nerve (a branch of V3) provides sensory innervation to this subsite and is in close proximity to it, often requiring resection of this structure. The contiguity of the floor of mouth mucosa with the lingual surface of the mandible can lead to mandibular invasion. This needs to be carefully examined bimanually on physical examination and using imaging (CT, MRI, or Panorex) because a marginal or segmental mandibulectomy may be required to excise these tumors (Fig. 18-28). If the lesion is not fixed to the mandibular cortex on physical examination, then a mandible-sparing procedure is feasible.117

Extension to the sublingual and submandibular ducts and spaces requires that the neck dissection specimen be removed en bloc with the primary tumor. Invasion of the intrinsic tongue musculature requires a partial glossectomy. In our experience, except for the smallest (T1) very superficial floor of mouth lesions, cancers at this subsite nearly always require a reconstructive procedure to separate the floor of mouth from the neck and to avoid tethering of the tongue using a pliable fasciocutaneous flap. If a segmental resection is performed, the vascularized osteocutaneous free flap is used. Given the anterior location of this tumor, a lip-splitting incision is rarely used unless resection of lip and chin skin is required as part of the resection in a select group of T4a tumors with through-and-through involvement.

Mandibular Alveolus and Gingiva The alveolar mucosa overlies the bone of the mandible and extends from the ginvobuccal sulcus to the mucosa of the floor of mouth to the second and third molar, which is the anterior border of the retromolar trigone subsite. Treatment of these lesions requires at the very least marginal resection of the mandibular bone given the proximity and early invasion of the periosteum in this region. A marginal resection is acceptable if there is only very early bony invasion (Fig. 18-29). If the inferior alveolar canal or the medullary cavity is invaded on physical examination or preoperative imaging, a negative locoregional prognostic factor, a segmental resection is recommended with appropriate reconstruction.118,119

Retromolar Trigone The retromolar trigone (RMT) is bordered medially by the anterior tonsillar pillar, anteriorly by the
second or third molar, posteriorly by the maxillary tuberosity, inferiorly by the posterior mandibular alveolus, superiorly by the coronoid process of the mandible, and laterally by the buccal mucosa. Negative margin resection often requires a marginal shave mandibulectomy, even when there is no evidence of mandibular cortical invasion, because of the close proximity to the mandibular periosteum. This is typically achieved through a transoral approach while carefully protecting the lips and cheek. Extension to adjacent subsites including the buccal mucosa, maxillary tuberosity, floor of mouth, and posterolateral tongue often requires these structures be resected as part of the margin. Trismus at this and other subsites is an advanced indication of involvement of the muscles of mastication in the masticator space, which can extend to the skull base. These tumors are aggressive. Infiltration into the masticator space and bony invasion (maxilla more often than mandible) significantly worsens the prognosis.

**Buccal Mucosa** The buccal mucosa includes all of the mucosal lining from the inner surface of the lips to the line of attachment of mucosa of the alveolar ridges and pterygomandibular raphe. The mucosa includes the parotid (Stenson’s) duct opening adjacent to the first and second maxillary molars. An understanding of the layers of the cheek from medial to lateral is important because these layers are very closely adherent to the buccal mucosa. Therefore, tumors in this region have a high propensity for early deep invasion and early lymphatic spread. The layers of the cheek from medial to lateral are: (a) buccal mucosa, (b) pharyngobasilar fascia, (c) buccinator muscle, (d) buccopharyngeal fascia, (e) buccinator fat pad, (f) masseter muscle, (g) muscles of facial expression and the superficial muscular aponeurotic system (SMAS), (h) subcutaneous tissue, and (i) facial skin. It is not uncommon for tumors with deep invasion into the cheek to require a through-and-through resection. Reconstruction aimed at providing both an internal and external lining may be accomplished with a folded fasciocutaneous free flap or a combination of a local flap for the external component and a free flap for the internal component. Marginal bone resection is often required in tumors that extend to the mandibular or maxillary alveolus.

**Maxillary Alveolus and Hard Palate** The hard palate and maxillary alveolus have classically been considered two separate subsites, but due to their anatomic contiguity and the similarities in their oncologic outcomes these two subsites should be discussed together. The junction between the hard palate and soft palate is the posterior border, while the maxillary tuberosity is the posterolateral border separating the retromolar trigone from the maxillary alveolus. The periosteum is at this subsite is closely adherent to the mucosa, and as such, superficial lesions require resection of the bone to achieve a clear margin. An infrastructure maxillectomy may be required for larger lesions involving the palate or maxillary antrum. The greater palatine nerve and foramen can be a pathway for neuropathic spread, and it is important to identify perineural invasion on these tumors in the biopsy specimen.

Although SCC continues to be the primary malignant pathology at this subsite, minor salivary gland tumors such as adenoid cystic carcinoma, mucoepidermoid carcinoma, and adenocarcinoma can also present in this location. Minor salivary gland tumors tend to arise at the junction of the hard and soft palate.

Nonmalignant pathology includes necrotizing sialometaplasia, which appears as a butterfly-shaped ulcer on the hard palate that otherwise looks like a neoplasm. Treatment is symptomatic as these lesions typical disappear with time; however, a biopsy is warranted to confirm the diagnosis. A torus palatinus is a benign bony outgrowth seen on midline of the hard palate. This does not require biopsy to confirm the diagnosis and only requires treatment to relieve symptoms.

Reconstruction of the maxillectomy defect depends on a number of variables, including patient preference, dentition, patient comorbidity, and extent of defect. A partial palatoplasty or partial infrastructure palatoplasty can often be reconstructed with a dental obturator or a soft tissue flap alone to separate the oral cavity from the nasal cavity and maxillary sinus. More extensive suprastructure maxillectomies can be reconstructed with a free flap composed only of soft tissue, although this will leave the patient with a significant malar asymmetry over an osseous free flap. The layered fibular free flap and the scapular tip have been recently popularized to reconstruct more extensive orbitomaxillary reconstruction. Supporting the orbital floor when it is resected is critical in supporting the orbital contents and avoiding eventual diploplia because there can be a drop in these contents when they are not supported.

**Oropharynx** The borders of the oropharynx start at the soft palate superiorly, the hyoid (vallecular root) inferiorly, the anterior tonsillar pillar anterolaterally, and the cricuvallate papilla at the junction between the anterior two-thirds and posterior third of the tongue. There are five subsites in the oropharynx: the tonsillar region that includes the anterior and posterior tonsillar pillars, the soft palate, the posterior pharyngeal wall, the lateral pharyngeal wall, and the base of tongue. Tumors at this subsite can have direct extension laterally in the parapharyngeal space, posteriorly into the retropharyngeal space, anteriorly into the oral cavity, superiorly into the nasopharynx, or inferiorly into...
the supraglottic larynx. Laterally, through the superior constrictor, invasion of the jugular vein, carotid artery, and cranial nerves IX to XII, as well as the sympathetic chain, is possible. The pharyngobasilar fascia (resectable) deep to the constrictor muscles is a natural barrier from invasion into the prevertebral fascia (unresectable). The ascending ramus of the mandible can be involved when tumors invade the medial pterygoid muscle.

Although SCC is the predominant pathology, minor salivary gland tumors can present as submucosal lesions in the soft palate or tongue base, and lymphoma can present in the tonsils as an asymmetric enlargement, underlying the importance of a tissue diagnosis before treatment.

Oropharyngeal cancers, other than those on the soft palate or tonsils, are often not obvious on oral cavity exam inspection; therefore, a high degree of suspicion should exist in patients with a muffled voice as would be experienced in tongue base tumors, patients with dysphagia and weight loss, or referred otalgia from the tympanic branches of CN IX and X. Trismus may indicate advanced disease with pterygoid involvement. As previously mentioned, because of the epidemic rise in incidence of oropharyngeal cancers, secondary to HPV-associated tumors, and the high regional metastatic rate for these tumors, the presenting symptom is often a nontender cervical lymphadenopathy, which should be investigated with a fine-needle aspiration (FNA) biopsy. Approximately 50% of patients have metastases at the time of diagnosis. Bilateral metastases are common in patients with soft palate and base of tongue tumors. Treatment of the neck should include the upper jugulodigastric nodes to which these tumors most commonly metastasize to, followed by levels II, IV, V, and the retropharyngeal lymph nodes.

A discussion about oropharyngeal cancer cannot be had without discussing the important prognostic information provided by the HPV status of these tumors. The incidence of oropharyngeal squamous cell carcinoma has increased significantly over the last four decades secondary to HPV-16 related development of this tumor.125 HPV infection can induce the production of two viral oncoproteins, E6 and E7, which inactivate tumor suppressors p53 and Rb leading to tumor promotion.126 HPV-positive tumors are more common in younger male patients and are associated with a history of a higher lifetime number of sexual partners and oral sex.127 Ang et al demonstrated that oropharyngeal cancers can be stratified on overall survival into low risk (HPV-positive tumors in patients with ≤10 pack years of smoking or >10 pack years of smoking but N0-N2a), intermediate risk (HPV-positive tumors with >10 pack years of smoking and N2b-N3 or HPV-negative tumors in patients with ≤10 pack years of smoking and T2-T3 tumors), and high risk (HPV-negative tumors in patients with ≤10 pack years of smoking and T4 tumors or HPV-negative tumors in patients with >10 pack years of smoking).12 The rate of distant metastases in the HPV-positive and HPV-negative tumors does not differ, and therefore the survival benefit in the HPV-positive group is due to improved locoregional control.

Management of squamous cell cancers of this region includes single modality (surgery or radiotherapy alone) treatment for early stage disease (stage I/II) and multimodality treatment for advanced stage (stage III/IV) disease (surgery followed by postoperative radiotherapy or concurrent chemoradiotherapy).108 Historically, from 1971 to 2000, oropharyngeal cancers, at the time mostly HPV-negative, were treated heterogeneously with surgery followed by radiotherapy or primary radiotherapy similar survival until Parsons et al demonstrated in a meta-analysis similar survival rates between the two treatment groups with improved locoregional control in the radiation-alone group and much higher complication rates in the surgery group (32% severe complications, 3.5% mortality) compared to the radiotherapy group (3.8% severe complications, 0.4% mortality).129 For this reason, for many years, advanced-stage tumors were treated with primary concurrent chemoradiotherapy. However, this is now a moving target given the excellent results in early and some intermediate-stage HPV-positive disease regardless of treatment. More recently, there has been a push to study de-escalation, particularly in the aforementioned low and intermediate risk groups given the excellent survival rates. The standard of care, regardless of HPV status, for advanced tumors (T3/T4 or N2b-N3 or evidence of gross ECE) continues to be concurrent chemoradiotherapy.129

The high complication and mortality rate in the surgical group analyzed by Parsons et al was associated not just with HPV-negative tumors but also with open resections for advanced tumors that necessitated a lip-splitting mandibulotomy approach. More recently, particularly for early stage tumors (T1, T2, N0-N2a), there has been a push towards minimally invasive transoral robotic surgery (TORS) using the da Vinci Surgical System. Oncologic outcomes are similar between surgery and radiotherapy in this group, and TORS has been demonstrated to be cost-effective in this setting.130-132 Functional outcomes related to swallowing (G-tube dependency) and airway (tracheotomy dependency) are also similar between the groups.130 These outcomes are heavily dependent on the surgeon’s ability to achieve negative margins, which can be challenging, and on good preoperative predictive value of imaging to stage the neck, given that advanced nodal disease, particularly with ECE, continues to benefit from adjuvant chemoradiotherapy. Positive margins or ECE ultimately leads to adjuvant chemoradiotherapy. This results in triple modality treatment with its associated higher morbidity. Therefore, clinical recommendations based on these favorable early retrospective poorly controlled studies with small sample sizes is not yet possible. Meanwhile, clinical trial evidence is pending to help elucidate in which settings and patients this new approach may be beneficial.133

Extensive oropharyngeal cancers that fail concurrent chemoradiotherapy are treated with resection. If the mandible is involved, a marginal mandibulectomy or segmental mandibulectomy may be required depending on the extent of bony involvement. Tongue base resection may necessitate total glossectomy depending on the contralateral extent of the tumor and the ability to save the lingual artery and to a lesser extent the hypoglossal nerve on that side. When the larynx is preserved many patients, if careful reconstruction is performed, 90% of patients can be decannulated and have acceptable voice outcomes.134 However, it is not uncommon to have to perform a total laryngectomy at the same time as the total glossectomy for tumors with supraglottic extent, and this is associated with poor quality of life. Generally, these patients also have poorer survival.135-137

The primary goal of oropharyngeal reconstruction is swallowing rehabilitation. For soft palate defects, palatal obturators may assist in providing a seal between the nasopharynx and the posterior pharyngeal wall. The modified Gehanno technique sutures the posterior wall of the remaining soft palate to the remaining incised pharyngeal mucosa to close off the ipsilateral hemi-nasopharyngeal port.138,139 A flap can then be inset overlying this defect, which has effectively separated the nasopharynx from the oropharynx. This prevents nasal regurgitation of air
and liquids, therefore impacting both speech and swallowing. Similarly, total glossectomy reconstruction has several goals, including filling the oral cavity dead space, allowing the neotongue to reach the premaxilla to assist with articulation, and, most importantly, creating posterior bulk to allow the base of tongue to touch the posterior pharyngeal wall, which assists with the pharyngeal phase of swallowing. This is often achieved with a large rectus abdominis or anterolateral thigh free flap. If the neotongue does not successfully touch the premaxilla and hard palate and speech is impeded, a palatal obturator can be used to bring down the palate and achieve better contact.

**Hypopharynx and Cervical Esophagus** The hypopharynx, which extends from the vallecular to the lower border of the cricoid cartilage (Fig. 18-30), has three subsites; the piriform sinuses, the lateral and posterior pharyngeal walls, and the post cricoid space. SCC of the hypopharynx typically presents with progressive dysphagia, first to solids then to liquids, followed by weight loss. Similar to oropharyngeal tumors, patients can also present with voice change, referred otalgia or a neck mass. Rarely, when the larynx is involved, patients may present with stridor and airway compromise necessitating an urgent tracheotomy.

Unfortunately, there is significant delay in diagnosis of patients with hypopharyngeal cancer and late presentation is common. Routine physical examination will not typically detect the tumor. Fiberoptic nasolaryngoscopy is important in assessing the extent of the tumor and laryngeal function. Vocal cord paralysis is a poor prognostic factor and indicates fixation of the cricoarytenoid joint from direct extension of the tumor or recurrent laryngeal nerve invasion. A Valsalva maneuver during laryngoscopy allows for a better evaluation of the opened pyriform sinuses and postcricoid space. Functional endoscopic evaluation of swallowing (FEES) can be useful to assess laryngeal penetration and aspiration, but a modified barium swallow (MBS) is better at assessing inferior extent of the disease, multifocality within the esophagus, and aspiration. A thorough metastatic workup is required, with special attention paid to paratracheal and upper mediastinal metastases.

This site has the poorest survival outcomes of all head and neck subsites. There is no difference in survival when surgery is used as the primary modality of treatment followed by radiotherapy or chemoradiotherapy compared to primary radiotherapy or concurrent chemoradiotherapy followed by surgery. Concurrent chemoradiotherapy appears to be the modality of choice for laryngeal preservation; however, when surgical salvage is required, there is a low cure rate and increased wound complications. Early T1 lesions without clinical or radiographic evidence of adenopathy can be treated with primary radiotherapy, but this is relatively rare for this subsite due to a high rate of adenopathy and an advanced T stage at presentation.

Surgical resection, typically in the salvage setting, involves a total laryngopharyngectomy typically with a circumferential defect or a very small strip of mucosa preserved in continuity with the cervical esophagus. A total thyroidectomy and central neck dissection (level VI) is simultaneously performed and removed en bloc with the specimen. Bilateral neck dissection of levels II to IV is indicated. Careful dissection of the central neck, and in some cases the upper mediastinum (level VII), is required to clear regional disease, and this is critical in preventing a peristomal recurrence.

Given the circumferential or near circumferential defect, reconstruction is required to prevent saliva from accumulating in the wound and to create a neopharynx. A pedicled pectoralis major flap sutured to the prevertebral fascia has been described, but advances in free flap reconstruction has popularized a number of fasciocutaneous flaps for reconstruction of this defect, namely the radial forearm flap and the anterolateral thigh free flap. When total laryngopharyngoesophagectomy is required, a gastric pull-up may be performed for the pharyngeal reconstruction.

**Larynx** Laryngeal carcinoma typical presents with a progressive voice complaint in a long-time smoker. A thorough understanding of laryngeal anatomy is critical in the proper diagnosis, staging, and treatment of laryngeal cancers. The larynx is divided into the supraglottis, glottis, and subglottis as previously described (Fig. 18-32). The larynx starts superiority at the epiglottis and ends inferiorly at the inferior border of the cricoid cartilage of the larynx span from the epiglottis superiority to the cricoid cartilage inferiorly. Laterally, it is separated from the hypopharynx by the aryepiglottic folds.

The supraglottis includes all of the laryngeal structures above the inferior half of the ventricle, and this includes the upper half of the ventricle, the false vocal cords, the arytenoids, the aryepiglottic folds, and the epiglottis. The membranes and cartilages of the larynx act as barriers to laryngeal spread: the thyroid and cricoid cartilage, conus elasticus, the quadrangular membrane, the ventricle, the hyoepiglottic ligament, thyrohyoid membrane, and cricothyroid membrane. Although the majority of tumors of the larynx are SCC, minor salivary glands, and their associated malignancies, can be found in the supraglottis and subglottis. Other rarer pathologies include granular cell

---

**Figure 18-30.** Relationship of nasopharynx, oropharynx, and hypopharynx.
tumors and laryngeal framework tumors, typically arising from the cricoid, such as chondroma and chondrosarcoma.

The larynx functions to (a) phonate, (b) protect the airway during swallowing, and (c) maintain airway patency. This is a fine balance. For instance, if the glottic aperture is enlarged and/or supraglottic structures are excised, phonation and airway protection suffer while airway patency is improved. It is therefore not surprising that patients with laryngeal tumors can present with dysphonia (hot potato voice in supraglottic tumors and hoarseness in glottic tumors), dysphagia, and airway concerns. These patients can also present with dysphagia, weight loss, referred otalgia, and a neck mass. Vocal cord fixation can be a result of a mass effect from large obstructing masses, secondary to direct extension into the paraglottic space or through direct invasion of the cricoarytenoid joint involving either the muscle or the recurrent laryngeal nerve (RLN). Although subglottic tumors represent <1% of laryngeal cancers, they can also present with vocal cord paralysis and/or airway compromise.

Direct laryngoscopy is beneficial in the assessment of laryngeal tumors to assess the local extent of tumor spread. This is particularly important in assessing vallecula and base of tongue as there can be direct extension to the oropharynx. Similarly, glottic cancers can have subglottic extension, which necessitates a wider radiation field and/or a more extensive resection.

Esophagoscopy and bronchoscopy are also recommended to assess second primary tumors. Furthermore, when a laryngectomy is planned, the direct laryngoscopy provides information about the best possible site of entry into the pharynx. Entry can be achieved through (a) a suprahyoid pharyngotomy, (b) lateral pharyngotomy (lateral to the thyroid cartilage), or (c) inferiorly through a postcricoid or hypopharyngeal pharyngotomy.

Appropriate preoperative staging with a CT scan with contrast is critical in assessing cervical lymphadenopathy and extralaryngeal spread. Erosion or invasion of the thyroid and cricoid cartilage can significantly impact outcomes and treatment as can extension into the preepiglottic or paraglottic spaces. The supraglottic and subglottic sites are lymphatic rich, and bilateral lymphadenopathy is not uncommon, whereas the glottic site has relatively poor lymphatic drainage (1%–4% regional metastasis for isolated larynx cancer). The supraglottic drains through the neurovascular bundle to the thyrohyoid membrane, mainly draining to the upper and lateral cervical nodes (levels II–IV), whereas the glottis and subglottis drain through the cricothyroid membrane and can have spread to the prelaryngeal (Delphian nodes), paratracheal, and lower cervical nodes (levels IV and VI), although in these cases we still treat levels II to IV surgically because of the significant occult nodes in this region.

The primary management of laryngeal cancer depends on a variety of factors, including tumor extent, patient comorbidities, and surgeon/center experience. In general, similar to other subsites, early-stage disease can be treated with single modality treatment (surgery or radiotherapy) while advanced stage disease is treated with at least two modalities, typically either surgery followed by radiotherapy (with or without chemotherapy) or concurrent chemoradiotherapy. Supraglottic and subglottic lesions are typically treated with primary concurrent chemoradiotherapy in an attempt to preserve the organ; however, in patients where the primary functions of the larynx are not being fulfilled preoperatively (tracheotomy– and gastrostomy tube–dependent), primary surgical management with a total laryngectomy (Fig. 18-33) can be considered. The original trials that popularized organ preservation techniques with concurrent chemoradiotherapy either excluded or had a very small sample size of large (T4) tumors.147,148 Similarly, advanced glottic cancers (T3/T4a), even when there is no evidence of nodal disease or supraglottic tumors of all stages, have superior survival outcomes when surgery is used as the primary treatment modality.149,150 This is particularly true for tumors that extend beyond the endolarynx or with cartilage destruction, for which total
laryngectomy followed by postoperative radiotherapy continues to be the standard of care. When primary chemoradiotherapy is used, surgical salvage is available if there is treatment failure or recurrent disease.

The early glottic and supraglottic lesions can be safely treated with CO\textsubscript{2} laser transoral microlaryngoscopic resection with excellent oncologic outcomes and laryngeal preservation rates.\textsuperscript{151,152} Patients with limited involvement of the arytenoid or anterior commissure are the best candidates for a good posttreatment vocal quality result with this approach. One of the benefits of this approach is that it does not burn any bridges to more invasive treatment. Often, multiple procedures are required to control the disease. Nonetheless, for early stage cancers of the glottis and the supraglottis, radiation therapy is equally as effective as surgery in controlling disease with excellent voice outcomes.

**Laryngeal Preservation Techniques** Beyond CO\textsubscript{2} laser transoral microlaryngoscopic resection for the most early of lesions, more advanced open laryngeal preservation techniques have been developed for the resection of select, moderately advanced supraglottic and glottic tumors. These techniques can be divided into vertical and horizontal partial laryngeal procedures.

Vertical partial laryngectomy (VPL) (Fig. 18-34) involves a midline thyrotomy followed by dissection of the inner perichondrium off of the thyroid cartilage with resection of the entire true cord and a portion of the false cords, followed by reconstruction with pedicle strap muscles and bipedicled outer perichondrial flaps. A temporoparietal fascial free flap has also been used to reconstruct these defects with excellent voice outcomes.\textsuperscript{153} This can be extended to include a frontal vertical VPL where the excision crosses the midline as far laterally as to leave only the posterior commissure and one functional cricoarytenoid unit. This procedure is best reserved for recurrent glottic T1/T2 lesions involving only one vocal cord (although anterior commissure involvement is not a contraindication), <5 mm sublottic extension, with a mobile cord, and no cricoid cartilage or extralaryngeal extension. This technique leads to excellent locoregional control with improvements in voice related quality of life with advanced reconstructive techniques.\textsuperscript{153}

Supraglottic and supracricoid partial laryngectomies are horizontally oriented resections. In a supraglottic laryngectomy, a laryngectomy is performed below the hyoid and includes the upper portion of the thyroid cartilage while preserving a lower portion approximately the height of the cricoid cartilage. This is reserved for lesions not involving the vocal cords, false cords, or the arytenoids. Cartilage invasion and extensive base of tongue involvement are contraindications. Most lesions amenable for resection using this procedure are typically small enough that a laser or TORS procedure is adequate for resection, and therefore this procedure is rarely performed. For T3 glottic lesions without preepiglottic space or cricoarytenoid joint involvement, a supracricoid laryngectomy with a cricohyoidopexy or cricothyroidopiglottopexy (CHEP) are options. A single cricoarytenoid unit is preserved to allow for phonation through apposition with the remnant epiglottis or base of tongue. The procedure is associated with excellent oncologic outcomes, tracheostomy decannulation rates, and swallowing function.\textsuperscript{154} Phonation is reasonable after this procedure but can be characterized as breathy and coarse. Many surgeons prefer not to decannulate patients until the patient has had a significant period of time with good oral intake to allow for pulmonary toilet given the high initial rate of aspiration with this procedure.

All partial laryngeal procedures are associated with a high risk of aspiration. Therefore, patients should have excellent pulmonary reserve through pulmonary function tests. When this is not possible, a simple measure includes whether patients can climb two flights of stairs without stopping.
Speech and Swallowing Rehabilitation

Speech and language pathology (SLP) assessment is critical in the management of patients with laryngeal and hypopharyngeal cancer. It is a critical part of the preoperative assessment and counseling and postoperative therapy. In the elderly larynx cancer population, Starmer et al demonstrated that SLP care is underutilized and is largely reserved for select patients in anticipation of total laryngectomy or after the onset of impaired airway and swallowing function. SLP care was, however, strongly associated with improved outcomes (lower rates of dysphagia, stricture, weight loss, and pneumonia).  

SLP often discusses with the patient speech rehabilitation options after total laryngectomy, which include esophageal speech, tracheoesophageal puncture, and use of an electrolarynx. Esophageal speech is produced by actively swallowing and releasing air from the esophagus, resulting in vibrations of the esophageal walls and pharynx that can then be articulated into words. This requires a very motivated patient, and unfortunately, <20% of postlaryngectomy patients develop fluent esophageal speech.

The electrolarynx is a device that creates vibratory electric type sounds when held against the neck or cheek that the patient can articulate into speech. This device is typically used in the postoperative inpatient setting, but it can also be used by patients who are not able to create esophageal speech.

The ultimate speech rehabilitation for patients with laryngectomy is a tracheoesophageal puncture (TEP) with insertion of a voice prosthesis. This prosthesis is a one-way valve that allows air from the trachea to enter the upper esophagus while preventing retrograde passage of food or saliva into the trachea. Patients who undergo placement of a tracheoesophageal puncture have a success rate of >90% in achieving functional speech. Many surgeons do not like to place a TEP at the time of the primary laryngectomy, particularly in the salvage setting after radiotherapy due to wound complication concerns. However, primary and secondary TEP patients experience similarly high complication rates, and the extent of the pharyngeal reconstruction rather than preoperative exposure to radiotherapy appear to be more important factors in selection of TEP timing. Free flap patients used their TEP more commonly for primary communication after secondary versus primary TEP.

Postoperative swallowing rehabilitation is another important task performed by SLPs. Modified barium swallows where the consistency and amount of food provided is varied to minimize aspiration can be critical particularly in the management of patients with partial laryngeal procedures. This is performed under fluoroscopy in the radiology suite to allow for the assessment of all phases of swallowing. A more limited examination in FEES utilizes the fiberoptic nasolaryngoscope to visualize the larynx during swallow and directly visualize whether there is any laryngeal penetration.

Unknown Primary Tumors

Patients with cervical nodal metastases confirmed to be carcinoma without clinical or radiologic evidence of an upper aerodigestive tract primary tumor are referred to as having carcinoma of unknown primary (CUP). CUP comprise 2% to 5% of all head and neck cancers, although the true incidence is probably lower given advances in surgical visualization and radiological imaging to identify the primary site. Recently, there has been a rise in CUP likely related to the increase in HPV-associated oropharyngeal cancer, although CUP could also be from a primary thyroid or skin malignancy. After a thorough history and physical examination including fiberoptic nasolaryngoscopy, an FNA biopsy is used to confirm carcinoma in the cervical metastases. This is preferred over an open biopsy to avoid the risk of tumor spillage, challenging revision surgery secondary to disruption of fascial planes, and increased risk of recurrence and distant metastases. If the primary is not identified on physical examination, patients should undergo a PET-CT scan. A recent systematic review of 7 studies (246 patients) demonstrates an overall sensitivity of 44% and specificity of 97% with this technique, which can often detect tumors >1 cm in size. This should be followed by thorough diagnostic operative endoscopy (nasopharyngoscopy, direct laryngoscopy, esophagoscopy, and bronchoscopy). Operative manipulation of the tissues in the upper aerodigestive tract specifically with biopsy may lead to false positive results on the PET-CT scan, and therefore PET-CT should be performed before endoscopy. Furthermore, having the PET-CT results prior to operative endoscopy allows the surgeon to focus on specific high-risk sites for biopsy, particularly as it relates to the base of tongue. When the primary site is not evident, bilateral tonsillectomies and bilateral base of tongue biopsies can be performed to try to identify the primary site. Patients in whom a primary is identified proceed to receive appropriate treatment, and if radiotherapy is part of this treatment regimen, a more limited radiation field is administered, highlighting the importance of identifying a primary site. When the primary site is not identified, primary chemoradiotherapy is advocated, treating all of the mucosal sources of the upper aerodigestive tract at risk (from nasopharynx to hypopharynx) and the cervical regional basin bilaterally. For patients with advanced neck disease (N2a or greater) or with persistent lymphadenopathy after radiation, a neck dissection may be necessary. In the preradiation setting, a neck dissection is preferred over radiotherapy for patients with N1 disease, according to the NCCN guidelines, because some of these patients will be upstaged, ECE is not accurately diagnosed on imaging alone, and because some patients without ECE and a pathologically N1 node benefit from radiation alone without chemotherapy. The additional prognostic information provided by a neck dissection can significantly impact treatment algorithms and is also associated with lower morbidity compared to postoperative neck dissection.

Nose and Paranasal Sinuses

Cancers of the nasal cavity and paranasal sinuses are exceedingly rare, and pathology in this anatomic subsite is dominated by infectious and inflammatory sources as previously discussed in the “Sinonasal Inflammatory Disease” section of this chapter. Malignant pathology at this site is often diagnosed after failed repeated treatment of suspected benign inflammatory sinonasal pathology. Concerning preoperative imaging findings (unilateral disease; extensive disease; bony, orbital or intracranial invasion) and unusual clinical features may raise concerns about malignancy, and in these cases referral to a tertiary head and neck oncology center is preferred. A concerning history is one that involves a slow progression and worsening of symptoms, which may include nasal obstruction, facial pain, headache, epistaxis, and facial numbness. Most tumors at this site present with advanced stage given the inevitable delay in diagnosis. Numbness in the V2 distribution suggests invasion of pterygopalatine fossa, and V3 distribution numbness can be an indication of extension to the infratemporal fossa and skull base invasion to foramen ovale. Proposis, epiphora, diplopia, and change in vision (typically starting with loss of color vision) are
SPECIFIC CONSIDERATIONS

all signs of advanced orbital invasion. Maxillary sinus tumors, the most common site for cancers of this site, can be prognos-ticated simply using Ohgren’s line (Fig. 18-35), an imaginary line from medial canthus to the angle of the mandible, which divides maxillary sinus into anterior-inferior and posterior-superior parts. Tumors from the anterior-inferior are more prognostically favorable.

Although the most common pathology at this site continues to be squamous cell carcinoma, a brief discussion of other histo-pathology is warranted given significant variety, prognostic, and treatment-related differences between these at this subsite. Benign pathology at this site includes inverted papilloma, hemangiomas, hemangiopericytomas, angiofibromas, minor salivary tumors, and benign fibrous histiocytomas. Fibro-osseous and osseous lesions, such as fibrous dysplasias, ossifying fibromas, osteomas, and myxomas, can also arise in this region. Additionally, encephaloceles and meningo-encephaloceles with herniation of intracranial content into the nasal cavity can present as sinonasal lesions; therefore, imaging, typically with an MRI, is warranted before biopsy of any sinonasal mass to prevent an iatrogenic CSF leak. In the evaluation of sinonasal malignant pathology, both CT and MRI are required because they provide complimentary information. MRI provides improved skull base, intracranial, and orbital invasion assessment, while CT provides better assessment of bony anatomy and invasion.

Beyond squamous cell carcinoma, the next two most common malignancies at this site include adenoid cystic carcinoma and adenocarcinoma. Other pathologies include sinonasal undiffer-enitized carcinoma (SNUC), mucosal melanoma, lymphoma, esthesioneuroblastoma (previously known as olfactory neuro-blastoma), rhabdomyosarcoma, and angiosarcoma. Unlike other head and neck cancers, metastases to the regional lymphatic basis are extremely rare, and rarely will patients require or receive primary or adjuvant treatment to the neck unless there is clinical or radiographic evidence of neck disease (approximately 15%).

The standard treatment for malignant tumors of the paranasal sinuses is driven by the primary pathology; however, for most pathology, including SCC, the standard of care includes surgical resection followed by adjuvant radiotherapy. Advances in endoscopic approaches has led to a shift in management of these tumors with minimally invasive approaches that are associated with significantly lower complication and morbidity rates with comparable oncologic outcomes. Open approaches are, however, indicated when there is tumor abutting the anterior wall of the frontal sinus, anterior extension into nasal bones, anterior maxillary wall invasion, facial skin or soft tissue invasion, dural involvement above the orbit or periorbital invasion, tumors with significant lateral temporal fossa invasion, and extension into the oral cavity, including the hard palate or the floor of the maxillary sinus. Many tumors can be treated with an endoscopic approach such as a medial maxillectomy when the tumor arises from the medial wall of the maxilla. Multidisciplinary assessment and treatment should include a skull base tumor board discussion with a head and neck oncologist/surgeon, a neurosurgeon, ophthalmologist including oculoplastics surgeons, prosthodontists, and reconstructive surgeons. Preoperative embolization within 24 hours of tumor excision can be useful for vascular tumors.

Extent of surgery and prognosis is dependent on the tumor location and extent. For tumors limited to the hard palate and lower maxillary sinus, an infrastructure maxillectomy is sufficient. A total maxillectomy without removal of the orbital floor may be warranted for more extensive tumors limited to the maxillary sinus. When the orbital periosteum is not invaded but tumor abuts this region, removal of the orbital floor with appropriate reconstruction is warranted. When there is invasion of periorbita, an orbital exenteration is warranted for most pathology. Tumors originating in the ethmoid sinuses may require excision of the cribriform plate and repair of subsequent skull base defect if the tumor originates or invades through the bony skull base. This is performed through an anterior craniofacial resection, where a neurosurgeon performs a frontal craniotomy for exposure of the anterior cranial fossa floor, while the head and neck surgeon performs a transfacial or endoscopic resection of the inferior bony and soft tissue structures. This approach often requires resection of dura and a dural repair to achieve negative margins. A less extensive surgery including a sphenoethmoidectomy or medial maxillectomy can be entertained for smaller tumors originating in the lateral nasal wall through endoscopic or open approaches.

Tumors are deemed to be unresectable if both optic nerves are involved, if there is carotid artery invasion, or if there is extensive intracranial extension. Chemotherapy has a limited application in the management of tumors at this subsite with two exceptions: rhabdomyosarcoma, which is primarily treated with chemotherapy followed by radiation therapy with surgery reserved for the salvage setting, and SNUC, where triple modal-ity treatment is required given tumor aggressiveness. Chemotherapy in this setting may help to reduce the tumor bulk and allow for orbital preservation.

**Nasopharynx**

The anatomic borders of the nasopharynx are superiorly the adenoid patch, superolaterally the fossa of Rosenmüller and the Eustachian tube orifices (torus tubarius), inferiorly the plane of the hard palate from the choana, anteriorly the posterior nasal cavity, and posteriorly the pharyngeal wall. Malignant
tumors of the nasopharynx are typically well differentiated or lymphoepithelial SCC. However, other tumors can present in this region including lymphoma, chordoma, chondroma, nasopharyngeal cyst (Tornwaldt’s cyst), angiofibroma, minor salivary gland tumor, paraganglioma, rhabdomyosarcoma, extramedullary plasmacytoma, and, rarely, sarcoma.

Unlike other head and neck cancers, the nasopharynx site has unique ethnic and geographic predilection, namely, a higher incidence in southern China, Africa, Alaska, and in Greenland Eskimos. EBV is also more commonly seen in patients with NPC, and EBV titers are helpful in following treatment response.

As previously discussed, a posterior (level V) neck mass should be considered NPC until proven otherwise. Other signs and symptoms include nasal obstruction, epistaxis, unilateral serous otitis media in an adult, and otalgia. Advanced disease can present with cranial neuropathies, particularly of the cranial nerves, which run in the cavernous sinus (CN V1, V2, III, IV, VI). Bilateral regional disease spread is common, and the lymphatic level involved include the posterior neck (level V), as well as the upper (level II) cervical and retropharyngeal nodes. Distant metastatic disease is present in 5% of patients at diagnosis, highlighting the importance of a thorough staging workup.

Staging includes a thorough physical examination using either a flexible or rigid endoscope to assess the mucosal extent of the disease. CT and MRI are complimentary as in the assessment of nasal cavity and paranasal sinus tumors with CT providing better assessment of bony invasion and the MRI providing better soft tissue delineation, skull base invasion, and perineural spread with cranial nerve enhancement. Multimodality therapy with chemoradiotherapy is superior to radiotherapy alone in the management of nasopharyngeal carcinoma.169 Recurrent tumors are treated typically with reirradiation; however, there has been recent success with surgical salvage procedures, particular in those patients in which a negative margin can be achieved.170

When resection is contemplated for recurrent nasopharyngeal carcinoma or for low-grade tumors such as some minor salivary gland tumors, a number of surgical approaches can be utilized for resection. These include endoscopic, transpalatal, transfacial via a maxillary swing procedure, and transcervical. In many cases, a combination of these techniques is required to achieve a negative margin. The transcervical approach provides the added benefit of early access and control of the carotid artery. For benign and low-grade tumors, advances in EEA have made use of the open approaches less common.

**Ear and Temporal Bone**

Temporal bone and ear tumors are rare account for <0.5% of all head and neck cancers. Subsites in this head and neck site from lateral to medial include the pinna (external ear), external auditory canal, middle ear, mastoid, and petrous portion of the temporal bone. Although the typical pathology at this site is squamous cell carcinoma, minor salivary gland tumors such as adenocarcinoma and adenoid cystic carcinoma can also present here. Given that the ear is in the high-risk region for aggressive skin cancers due to its unique exposure to ultraviolet light, cutaneous malignancies such as basal cell carcinoma and melanoma can also present here. In the pediatric population, soft tissue sarcomas, most commonly rhabdomyosarcoma, can present at this site. These tumors typically present with an advanced stage,171 and resection with clear margins and functional preservation is challenging because of the close proximity of vital structures, namely the facial nerve and the external auditory canal.172

Tumors involving the petrous apex or intracranial structures may present with headache and palsies of CN V and VI as well.

Patients can present with ulceration, granulation, or bleedings from the external ear and auditory canal. This is often mistaken for an infectious or inflammatory process given the rarity of malignancy at this subsite; however, persistent granulation tissue in the ear should be biopsied and imaged to rule out malignancy. Patients can then present with otitis media, otalgia, hearing loss, vertigo, and facial nerve paralysis. Appropriate imaging with CT and MRI is often required to appropriately delineate the lesion and stage and assist with the appropriate management plan.

Cutaneous malignancies of the pinna and tragus can usually be locally excised. However, at this subsite, spread into the perichondrium and cartilage can lead to rapid spread along the tissue plane. The importance of negative margins cannot be overstated at this subsite. Mohs microsurgery has been advocated for select tumors at this subsite for this reason; however, some tumors are so extensive that a total auriculectomy provides the best oncologic and cosmetic result. When there is extension of tumor to the bony cartilaginous EAC junction, spread to parotid, temporomandibular joint, and skull base is possible. Advanced tumors anterior to a vertical line along the EAC from a sagittal view benefit from a parotidectomy as well as a supraomohyoid neck dissection (levels I–III), whereas those behind this line benefit from a posterosilateral neck dissection (levels II–V). As with other cutaneous malignancies, adjuvant radiotherapy is indicated for positive margins, perineural spread, or multiple involved lymph nodes.

Tumors involving the EAC and middle ear require different management, including a sleeve resection of the external auditory canal, a lateral temporal bone resection, or a subtotal temporal bone resection (Fig. 18-36). A sleeve resection of the EAC skin and cartilage is rarely enough to achieve negative margins with the exception of some basal cell carcinomas of the skin overlying the cartilaginous EAC. For more extensive

![Figure 18-36.](image-url) Levels of the neck denoting lymph node bearing regions.
tumors and more aggressive pathology, a lateral temporal bone resection may be required removing the cartilaginous and bony external auditory canal as well as the middle ear en bloc. A subtotal temporal bone resection also removes the inner ear and facial nerve as part of the resection and is indicated when the tumor extends into the middle ear and a deeper resection margin is required. Both of these procedures are followed by postoperative radiotherapy, which provides improved locoregional control. The neck is managed in a similar fashion to pinna and external auditory canal malignancies typically requiring a supraomohyoid (levels I–III) neck dissection. Survival outcomes are poor with a 5-year overall survival of <40%. Important predictors of disease free survival include margin status, perineural invasion, and regional lymphatic spread; the most important of these on multivariate analysis being lymphatic spread of disease.

Lateral temporal bone resections often require reconstruction to close the wound, provide bulk, and vascularize tissue. If dura is encountered and even resected, a watertight dural closure is required to prevent a CSF leak and meningitis. Vascularized tissue has the added benefit of preparing the surgical bed for postoperative radiotherapy. These defects can be reconstructed with regional pedicled flaps (e.g., submental) or free flaps. The most common free flaps used are the anterolateral thigh, although depending on body habitus and the depth of the defect, the radial forearm, lateral arm, and rectus abdominus may also be used. The deformity resulting from a total auriculotomy is often not reconstructed primarily, but an auricular prosthesis can be designed for further rehabilitation. Facial nerve reconstruction when sacrifice is required is typically performed with cable grafts from the proximal facial nerve to select distal facial nerve branches. Because of the long distance between the proximal and distal branches, facial movement is typically delayed 6 to 12 months. However, if the masseteric nerve is connected through a cable graft to select distal facial nerve branches (typically the zygomatic branch), a shorter cable graft is required, and facial movement can be achieved earlier. A variety of other static and dynamic procedures can be performed secondarily. The most important of these procedures are related to preserving eye closure to avoid corneal abrasions or desiccation, which can ultimately lead to blindness. In the immediate postoperative period, taping of the eyelids and generous application of eye lubrication is required to prevent exposure keratitis. Upper lid gold weight implants, lower lid shortening procedures, and tarsorrhaphy can be performed secondarily to assist with eye closure.

**Neck**

An undiagnosed neck mass needs to be carefully evaluated and worked up so as to not interfere with the definitive management of the patient and future treatment options. The patient’s age, social history, including alcohol and smoking history, preceding illness history, and synchronous upper aerodigestive tract physical examination findings can significantly impact the differential diagnosis and the investigation to work up a neck mass. A thorough history and head and neck examination, including fiberoptic nasolaryngoscopy, are therefore paramount to complete evaluation. With regard to age, in children, a neck mass is far more likely to be congenital, inflammatory, or infectious, whereas in adults, neck masses >2 cm have a >80% probability of being malignant. Typically, the first investigation is an FNA biopsy, which can be performed with ultrasound or CT guidance when the mass is not easily palpable or largely cystic with a small solid component. Imaging is critical in characterizing the neck mass, particularly assessing the borders, consistency, and location which then impacts the differential diagnosis. For instance, a cystic neck mass can be a branchial cleft cyst or a regional metastasis from an oropharynx cancer or metastatic papillary thyroid cancer. Therefore, the imaging findings also significantly impact the differential diagnosis.

When the imaging and FNA does not provide adequate information for a diagnosis, a core biopsy can be considered, particularly if the diagnosis of lymphoma is suspected and an open biopsy wants to be avoided. For a suspected carcinoma, an open biopsy may be required; however, in that case, the incision needs to be planned such that the procedure can be converted to a neck dissection, and a frozen section can be sent. If the diagnosis of squamous cell carcinoma is confirmed on frozen section, then a neck dissection should be performed to further prognosticate the disease. In the case of lymphoma, biopsy does not need to remove the entire lymphoma, particularly if there is an added risk of injuring normal anatomical structures.

**Patterns of Lymph Node Metastasis.** The lymphatic drainage into the neck is divided into seven levels with standardized reporting within and across specialties, particularly as radiologists, pathologists, surgeons, radiation oncologists, and radiologists share the findings (Fig. 18-37). The levels include:

- **Level I**—the submental and submandibular nodes
- **Level Ia**—the submental nodes; medial to the anterior belly of the digastric muscle bilaterally, symphysis of mandible superiorly, and hyoid inferiorly; this level does not have any laterality as it includes both right and left sides
- **Level Ib**—the submandibular nodes and gland; posterior to the anterior belly of digastric, anterior to the posterior belly of digastric, and inferior to the body of the mandible

![Figure 18-37. Shaded region indicates the region included in a supraomohyoid neck dissection.](image-url)
There is a well-established pattern of regional spread from upper aerodigestive tract primary tumors. Lesions of the lip and oral cavity typically metastasize to levels I to III and skip metastasizes to the lower basin (levels III–IV) without involvement of the upper level (levels I–II). Oropharyngeal, laryngeal, and hypopharyngeal tumors most commonly spread to the lateral neck (levels II–IV). It is rare for any of these tumors to have isolated regional metastases to level V; however, nasopharyngeal, thyroid, and head and neck malignant melanoma can metastasize to this level. Other sites for metastasis include the retropharyngeal nodes (oropharyngeal, nasopharyngeal, and hypopharyngeal tumors), paratracheal and level VII nodes (thyroid, hypopharynx, and cervical esophageal tumors), and pretracheal (Delphian) nodes (thyroid and advanced glottic tumors with subglottic extension).

Historically, a radical neck dissection (RND) was performed for all upper aerodigestive tract malignancies with sacrifice of the SCM, internal jugular vein (IJV), and accessory nerve (CN XI) and removal of all lymphatic level (levels I–V). This was because cervical metastasis decreased the 5-year overall survival rate by approximately 50%. However, growing evidence demonstrated that this was not necessary, and now a neck dissection is only recommended for upper aerodigestive tract malignancies when the risk of occult disease is >20% in the clinically negative neck. When the neck is clinically positive, the level discussed in the previous paragraph for each site are excised with every attempt to preserve the SCM, IJV, and CN XI (selective neck dissection; SND). When there is direct extension of the tumor or extralymphatic spread into these structures, sacrifice may be necessary in a modified radical neck dissection (MRND). The RND has been largely abandoned because the SND and MRND have been demonstrated to be equally effective when it comes to oncologic outcomes with far improved functional outcomes.  

SND has become the standard of care for most patients who are clinically node negative (cN0) and in those with limited nodal extension (cN1) disease. Patients with oral cavity cancer typically receive a supraomohyoid (Fig. 18-38) neck dissection (levels I–III). Many surgeons will include a portion of level IV just below the omohyoid muscle given the rate of skip metastases previously discussed. Approximately 80% of patients with oral cavity cancer present cN0; however, the rate of occult metastatic disease is approximately 30% and differs by subsite. This rate is further impacted by tumor thickness at the tongue subsite, with tumors 4 mm or thicker having a higher rate of occult disease. A recent prospective, randomized trial demonstrated the oncologic benefit of an elective neck dissection in cN0 oral cavity patients regardless of tumor thickness over an observation followed by therapeutic neck dissection in those with regional failures. An additional role of SND is as a staging tool to determine the need for postoperative radiation therapy. The lateral (Fig. 18-39) neck dissection (levels II–IV) is typically used in laryngeal and hypopharyngeal cancers. The posterolateral (Fig. 18-40) neck dissection (levels II–V) is typically recommended in thyroid cancers, although recent evidence has demonstrated that a partial level V dissection may be all that is necessary for equivalent outcomes to a full level II to V neck dissection. 

Despite advances in the surgical management of neck disease, in clinically advanced nodal disease (with the exception of uncomplicated N1 disease), an MRND remains the treatment of choice. When the neck disease is advanced with extranodal extension (ENE), perineural invasion (PNI), lymphovascular invasion (LVI), and the presence of multiple involved nodes, postoperative radiotherapy improves locoregional control. If there is a positive margin or ENE, then the addition of adjuvant chemotherapy to radiotherapy provides a survival benefit. In patients receiving primary radiotherapy with advanced N stage disease (N2a or greater) or only a partial response to
treatment, a planned postradiotherapy neck dissection can be performed 6 to 8 weeks after completion of radiotherapy. This is to consolidate the treatment and provide prognostic information.

Tumor factors that preclude surgery include prevertebral fascia invasion, skull base invasion, and >270° circumferential encasement of the internal carotid artery. These factors are associated with very poor 5-year survival (<20%). In such cases, sacrifice of the carotid is not indicated given the risk of stroke and death. Surgical debulking is also not associated with improved survival. However, there is a role for neoadjuvant chemotherapy, and in those that respond and if the disease becomes resectable, survival benefit has been demonstrated.189 Recurrent neck metastasis after radiotherapy to the neck or a comprehensive neck dissection is associated with very poor survival.190

Parapharyngeal Space Masses. The parapharyngeal space is a potential inverted pyramidal space bordered superiorly at the skull base along the sphenoid and inferiorly at the greater cornu of the hyoid. Medially it is bordered by the buccopharyngeal fascia covering the superior constrictor, anteriorly the pterygomandibular raphe, posteriorly the prevertebral fascia, and laterally by the deep surface of the parotid gland and ramus of the mandible. The differential diagnosis for parapharyngeal masses is very much dependent on the anatomy and contents of this space which is divided into the pre- and poststyloid spaces by the tensor-styloid fascia. This fascia attaches the tensor veli palatini muscle to the styloid. The contents of the prestyloid parapharyngeal space include fat, the deep lobe of the parotid, and lymph nodes, and branches of V3 (lingual, inferior alveolus, and auriculotemporal nerves), whereas the contents of the poststyloid space including cranial nerves IX to XII, the internal jugular vein, the internal carotid artery, and the sympathetic chain. Nearly half of all parapharyngeal masses are of parotid origin, while 20% to 25% are of neurogenic origin, such as paragangliomas (glomus vagale, carotid body tumor), schwannomas, and neurofibromas. Lymphatic origin masses such as lymphoma and lymph node metastases represent 15% of tumors at this subsite. Therefore, most prestyloid lesions are considered of salivary gland origin, whereas poststyloid lesions are typically vascular or neurogenic.

Tumors of the parapharyngeal space can displace the lateral pharyngeal wall medially into the oropharynx (Fig. 18-41) and can thus cause obstructive sleep apnea, voice change, and dysphagia in addition to cranial neuropathies, Horner’s syndrome, or vascular compression. In addition to CT and MRI, poststyloid lesions should be investigated with a 24-hour urinary catecholamine collection because some paragangliomas are functional and this should be managed preoperatively.

Surgical access to these tumors can be performed using a purely transcervical approach with the excision of the submandibular gland for access. A transfacial or transparotid approach can be used as an adjunct for certain tumors by removing the parotid gland. This ensures identification of the facial nerve.

**Figure 18-39.** Shaded region indicates the region included in a posterolateral neck dissection.

**Figure 18-40.** Parapharyngeal mass—prestyloid with prominent oropharyngeal presentation typical of a dumbbell tumor.
prior to removal of the mass, which is just deep to it. Rarely, a transmandibular approach is required by performing a midline or parasymphyseal mandibulotomy with a lateral swing. Transoral approaches have been described, but they are not recommended and are largely contraindicated due to poor exposure and control of the associated vasculature.

Benign Neck Masses. Many benign neck masses require surgical intervention for diagnostic, cosmetic, and symptomatic relief. This is particularly true for lesions that are prone to recurrent infections, especially in the pediatric population. Such masses include thyroglossal duct cyst, branchial cleft cyst, lymphangioma (cystic hygroma), hemangioma, and dermoid cyst. Lymphangioma and hemangioma were previously discussed and will not be discussed in this section.

During fetal growth, the thyroid gland descends along a tract from the foramen cecum at the base of tongue into the anterior low neck. A vestigial remainder of this tract is called a thyroglossal duct cyst, which typically presents as a subcutaneous swelling near the hyoid in the midline or slightly paramedian. Patients may complain of recurrent infections of this mass after an upper respiratory tract infection. Investigations include thyroid function tests and a neck and thyroid ultrasound to confirm that the patient has thyroid tissue in the lower neck. Treatment involves removal of the cyst, the tract, and the central portion of the hyoid (Sistrunk procedure), often with a small portion of the base of tongue if the tract extends above the hyoid.

During fetal growth, the branchial cleft apparatus may persist, forming a branchial cleft remnant (cyst, sinus, or tract), numbered to their corresponding embryologic branchial cleft. First branchial cleft anomalies parallel the EAC (Work Type I; preauricular) or go through the parotid gland ending at the bony-cartilaginous EAC junction (Work Type II; angle of the mandible). Second branchial anomalies (Fig. 18–42), the most common type, start at the anterior border of the SCM and head toward the tonsillar fossa traveling deep to second arch structures (CN VII and external carotid artery) and superficial to third arch structures (stylopharyngeus, IX, and internal carotid artery). Third and fourth branchial anomalies are difficult to distinguish clinically and frequently open into the pyriform sinus often presenting with recurrent thyroid infections. These anomalies ascend posterior the internal carotid artery and deep to CN IX but superficial to CN XI and XII. Dermoid cysts tend to present as midline masses and represent trapped epithelium originating from the embryonic closure of the midline. These can be reliably diagnosed and distinguished from thyroglossal duct cysts using an ultrasound predictive model.

Cervical Fascial Planes. The fascial planes often predict the pathway and extent of infectious spread in the neck and are therefore clinically important. The deep fascial layers of the neck

![Figure 18-41](image1.png)

Figure 18-41. Computed tomography scan demonstrating a branchial cleft cyst with operative specimen.

![Figure 18-42](image2.png)

Figure 18-42. Example of a tumor in the parotid with the pattern of the facial nerve and associated anatomy. m. = muscle; n. = nerve; v. = vein.
include three separate layers: the superficial deep (investing) layer, the pretracheal (visceral) layer, and the prevertebral layer. The investing layer forms a cone around the neck and surrounds the SCM muscle and the anterior and posterior neck. It spans from the mandible to the clavicle and manubrium. The visceral layer surrounds the trachea, thyroid, and esophagus and blends laterally with the carotid sheath extending inferiorly to the upper mediastinum. Between this layer and the prevertebral fascia is the retropharyngeal space. The prevertebral fascia covers the prevertebral musculature and space and extends down to the thoracic vertebral and diaphragm. Infections of the prevertebral space between this fascia and the prevertebral musculature are considered to be in the prevertebral space and can extend all the way down to the sacrum. Therefore, neck infections can extend to the mediastinum or beyond and need to be treated aggressively.

Salivary Gland Tumors

Primary malignant tumors of the salivary glands are relatively rare and account for <2% of all head and neck malignancies. As previously mentioned, minor salivary gland malignancies can present anywhere in the upper aerodigestive tract, particularly on the palate; however, the major salivary glands are the parotid, submandibular, and sublingual glands. The majority of tumors (80%) arise in the parotid gland (Fig. 18-44); however, 80% of these are benign, most commonly, pleomorphic adenomas (benign mixed tumors). As the salivary gland gets smaller, the proportion of tumors that are malignant increases; 50% of submandibular/sublingual tumors and 80% of minor salivary gland tumors are malignant.

Patients typically present with a mass because these tumors are well circumscribed and slow growing. However, certain signs and symptoms, such as pain, paresthesia, facial nerve weakness, or rapid growth, raise the concern for malignancy. If there is facial nerve weakness (10%–15% of cases), this usually represents tumor invading the facial nerve. Submandibular and sublingual tumors present with a mass or swelling in the neck or floor of the mouth, respectively. Tumors in this region can invade the lingual nerve leading to tongue paresthesia or the hypoglossal nerve invasion leading to paralysis. The close proximity to the mandible and tongue necessitates a thorough bimanual palpation to assess for fixation to these structures.

The decision to dissect the neck in parotid cancers is fraught with uncertainty. However, parotid malignancies, particularly carcinomas, have a propensity for regional lymphatic spread, first to the intra- and periglandular nodes followed by the upper cervical chain (levels I–III). Occult nodal metastases are present in 30% of cases and are predicted by intra- or periglandular nodes, high-risk histology (high histological grade), and extraparotid extension. Patients with advanced tumor stage (T3/T4a), perineural invasion, high risk histology, or clinically involved adenopathy should have their neck dissected. Submandibular gland cancers metastasize to the submental (Ia) and submandibular triangle lymph nodes followed by the upper cervical chain (levels II–III). Extraglandular extension and regional metastases are poor prognostic factors.

Following a thorough history and physical examination, an FNA biopsy should be performed to provide an accurate preoperative diagnosis in 70% to 80% of cases when reviewed by an experienced cytopathologist. If the biopsy is nondiagnostic, a repeat biopsy should be performed under image-guidance, typically with an ultrasound. An open or incisional biopsy should be avoided because of the risk of tumor spillage and cutaneous spread. Also, this approach is fraught with risk to the facial nerve. Salivary gland tumors are worked up with appropriate imaging, typically with an MRI because of the increased soft tissue definition. FNA and imaging results are critical in guiding the surgeon to the extent of surgery. The minimal extent of surgery for salivary gland tumors is a superficial parotidectomy, removing all of the salivary gland tissue superficial to CN VII, which is meticulously dissected during this procedure.

The final histopathologic diagnosis in salivary gland tumors can be challenging. Nonetheless, there is a well-outlined histological classification used by pathologists. Benign and malignant tumors of the salivary glands are divided into epithelial, nonepithelial, and metastatic neoplasms. Benign epithelial tumors are most commonly pleomorphic adenoma (85%), monomorphic adenoma, Warthin’s tumor (papillary cystadenoma lymphomatosum), oncocytoma, or sebaceous neoplasm. Nonepithelial benign lesions include lipoma and hemangioma. Treatment of benign neoplasms is surgical excision for diagnostic and therapeutic purposes. The parotid superficial lobe is usually dissected off of the facial nerve, which is preserved. For pleomorphic adenoma, an extracapsular dissection is favored over enucleation due to tumor pseudopods, incomplete excision, and a higher risk of tumor spillage, all of which are associated with higher recurrence rates. Recurrence is associated with a high degree of morbidity.

Malignant epithelial tumors range in aggressiveness based on tumor histology, grade, perineural invasion, and regional metastases. Mucoepidermoid carcinoma is the most common primary malignancy of the salivary glands and can be high grade (more epidermoid) or low grade (more mucinous). High grade mucoepidermoid carcinoma can be hard to differentiated from squamous cell carcinoma, particularly on FNA. Adenoid cystic is the second most common primary salivary gland malignancy and has three histological subtypes: tubular, cribriform, and solid. Higher grade/risk tumors have a higher degree of solid differentiation. Adenoid cystic cancers are known for perineural invasion and late recurrences and distant metastases. Carcinoma ex pleomorphic adenoma is an aggressive malignancy that arises from a preexisting benign mixed tumor highlighting the importance of removing these benign masses before malignant transformation.

Surgical excision remains the standard of care, typically with facial nerve preservation unless the nerve is directly invaded by tumor. For tumors that extend beyond the superficial lobe, nerve branches can be spared, and a total parotid can be performed by removing parotid tissue deep to the nerve while preserving the integrity and function of the nerve. Whenever possible, the nerve is preserved even if microscopic disease is left on the nerve, so long as gross tumor is not left behind (i.e., the nerve is not encased). If this is not possible or if the nerve is not working preoperatively, nerve sacrifice is usually recommended.

Elective neck dissection is warranted in high-grade mucoepidermoid carcinomas and other high-risk pathology and grade where the risk of occult disease is greater than 15% to 20%. Therapeutic neck dissection is recommended in patients with clinically or radiographically evident disease. Postoperative radiotherapy is indicated in patients with perineural invasion, advanced local disease (T4a), extraglandular disease including regional metastases, and high-grade histology.
Local Flaps and Skin Grafts

Local flaps are commonly used for cutaneous reconstruction in the head and neck. Local flaps are most commonly utilized for reconstruction after Mohs micrographic surgery for cutaneous malignancy, or for reconstruction of melanoma defects. Skin grafts are also commonly used for reconstruction of scalp defects after surgical resection of cutaneous malignancies. Skin grafts may also be utilized in the oral cavity for resurfacing of superficial defects of the tongue, floor of mouth, and buccal mucosa.

Regional Flaps

Three regional flaps deserve mention as potential flaps for head and neck reconstruction. The first is the pectoralis major myocutaneous flap, based upon the thoracoacromial artery.196 This flap may be used as a primary option for hypopharyngeal reconstruction and/or parotid and temporal bone reconstruction. Care must be taken during the neck dissection in order to preserve the submental vessels that supply this flap. Finally, the supraclavicular flap is based upon the suprascapular artery, arising from the transverse cervical artery.198 This is a thin, fasciocutaneous flap that is commonly used for external neck and facial reconstruction in which thin tissue is desired.

Free Tissue Transfer

The majority of major defects of the head and neck require free tissue transfer for optimal reconstruction.199 A full discussion of head and neck reconstructive microsurgery is beyond the scope of this chapter; however, a brief overview of free tissue transfer is provided in this section. Free tissue transfer allows the surgeon to transplant tissue from a wide array of donor sites, each of which have distinct advantages.200 For example, for floor of mouth reconstruction, where thin tissue is desired, the surgeon may select the radial forearm as the donor site. On the other hand, when presented with a total glossectomy defect, where thick tissue is desired for adequate volume reconstruction, the rectus may be the optimal donor site. Considering osseous defects, for reconstruction of a segmental mandible defect with minimal soft tissue deficit, the fibula osseocutaneous free tissue transfer may be the optimal choice.201 On the other hand, reconstruction of an osseous mandible defect with a large mucosal and external soft tissue deficit may be best served by the scapula donor site, where vascularized bone can be combined with a large skin paddle, and an additional latissimus dorsi myocutaneous free tissue transfer, if needed.202 The ability to harvest tissue from multiple donor sites is critical to obtaining the optimal reconstructive result. Table 18-6 lists the commonly utilized donor sites and their reconstructive advantages and disadvantages.

Table 18-6

Free tissue transfer donor sites for head and neck reconstruction
Figure 18-43 shows a prototypical hemiglossectomy defect from a T2 N0 oral tongue cancer that was reconstructed with a rectangle template radial forearm free tissue transfer. The radial forearm free tissue transfer provides thin, pliable tissue, with a long pedicle, and is a staple for hemiglossectomy and partial glossectomy reconstruction.

Figure 18-44 shows a composite mandible defect from a T4a N0 mandibular alveolus cancer, after segmental mandibulectomy, reconstructed with a fibula osseocutaneous free tissue transfer. The 2.5-mm titanium reconstruction plate was bent to a mandible model. A template of the osseous defect is made and transferred to the fibula, and wedge ostectomies are made in the bone so that it can be snug fit into the bone defect.

Figure 18-45 shows a palate defect after an infrastructure maxillectomy for a T2 N0 maxillary alveolus cancer. The defect resulted in direct communication with the buccal space, nasal cavity, and maxillary sinus. A radial forearm free tissue transfer was utilized to achieve oronasal separation.

TRACHEOTOMY

Indications and Timing
The most common cause for tracheotomy is prolonged intubation typically in critically ill intensive care unit patients. Prolonged intubation increases the risk of laryngeal and subglottic injury, which may lead to stenosis. In the critically ill patient, it has been hypothesized that early tracheotomy may improve inpatient survival and decreased intensive care unit length of stay while increasing patient comfort. However, a large randomized clinical trial demonstrated no benefit from early tracheotomy on short- or long-term survival and other important secondary outcomes. Furthermore, clinicians are poor predictors of which patients require extended ventilatory support. Another study demonstrated no evidence that early tracheostomy reduced mortality, duration of mechanical ventilation, intensive care unit stay, or ventilatory associated pneumonia. It did, however, provide a shorter duration of sedation. Beyond prolonged intubation, tracheotomy is also indicated in patients who require frequent pulmonary toilet, in patients with neurologic deficits that impair protective airway reflexes, and in head and neck upper aerodigestive tract surgery as a temporary airway in the perioperative period to bypass airway obstruction.

Technique and Complications
The procedure can be performed using an open or a percutaneous technique. Complications of tracheostomy include pneumothorax, tracheal stenosis, wound infection/stomatitis with large-vessel erosion, and failure to close after decannulation. A meta-analysis of 15 randomized studies assessing nearly 1000 patients demonstrated no difference between the open and percutaneous techniques, although there was a trend toward fewer complications in the percutaneous approach. The percutaneous approach was also found to be cheaper and had the added benefit of being performed at the bedside outside of the operating room. A Cochrane review on the topic lower wound infection/stomatitis and unfavorable scarring rates with the percutaneous approach. Mortality and serious adverse events did not differ between the two techniques.

The use of cricothyroidotomy, typically in the emergency setting, is inferior to a tracheotomy due to higher incidence of vocal cord dysfunction and subglottic stenosis. Therefore, soon after a cricothyroidotomy is performed, a formal
tracheotomy should be used with decannulation of the cricothyroidotomy site. Most tracheostomies are not permanent and can be reversed simply by removing the tube and applying a pressure dressing. The stoma usually spontaneously heals within 2 to 3 weeks.

**Speech with Tracheotomy and Decannulation**

When a large cuffed tracheostomy is initially placed, speech is not possible, particularly when the cuff is up. However, when the tube is downsized to a cuffless tracheostomy tube,
intermittent finger occlusion or placement of Passy-Muir valve can allow the patient to voice while still bypassing the upper airway obstruction in inspiration. Prior to decannulation, the patient has to tolerate capping for 24 to 48 hours, but this period can be extended in patients with concerns for pulmonary toilet and an inability to clear secretions.

**LONG TERM MANAGEMENT AND REHABILITATION**

**Palliative Care**

For patients with unresectable disease (greater than 180° of encasement around the carotid artery, prevertebral fascia invasion, and skull base invasion) or distant metastases, palliative care options exist. The NCCN guidelines recommend clinical trials for patients in this category because there is not a single accepted regimen for patients with incurable disease but the goal of treatment is to control symptoms and maintain quality of life while minimizing the side effects of treatment. This may include a combination of radiotherapy, usually in a hypofractionated pattern with high dose per fraction regimen, chemotherapy, or simply pain management. A recent trial demonstrated the utility of immunotherapy, specifically, Nivolumab, in the management of recurrent unresectable head and neck cancer, showing a higher response rate (13.3%) compared to standard therapy (5.8%) with lower treatment-related adverse events (13.1% vs. 35.1%, respectively). From a surgical perspective, some patients require tracheostomy or gastrostomy tube placement to manage airway compromise and dysphagia, respectively. Palliative care facilities and hospice care allow patients to retain dignity when they have a limited short-term outlook.

**Follow-Up Care**

Patients diagnosed and treated for a head and neck tumor require follow-up care aimed at monitoring for recurrence and the side effects of therapy. The NCCN guidelines recommend follow-up assessment every 3 months for the first year after treatment, every 4 months during the following year, and then every 6 months until year 4, with an annual follow-up at 5 years post treatment and thereafter. This regimen is not well followed in North America, and further investigation is required to assess why this might be and to improve adherence rates. Follow-up should consist of a thorough history to assess for any emerging symptoms such as pain, otalgia, or dysphagia as these are often the first sign of a recurrence. Assessment by speech language pathology and a dietician is often beneficial to ascertain swallowing function and nutritional intake, respectively. Some patients require dilation or reinsertion of a gastrostomy tube if they develop pharyngeal strictures and are unable to maintain their weight. The history should be followed with a thorough head and neck examination, including fiberoptic nasolaryngoscopy, because of the significant risk of developing a second primary in the upper aerodigestive tract. Patients should have their thyroid stimulating hormone (TSH) checked once a year, especially in those that have radiation as they may develop hypothyroidism at an earlier age than the general population. Shoulder dysfunction after neck dissection with extensive accessory nerve dissection or in patients who have had a scapular system free flap should be managed with physiotherapy to minimize the long-term effects and improve function. Chronic pain can occur in head and neck cancer patients, and this is often assessed and managed by a pain specialist. Ongoing dental evaluation is needed in some patients to treat caries and prevent osteoradionecrosis.

TRACHEA

Anatomy
The trachea is composed of cartilaginous and membranous portions, beginning with the cricoid cartilage, the first complete cartilaginous ring of the airway. The cricoid cartilage consists of an anterior arch and a posterior broad-based plate. Articulating with the posterior cricoid plate are the arytenoid cartilages. The vocal cords originate from the arytenoid cartilages and then attach to the thyroid cartilage. The subglottic space, the narrowest part of the trachea with an internal diameter of approximately 2 cm, begins at the inferior surface of the vocal cords and extends to the first tracheal ring. The remainder of the distal trachea is 10.0 to 13.0 cm long, consists of 18 to 22 rings, and has an internal diameter of 2.3 cm (Fig. 19-1).

Bronchoscopically, the tracheal rings are visible as C-shaped hyaline cartilaginous structures that provide rigidity to the anterior and lateral tracheal walls. The open ends of the C-rings are connected by the trachealis smooth muscle and encased in a dense band of connective tissue called perichondrium. The first tracheal ring is attached directly to the cricoid cartilage; there are approximately two rings for every 1 cm of tracheal length.

The tracheal blood supply, which includes the inferior thyroid, subclavian, supreme intercostal, internal thoracic, innominate, and superior and middle bronchial arteries, enters the airway near the junction of the membranous and cartilaginous portions (Fig. 19-2). Each arterial branch supplies a segment of 1.0 to 2.0 cm, thereby limiting circumferential mobilization to that same distance. The vessels are interconnected along the lateral surface of the trachea by an important longitudinal vascular anastomosis that feeds transverse segmental vessels to the soft tissues between the cartilages.

Tracheal Injury
Tracheal injury can result from a variety of causes, including inhalation of smoke or toxic fumes, aspiration of liquids or solid objects, endotracheal intubation, blunt and penetrating trauma, and iatrogenic injury during operative procedures. Early diagnosis is critical to avoid subsequent complications, including respiratory infection and tracheal stenosis. Management of smoke or toxic fume inhalation and liquid aspiration is commonly supportive; use of antibiotics, respiratory support, and airway clearance with flexible bronchoscopy is dictated by the patient’s condition. In rare circumstances, extracorporeal membrane oxygenation is required if there is associated injury to the more distal airways and lung parenchyma.

Despite ubiquitous use of high-volume–low-pressure cuffs, overinflation of the endotracheal cuff is the most common cause of injury secondary to endotracheal intubation. High cuff pressures can cause ischemia of the contiguous airway wall in as short as 4 hours. Prolonged overinflation can lead to scarring...
Key Points

1. Lung cancer continues to be a highly lethal and extremely common cancer, with 57% of patients presenting with distant metastasis and 5-year survival of 18%. Lung cancer incidence is second only to the incidence of prostate cancer in men and breast cancer in women, with 222,500 estimated new cases in 2017. Squamous cell carcinoma and adenocarcinoma of the lung are the most common subtypes and are rarely found in the absence of a smoking history. Nonsmokers who live with smokers have a 24% increased risk of lung cancer compared to nonsmokers who do not live with smokers.

2. A multidisciplinary approach to evaluation of NSCLC, with standardized criteria and terminology for diagnosis in cytologic and small biopsy specimens, and routine molecular testing for known mutations, such as EGFR mutations and EML4-ALK fusion oncogenes is now recommended for the evaluation and management of lung nodules due to major advances in targeted therapy. Adequate tissue acquisition at the time of diagnostic workup is critical and facilitates patient care while minimizing the number of procedures to which the patient is subjected.

3. The terms bronchioloalveolar carcinoma and mixed subtype adenocarcinoma have been eliminated from the classification of lung adenocarcinoma as a result of increased understanding of important clinical, radiologic, pathologic, and genetic differences between mucinous and nonmucinous adenocarcinomas. The classification system delineates a stepwise pathologic progression, from AAH to nonmucinous adenocarcinomas. The classification system includes many tumor cell types, including large cell, squamous cell, and adenocarcinoma. The approach to diagnosis and management and the terminology used in describing these tumors are evolving rapidly. In particular, the evaluation and management of adenocarcinoma of the lung has shifted dramatically and firm establishment of NSCLC cell type prior to chemotherapy for advanced stage lung cancer is essential.

4. The U.S. Preventive Services Task Force now recommends annual screening for lung cancer with low-dose computed tomography screening in high risk patients. Annual screening averted 14% of lung cancer deaths when applied to a population of asymptomatic adults age 55 to 80 years who have a 30 pack-year smoking history and are either currently smoking or have quit within the past 15 years. Patients should be healthy enough to tolerate curative treatment, specifically surgery per guidelines, and screening should be discontinued once the patient has not smoked for 15 years or develops a life-limiting health condition, becomes unable to tolerate lung surgery, or is unwilling to undergo curative lung resection. With this approach, it is expected that 50% of diagnosed cancers will be early stage. Screening of patients age 50 years or older with a 20 pack-year or greater history and additional risk factors (as determined by the Tammemagi lung cancer risk calculator or other validated risk scores) that increase the risk of lung cancer to 1.3% or greater should also be considered as part of lung cancer screening programs. In all cases, patient–physician shared decision-making should be undertaken, with a discussion of the risks and benefits of screening.

5. Assessment of patient risk before thoracic resection is based on clinical judgment and systematic assessment of cardiopulmonary status using established algorithms.

6. Maximum oxygen consumption ($$\text{VO}_{2\text{max}}$$) values provide important additional information in those patients with severely impaired DLco and forced expiratory volume in 1 second. Values of <10 mL/kg per minute generally prohibit any major pulmonary resection because the mortality in patients with these levels is 26% compared with only 8.3% in patients whose $$\text{VO}_{2\text{max}}$$ is ≥10 mL/kg per minute; values of >15 mL/kg per minute generally indicate the patient’s ability to tolerate pneumonectomy.

7. Tumor ablative strategies are viable alternatives to surgical resection for early stage lung cancer in inoperable patients. While premature, ablative techniques may ultimately be shown to have efficacy equivalent to lobectomy for the primary treatment of very small peripheral early-stage lung cancers and become primary therapy, even in operable patients, although limited resection with wedge (at least 2 cm margin and at least 1:1 tumor/margin ratio) and segmentectomy provide better margins of treatment and nodal sampling ensures occult nodal metastasis are identified. Multidisciplinary collaboration among thoracic surgery, interventional radiology/pulmonology, and radiation oncology is required to ensure that development of these ablative techniques occurs through properly designed and well-controlled prospective studies and will ensure that patients receive the best available therapy, regardless of whether it is surgical resection or ablative therapy.

8. The term non–small cell lung carcinoma (NSCLC) includes many tumor cell types, including large cell, squamous cell, and adenocarcinoma. The approach to diagnosis and management and the terminology used in describing these tumors are evolving rapidly. In particular, the evaluation and management of adenocarcinoma of the lung has shifted dramatically and firm establishment of NSCLC cell type prior to chemotherapy for advanced stage lung cancer is essential.

9. Increasing evidence suggests a significant role for gastroesophageal reflux disease in the pathogenesis of chronic lung diseases such as bronchiectasis and idiopathic pulmonary fibrosis, and it may also contribute to bronchiolitis obliterans syndrome in lung transplant patients.

10. Treatment of pulmonary aspergillosis/aspergilloma is individualized. Following colonization of a lung cavity or area of bronchiectasis, fungal growth within the cavity appears as an irregular cavity lining, progressing over time as a late finding in chronic pulmonary aspergillosis to a fungal ball called an aspergilloma. Asymptomatic patients can be observed without any additional treatment. Similarly, mild hemoptysis, which is not life-threatening, can be managed with medical therapy, including antifungals and cough suppressants. Oral triazole therapy is now considered the standard of care for chronic, cavitary pulmonary aspergillosis. Massive hemoptysis had traditionally been an indication for urgent or emergent operative intervention. However, with the advancement of endovascular techniques, bronchial artery embolization in select centers with experience in these techniques has been effective.

11. In patients with malignant pleural effusion, poor expansion of the lung (because of entrapment by tumor or adhesions) generally predicts a poor result with pleurodesis and is the primary indication for placement of indwelling pleural catheters. These catheters have dramatically changed the management of end-stage cancer treatment because they substantially shorten the amount of time patients spend in the hospital during their final weeks of life.
and stenosis; full-thickness injury can result in fistulae between the innominate artery anteriorly and the esophagus posteriorly. Avoidance requires careful cuff management to keep pressures as low as possible; in circumstances of prolonged ventilatory support and high airway pressure, cuff pressure monitoring (to maintain pressures <20 mmHg) is advisable.

Historically, clinically significant tracheal stenosis after tracheostomy occurred in 3% to 12% of cases, with severe stenosis in 1% to 2%. With the use of low-pressure cuffs, the estimated incidence has decreased to 4.9 cases per million patients per year. Intubation-related risk factors include prolonged intubation; high tracheostomy through the first tracheal ring or cricothyroid membrane; transverse rather than vertical incision on the trachea; oversized tracheostomy tube; prior tracheostomy or intubation; and traumatic intubation. Stenosis is also more common in older patients, in women, after radiation, or after excessive corticosteroid therapy, and in the setting of concomitant diseases such as autoimmune disorders, severe reflux disease, or obstructive sleep apnea and the setting of severe respiratory failure. However, even a properly placed tracheostomy can lead to tracheal stenosis because of scarring and local injury. Mild ulceration and stenosis are frequently seen after tracheostomy removal. Use of the smallest tracheostomy tube possible, rapid downsizing, and a vertical tracheal incision minimize the risk for posttracheostomy stenosis.

Stridor and dyspnea on exertion are the primary symptoms of tracheal stenosis. In the setting of postintubation injury, a significant portion of the cartilaginous structural support to the airway is destroyed by regional ischemic necrosis; during healing, a weblike fibrous growth develops and narrows the airway (Fig. 19-3). In contrast, stenosis caused by tracheostomy is most commonly due to an excess of granulation tissue formation around the tracheal stoma site. Time to onset of symptoms after extubation or tracheostomy decannulation usually ranges from 2 to 12 weeks, but symptoms can appear immediately or as long as 1 to 2 years later. Frequently, patients are misdiagnosed as having asthma or bronchitis, and treatment for such illnesses can persist for some time before the correct diagnosis is discovered. Generally, symptom intensity is related to the degree of stenosis and to the patient’s underlying pulmonary disease.
Figure 19-3. Diagram of the principal postintubation lesions. A. A circumferential lesion at the cuff site after the use of an endotracheal tube. B. Potential lesions after the use of tracheostomy tubes. Anterolateral stenosis can be seen at the sternal level. Circumferential stenosis can be seen at the cuff level (lower than with an endotracheal tube). The segment in between is often inflamed and malacic. C. Damage to the subglottic larynx. D. Tracheoesophageal fistula occurring at the level of the tracheostomy cuff; circumferential damage is usual at this level. E. Tracheoinnominate artery fistula. (Adapted with permission from Grillo H. Surgical treatment of postintubation tracheal injuries. J Thorac Cardiovasc Surg. 1979 Dec;78(6):860-875.)

**Acute Management.** A comprehensive bronchoscopic evaluation is critical in the initial phase of evaluation. Stenosis length, location, distance between the vocal cords and proximal stenosis, and distance from the distal aspect to the major carina must be documented. In patients with severe stenosis and respiratory compromise, rigid bronchoscopy can be used to dilate the stenosis; this provides immediate relief of the airway obstruction and facilitates thorough evaluation of the stenosis. Rarely, if ever, is tracheostomy necessary.

Most intubation injuries are located in the upper third of the trachea and can be accessed for resection through a collar incision. Resection typically involves 2 to 4 cm of trachea for benign stenosis. It is critical to fully resect all inflamed and scarred tissue. However, a primary anastomosis can still be performed without undue tension, even if up to one half of the trachea requires resection. Ideally, the patient is extubated in the operating room or shortly thereafter. For patients in whom tracheal resection is not possible, such as patients with significant comorbidities or with an excessively long stenosis, endotracheal stenting, typically silicone T-tubes, can provide palliation. Wire mesh stents should not be used, given their known propensity to erode through the wall of the airway. Balloon dilation, laser ablation, and tracheoplasty have also been described, though the efficacy is marginal.

Tracheal replacement is evolving as an option for management of tracheal stenosis as bioengineering techniques for decellularizing donor trachea have been developed. This removes all antigens against which the recipient immune system might react and enables use of the donor trachea scaffold without risk of rejection. Following decellularization, the donor tracheal scaffold is seeded with recipient chondrocytes, to restore tracheal rigidity, and with recipient epithelial cells, to recreate the inner epithelial lining. Several case reports of successful allogeneic tracheal transplantation have been published. The technique continues to be limited to a few highly specialized centers, due, in part, to the scarcity of donor trachea and the need for tissue bioengineering expertise as well as the lack of established efficacy for the approach. Current efforts are focused on creation of biosynthetic scaffolding that can be used instead of donor trachea. This would substantially increase the availability of the tracheal replacement material and enable widespread use of the technique, but early results have been contested, including three case reports called into question as containing multiple data fabrications and omissions.

**Tracheal Fistulas**

**Tracheoinnominate Artery Fistula.** Tracheoinnominate artery fistula has two main causes: low placement of a tracheostomy and hyperinflation of the tracheal cuff. Tracheostomy placement should be through the second to fourth tracheal rings without reference to the location of the sternal notch. When placed below the fourth tracheal ring, the inner curve of the tracheostomy cannula will be positioned to exert pressure on the posterior aspect of the innominate artery, leading to arterial erosion. Similarly, the tracheal cuff, when hyperinflated, will cause ischemic injury to the anterior airway and subsequent erosion into the artery. Most cuff-induced fistulas will develop within 2 weeks after placement of the tracheostomy. Clinically, tracheoinnominate artery fistulas present with bleeding. A premonitory hemorrhage often occurs and, although it is usually not massive, must not be ignored or simply attributed to general airway irritation or wound bleeding. With significant bleeding, the tracheostomy cuff can be hyperinflated to temporarily occlude the arterial injury. If such an effort is unsuccessful, the tracheostomy incision should be immediately opened widely and a finger inserted to compress the artery.
against the manubrium (Fig. 19-4). The patient can then be orally intubated, and the airway suctioned free of blood. Emergent surgical resection of the involved segment of artery is performed, usually without reconstruction.

**Tracheoesophageal Fistula.** Tracheoesophageal fistulas (TEFs) occur primarily in patients receiving prolonged mechanical ventilator support concomitant with an indwelling nasogastric tube. Cuff compression of the membranous trachea against the nasogastric tube leads to airway and esophageal injury and fistula development. Clinically, airway suctioning reveals saliva, gastric contents, or tube feedings. Gastric insufflation, secondary to positive pressure ventilation, can occur. Bronchoscopy is diagnostic; with the bronchoscope inserted, the endotracheal tube is withdrawn, and the fistula at the cuff site is exposed. Alternatively, esophagoscopy demonstrates the cuff of the endotracheal tube in the esophagus.

Treatment, first and foremost, requires removing tubes from the esophagus and weaning the patient from the ventilator. The cuff of the endotracheal tube should be placed below the fistula, avoiding overinflation. To minimize aspiration, a gastrostomy tube should be placed for gastric decompression (to prevent reflux) and a jejunostomy tube for feeding. If aspiration persists, esophageal diversion with cervical esophagostomy can be performed. Once weaned from the ventilator, tracheal resection and primary anastomosis, repair of the esophageal defect, and interposition of a muscle flap between the trachea and esophagus can be performed (Fig. 19-5).

**Tracheal Neoplasms**

Although extremely rare, the most common primary tracheal neoplasms are squamous cell carcinomas (related to smoking) and adenoid cystic carcinomas. Clinically, tracheal tumors present with cough, dyspnea, hemoptysis, stridor, or symptoms of invasion of contiguous structures (such as the recurrent laryngeal nerve or the esophagus). The most common radiologic finding of tracheal malignancy is tracheal stenosis, but it is found in only 50% of cases. With tumors other than squamous cell carcinomas, symptoms may persist for months because of slow tumor growth rates. Stage of presentation is advanced, with approximately 50% of patients presenting with stage IV disease. Five-year survival for all tracheal neoplasms is 40% but falls to 15% for those with stage IV disease.

Squamous cell carcinomas often present with regional lymph node metastases and are frequently unresectable at presentation. Their biologic behavior is similar to that of squamous cell carcinoma of the lung. Adenoid cystic carcinomas, a type of...
salivary gland tumor, are generally slow growing, spread submucosally, and tend to infiltrate along nerve sheaths and within the tracheal wall. Although indolent in nature, adenoid cystic carcinomas are malignant and can spread to regional lymph nodes, lung, and bone. Squamous cell carcinoma and adenoid cystic carcinomas represent approximately 65% of all tracheal neoplasms. The remaining 35% is comprised of small cell carcinomas, mucoepidermoid carcinomas, adenocarcinomas, lymphomas, and others.7

**Therapy.** Evaluation and treatment of patients with tracheal tumors should include neck and chest computed tomography (CT) and rigid bronchoscopy. Rigid bronchoscopy permits general assessment of the airway and tumor; it also allows debridement or laser ablation of the tumor to provide relief of dyspnea. If the tumor is judged to be completely resectable, primary resection and anastomosis is the treatment of choice for these tumors (Fig. 19-6). Up to 50% of the length of the trachea can be resected with primary anastomosis. In most tracheal resections, anterolateral tracheal mobilization and suturing of the chin to the sternum for 7 days are done routinely. Use of laryngeal and hilar release is determined at the time of surgery, based on the surgeon’s judgment of the degree of tension present. For longer resections, specialized maneuvers are necessary such as laryngeal release and right hilar release to minimize tension on the anastomosis.

Postoperative mortality, which occurs in up to 10% of patients, is associated with the length of tracheal resection, use of laryngeal release, the type of resection, and the histologic type of the cancer. Factors associated with improved long-term survival include complete resection and use of radiation as adjuvant therapy in the setting of incomplete resection.9 Due to their radiosensitivity, radiotherapy is frequently given postoperatively after resection of both adenoid cystic carcinomas and squamous cell carcinomas. A dose of 50 Gy or greater is usual. Nodal positivity does not seem to be associated with worse survival. Survival at 5 and 10 years is much better for adenoid...
the nodes of the lymphatic sump lie around the bronchus intermedius (bounded above by the right upper lobe bronchus and below by the middle lobe and superior segmental bronchi). On the left, the lymphatic sump is confined to the interlobar fissure, with the lymph nodes in the angle between the lingular and lower lobe bronchi. These nodes are always in close proximity to pulmonary arterial branches and typically must be carefully dissected to identify the pulmonary arterial segments for division during lung resection.

The N2 lymph nodes consist of four main groups. (a) The anterior mediastinal nodes are located in association with the upper surface of the pericardium, the phrenic nerves, the ligamentum arteriosum, and the left aspect of the innominate vein. (b) The posterior mediastinal group includes paraeosophageal lymph nodes within the inferior pulmonary ligament and, more superiorly, between the esophagus and trachea near the arch of the azygos vein. (c) The tracheobronchial lymph nodes are made up of three subgroups that are located near the bifurcation of the trachea. These include the subcarinal nodes, which lie in the obtuse angle between the trachea and each main stem bronchus, and the nodes that lay anterior to the lower end of the trachea. (d) Paratracheal lymph nodes are located in proximity to the trachea in the superior mediastinum. Those on the right side form a chain with the tracheobronchial nodes inferiorly and with some of the deep cervical nodes above (scalene lymph nodes).

Lymphatic drainage to the mediastinal lymph nodes from the right lung is ipsilateral, except for occasional bilateral drainage to the superior mediastinum. In contrast, in the left lung, particularly the left lower lobe, lymphatic drainage occurs with equal frequency to ipsilateral and contralateral superior mediastinal nodes.

cystic (73% and 57%, respectively) than for tracheal cancers (47% and 36%, respectively; \( P < .05 \)). For patients with unresectable tumors, radiation may be given as the primary therapy to improve local control, but it is rarely curative. For recurrent airway compromise, stenting or laser therapies should be considered as part of the treatment algorithm.

**LUNG**

**Anatomy**

**Segmental Anatomy.** The segmental bronchial and vascular anatomy of the lungs allows subsegmental and segmental resections, if the clinical situation requires or if lung tissue can be preserved\(^a\) (Fig. 19-7). Note the continuity of the pulmonary parenchyma between adjacent segments of each lobe.

**Lymphatic Drainage.** Lymph nodes that drain the lungs are divided into two groups according to the tumor-node-metastasis (TNM) staging system for lung cancer: the pulmonary lymph nodes (N1) and the mediastinal nodes (N2) (Fig. 19-8).

The N1 lymph nodes constitute the following: (a) intrapulmonary or segmental nodes that lie at points of division of segmental bronchi or in the bifurcations of the pulmonary artery; (b) lobar nodes that lie along the upper, middle, and lower lobe bronchi; (c) interlobar nodes located in the angles formed by the main bronchi bifurcating into the lobar bronchi; and (d) hilar nodes along the main bronchi. The interlobar lymph nodes lie in the depths of the interlobar fissure on each side and constitute a lymphatic sump for each lung, referred to as the **lymphatic sump of Borrie**; all of the pulmonary lobes of the corresponding lung drain into this group of nodes (Fig. 19-9). On the right,
Normal Lung Histology

The lung can be conveniently viewed as two linked components: the tracheobronchial tree (or conducting airways component) and the alveolar spaces (or gas exchange component). The tracheobronchial tree consists of approximately 23 airway divisions to the level of the alveoli. It includes the main bronchi, lobar bronchi, segmental bronchi (to designated bronchopulmonary segments), and terminal bronchioles (i.e., the smallest airways still lined by bronchial epithelium and without alveoli). The tracheobronchial tree is normally lined by pseudostratified ciliated columnar cells and mucous (or goblet) cells, which both derive from basal cells (Fig. 19-10). Ciliated cells predominate. Goblet cells, which release mucus, can significantly increase in number in acute bronchial injury, such as exposure to cigarette smoke. The normal bronchial epithelium also contains bronchial submucosal glands, which are mixed salivary-type glands.
containing mucous cells, serous cells, and neuroendocrine cells called Kulchitsky cells, which are also found within the surface epithelium. The bronchial submucosal glands can give rise to salivary gland–type tumors, including mucoepidermoid carcinomas and adenoid cystic carcinomas.

Two cell types, called type I and type II pneumocytes, make up the alveolar epithelium. Type I pneumocytes comprise 40% of the total number of alveolar epithelial cells, but cover 95% of the surface area of the alveolar wall. These cells are not capable of regeneration because they have no mitotic potential. Type II pneumocytes cover only 3% of the alveolar surface, but comprise 60% of the alveolar epithelial cells. In addition, clusters of neuroendocrine cells are seen in the alveolar spaces.

**Preinvasive Lesions**

The term “precancerous” does not mean that an inevitable progression to invasive carcinoma will occur, but such lesions, particularly those with high-grade dysplasia,\(^{11,12}\) do constitute a clear marker for potential development of invasive cancer.

Three precancerous lesions of the respiratory tract are currently recognized.

1. **Squamous dysplasia and carcinoma in situ.** Cigarette smoke can induce a transformation of the tracheobronchial pseudostratified epithelium to metaplastic squamous mucosa, with subsequent evolution to dysplasia as cellular abnormalities accumulate. Dysplastic changes include altered cellular polarity and increased cell size, number of cell layers, nuclear-to-cytoplasmic ratio, and number of mitoses. Gradations are considered mild, moderate, or severe. Carcinoma in situ represents carcinoma still confined by the basement membrane.

2. **Atypical adenomatous hyperplasia (AAH).** AAH is a lesion smaller than 5.0 mm, comprising epithelial cells lining the alveoli that are similar to type II pneumocytes. Histologically, AAH is similar to adenocarcinoma in situ; it represents the beginning stage of a stepwise evolution to adenocarcinoma in situ and then to adenocarcinoma. With the availability of thin-section CT, it is possible to detect

Variants of invasive adenocarcinoma

- Invasive mucinous adenocarcinoma (formerly mucinous BAC)
- Colloid
- Fetal (low and high grade)
- Enteric

Abbreviations: BAC = bronchioloalveolar carcinoma; IASLC = International Association for the Study of Lung Cancer; ATS = American Thoracic Society; ERS = European Respiratory Society.

but occasionally it will present as part of a solid or part-solid nodule. Mucinous AIS is more likely to appear solid or to have the appearance of consolidation. As with AAH, the lesions can be single or multiple; the ground-glass changes in AIS, however, tend to have a higher attenuation compared to AAH. The 8th edition American Joint Committee on Cancer (AJCC) staging manual t-stage for AIS is tumor in situ (Tis).

2. Minimally invasive adenocarcinoma (MIA). In the same size solitary lesion, if less than 5 mm of invasion are noted within a predominantly lepidic growth pattern, the lesion is termed minimally invasive adenocarcinoma (MIA) to indicate a patient group with near 100% survival when the lesion is completely resected. This differentiates patients with AIS, but recognizes the fact that the presence of invasion becomes prognostically significant when the size of the invasive component reaches 5 mm or greater in size.16 If multiple areas of microscopic invasion are found within the lepidic growth, the size of the largest invasive area, measured in the largest dimension, is used; this area must be $\leq 5$ mm to be considered MIA. As with AIS, MIA is very rarely mucinous. The invasive component histologically is acinar, papillary, micropapillary, and/or solid and shows tumor cells infiltrating into the surrounding myofibroblastic stroma. On CT scan, the appearance of MIA is often a part-solid nodule ($\leq 5$ mm) with a predominant ground-glass component, but can be highly variable. The 8th edition American Joint Committee on Cancer (AJCC) staging manual t-stage for MIA is T1mi.

3. Lepidic predominant adenocarcinoma (LPA). If lymphovascular invasion, pleural invasion, tumor necrosis, or more than 5 mm of invasion are noted in a lesion that has lepidic growth as its predominant component, MIA is excluded, the lesion is called lepidic predominant adenocarcinoma (LPA), and the size of the invasive component is recorded for the T stage.

4. Invasive adenocarcinoma. The new classification system now recommends classifying invasive adenocarcinoma by the most predominant subtype after histologic evaluation of the resection specimen. To determine the predominant subtype, histologic sections are evaluated, and the patterns are determined, in 5% increments, throughout the specimen. This semiquantitative method encourages the viewer to identify and quantify all patterns present, rather than focusing on a single pattern. In the pathology report, the tumor is classified by the predominant pattern, with percentages of the subtypes also reported (Fig. 19-11). Subtypes include:

   a. Lepidic predominant
   b. Acinar predominant
   c. Papillary predominant
   d. Micropapillary predominant
   e. Solid predominant

Adenocarcinoma is often peripherally located and frequently discovered incidentally on routine chest radiographs, unlike squamous cell cancers. When symptoms occur, they are due to pleural or chest wall invasion (pleuritic or chest wall pain) or pleural seeding with malignant pleural effusion. Invasive adenocarcinoma is usually solid by CT scan, but can also be part-solid and even a ground-glass nodule. Occasionally, a lobular ground-glass opacification may be present, which is often associated with significant respiratory compromise and can be mistaken for lobar pneumonia. Bubble-like or cystic lucency on CT scan in small ($\leq 2$ cm) adenocarcinomas or extensive associated ground-glass components correlate with slow growth and well-differentiated tumors and a more favorable prognosis. Intratumoral air bronchograms are usually indicative of well-differentiated tumor, whereas spiculations that are coarse and thick ($\geq 2$ mm) portend vascular invasion and nodal metastasis and are associated with decreased survival following complete surgical resection. Pleural retraction is also a poor prognostic indicator.

5. Additional histologic variants include colloid adenocarcinoma (formerly mucinous cystadenocarcinoma), fetal adenocarcinoma, and enteric adenocarcinoma. Clear cell and signet ring cell types are no longer considered to be distinct subtypes as they are found in association with most of the five dominant histologic patterns (lepidic, acinar, papillary, micropapillary, and solid). However, they are still notable, as they can signal clinically relevant molecular changes, such as the presence of the EML4-ALK fusion gene in solid tumors with signet ring features.

Squamous Cell Carcinoma Representing 30% to 40% of lung cancers, squamous cell carcinoma is the most frequent cancer in men and highly correlated with cigarette smoking. They arise primarily in the main, lobar, or first segmental bronchi, which are collectively referred to as the central airways. Symptoms of airway irritation or obstruction are common, and include cough,
hemoptysis, wheezing (due to high-grade airway obstruction), dyspnea (due to bronchial obstruction with or without postobstructive atelectasis), and pneumonia (caused by airway obstruction with secretion retention and atelectasis).

Occasionally a more peripherally based squamous cell carcinoma will develop in a tuberculosis scar or in the wall of a bronchiectatic cavity. Histologically, cells develop a pattern of clusters with intracellular bridges and keratin pearls. Central necrosis is frequent and may lead to the radiographic findings of a cavity (possibly with an air-fluid level). Such cavities may become infected, with resultant abscess formation.

**Large Cell Carcinoma** Large cell carcinoma accounts for 10% to 20% of lung cancers and may be located centrally or peripherally. These tumors have cell diameters of 30 to 50 µm, which are often admixed with various other malignant cell types. Large cell carcinoma can be confused with a large cell variant of neuroendocrine carcinoma, but can be differentiated by special immunohistochemical stains.

**Salivary Gland–Type Neoplasms.** Salivary-type submucosal bronchial glands throughout the tracheobronchial tree can give rise to tumors that are histologically identical to those seen in the salivary glands. The two most common are adenoid cystic carcinoma and mucoepidermoid carcinoma. Both occur centrally due to their site of origin. Adenoid cystic carcinoma is a slow-growing tumor that is locally and systemically invasive, growing submucosally and infiltrating along perineural sheaths. Mucoepidermoid carcinoma consists of squamous and mucous cells and is graded as low or high grade, depending on mitotic rate and degree of necrosis.

**Neuroendocrine Neoplasms.** Neuroendocrine lung tumors are classified into neuroendocrine hyperplasia and three grades of neuroendocrine carcinoma (NEC). Immunohistochemical staining for neuroendocrine markers (including chromogranins, synaptophysin, CD57, and neuron-specific enolase) is essential to accurate diagnosis.17

Grade I NEC (classic or typical carcinoid) is a low-grade NEC; 80% arise in the central airway epithelium and occur primarily in younger patients. Because it is a central lesion, hemoptysis, with or without airway obstruction and pneumonia is the most common presentation. Histologically, tumor cells

---

Figure 19-11. Major histologic patterns of invasive adenocarcinoma. A. Lepidic predominant pattern with mostly lepidic growth (right) and a smaller area of invasive acinar adenocarcinoma (left). B. Lepidic pattern consists of a proliferation type II pneumocytes and Clara cells along the surface alveolar walls. C. Area of invasive acinar adenocarcinoma (same tumor as in A and B). D. Acinar adenocarcinoma consists of round to oval-shaped malignant glands invading a fibrous stroma. E. Papillary adenocarcinoma consists of malignant cuboidal to columnar tumor cells growing on the surface of fibrovascular cores. F. Micropapillary adenocarcinoma consists of small papillary clusters of glandular cells growing within this airspace, most of which do not show fibrovascular cores. G. Solid adenocarcinoma with mucin consisting of sheets of tumor cells with abundant cytoplasm and mostly vesicular nuclei with several conspicuous nucleoli. No acinar, papillary, or lepidic patterns are seen, but multiple cells have intracytoplasmic basophilic globules that suggest intracytoplasmic mucin. H. Solid adenocarcinoma with mucin. Numerous intracytoplasmic droplets of mucin are highlighted with this diastase-periodic acid Schiff stain. (Reproduced with permission from Travis WD, Brambilla E, Noguchi M, et al: International association for the study of lung cancer/american thoracic society/european respiratory society international multidisciplinary classification of lung adenocarcinoma, J Thorac Oncol. 2011 Feb;6(2):244-285.)
are arranged in cords and clusters with a rich vascular stroma, which can lead to life-threatening hemorrhage with even simple bronchoscopic biopsy maneuvers. Regional lymph node metastases are seen in 15% of patients, but systemic spread and death from Grade I NEC is rare.

Grade II NECs (atypical carcinoid) have a much higher malignant potential and, unlike grade I NEC, are etiologically linked to cigarette smoking and more likely to be peripherally located. Histologic findings may include areas of necrosis, nuclear pleomorphism, and higher mitotic rates. Lymph node metastases are found in 30% to 50% of patients. At diagnosis, 25% of patients already have remote metastases.

Grade III NEC large cell–type tumors occur primarily in heavy smokers and in the mid to peripheral lung fields. Often large with central necrosis and a high mitotic rate, their neuroendocrine nature is revealed by positive immunohistochemical staining for at least one neuroendocrine marker.

Grade IV NEC (small cell lung carcinoma [SCLC]) is the most malignant NEC and accounts for 25% of all lung cancers; these NECs often have early, widespread metastases. These cancers also arise primarily in the central airways. As with squamous cell cancers, symptoms include cough, hemoptysis, wheezing (due to high-grade airway obstruction), dyspnea (due to bronchial obstruction with or without postobstructive atelectasis), and pneumonia (caused by airway obstruction with secretion retention and atelectasis). Evaluation includes expert pathology review and comprehensive evaluation for metastatic disease. Three groups of grade IV NEC are recognized: pure small cell carcinoma (previously referred to as oat cell carcinoma), small cell carcinoma with a large cell component, and combined (mixed) tumors.

Grade IV NECs consist of smaller cells (diameter 10 to 20 µm) with little cytoplasm and very dark nuclei; they can be difficult to distinguish from lymphoproliferative lesions and atypical carcinoid tumors. Histologically, a high mitotic rate with easily visualized multiple mitoses and areas of extensive necrosis are characteristic. Importantly, very small bronchoscopic biopsies can distinguish NSCLC from SCLC, but crush artifact may make NSCLC appear similar to SCLC. If uncertainty exists, special immunohistochemical stains or rebiopsy (or both) will be necessary. These tumors are the leading producer of paraneoplastic syndromes.

Lung Cancer Epidemiology
Lung cancer is the leading cancer killer and second most frequently diagnosed cancer in the United States, accounting for 26% of all cancer deaths in 2017—more than cancers of the breast, prostate, ovary, and colon and rectum combined (Fig. 19-12).14 Lung cancer incidence continues to decline, though at twice the rate for men compared to women (Fig. 19-13A, B). It is encouraging, however, that the average annual death rate declined by 3.5% per year for men and 2% per year for women from 2010 to 2014, representing a 43% decline in mortality for men and a 17% decline for women from 1990 to 2014.

Figure 19-13. Trends in death rates by sex for select cancers, United States, 1930 to 2014. **A.** Males. **B.** Female rates are age-adjusted to the 2000 U.S. standard population. Due to improvements in International Classification of Diseases (ICD) coding over time, numerator data for cancers of the lung and bronchus, colon and rectum, liver, and uterus differ from the contemporary time period. For example, rates for lung and bronchus include pleura, trachea, mediastinum, and other respiratory organs. *(Adapted with permission from Siegel RL, Miller KD, Jemal A: Cancer Statistics, 2017, CA Cancer J Clin. 2017 Jan;67(1):7-30.)*
to 2014. Unfortunately, most patients are still diagnosed at an advanced stage of disease (22% with regional metastasis and 57% with distant metastasis), so therapy is rarely curative.

Prognostic markers for lung cancer survival include female sex (5-year survival of 18.3% for women vs. 13.8% for men), younger age (5-year survival of 22.8% for those <45 years vs. 13.7% for those >65 years), and white race (5-year survival of 16.1% for whites vs. 12.2% for blacks). When access to advanced medical care is unrestricted, as for the military population, the racial difference in survival disappears, suggesting that, at least in part, differences in survival may be explained by less access to advanced medical care and later diagnosis.

**Risk Factors for Lung Cancer.** Cigarette smoking is the leading preventable cause of cancer death, accounting for 29% of the population attributable fraction in 2010, and is implicated as a causal factor in approximately 90% of lung cancers in men and nearly 80% in women. Two lung cancer types—squamous cell and small cell carcinoma—are extraordinarily rare in the absence of cigarette smoking. The risk of developing lung cancer escalates with the number of cigarettes smoked, the number of years of smoking, and the use of unfiltered cigarettes. Conversely, the risk of lung cancer declines with smoking cessation, but never drops to that of never smokers, regardless of the length of abstinence (Table 19-3).

Radon exposure accounts for the vast majority of the remaining cancers. Approximately 25% of all lung cancers worldwide and 53% of cancers in women are not related to smoking, and most of them (62%) are adenocarcinomas. Table 19-4 summarizes the existing data regarding the etiology of lung cancer in nonsmokers.

Nearly 3500 deaths from lung cancer each year are attributable to secondhand (environmental) smoke exposure, which confers an excess risk for lung cancer of 24% when a nonsmoker lives with a smoker. Risk is conferred by exposure to any burning tobacco, including cigars. The amount of secondhand exposure from one large cigar is equivalent to the exposure from 21 cigarettes. As with active smoking, risk of developing lung cancer increases with longer duration and higher level of exposure to environmental tobacco.

Over 7000 chemicals have been identified in tobacco smoke, and more than 70 of the compounds are known to be carcinogens. The main chemical carcinogens are polycyclic aromatic hydrocarbons, which are actively or passively inhaled in the tobacco smoke and absorbed; these compounds are activated by specific enzymes and become mutagenic, bind to macromolecules such as deoxyribonucleic acid (DNA), and induce genetic mutations. In treating any patient with a previous smoking history, it is important to remember that there has been field cancerization of the entire aerodigestive tract. The patient’s risk is increased for cancers of the oral cavity, pharynx, larynx, tracheobronchial tree and lung, and esophagus. In examining such patients, a detailed history and physical examination of these organ systems must be performed.

Other causes of lung cancer include exposure to a number of industrial compounds, including asbestos, arsenic, and chromium compounds. In fact, the combination of asbestos and cigarette smoke exposure has a multiplicative effect on risk. Pre-existing lung disease confers an increased risk of lung cancer—up to 13%—for individuals who have never smoked. Patients with chronic obstructive pulmonary disease are at higher risk for lung cancer than would be predicted based on smoking risk alone. Patients with secondary scar formation related to a history of tuberculosis or other lung infections also have a higher risk of primary lung carcinoma. This increase is thought to be related to poor clearance of inhaled carcinogens and/or to the effects of chronic inflammation.

**Screening for Lung Cancer in High-Risk Populations**

In 2002, the National Lung Screening Trial (NLST) was launched to determine whether screening with CT in high-risk populations would reduce mortality from lung cancer. The study randomized 53,353 eligible patients age 55 to 74 years to either three annual low-dose helical CT scans (LDCT; aka spiral CT) or posteroanterior view chest radiograph. Patients were eligible for the trial if they had a greater than 30 pack-year history of cigarette smoking; had smoked within the past 15 years if a former smoker; had no prior history of lung cancer; had no history of other life-threatening cancers in the prior 5 years; did not have symptoms suggestive of an undiagnosed lung cancer (such as hemoptysis or weight loss); and had not had a chest CT scan in the prior 18 months. Accrual to the study was excellent, and the primary endpoint of a 20% relative reduction in mortality was achieved in 2010. An absolute risk reduction of lung cancer death of four per 1000 individuals screened by LDCT was realized. Interestingly, all-cause mortality was also reduced by nearly 7% in the LDCT group, further emphasizing the impact of lung cancer on the mortality of smokers and former smokers.

The U.S. Preventive Services Task Force (USPSTF) now recommends annual screening for lung cancer with low-dose computed tomography screening in high risk patients. Annual screening averted 14% of lung cancer deaths when applied to a population of asymptomatic adults age 55 to 80 years who have a 30 pack-year smoking history and are either currently smoking or have quit within the past 15 years. Patients should be healthy enough to tolerate curative treatment, specifically surgery per guidelines, and screening should be discontinued once the patient has not smoked for 15 years or develops a life-limiting health condition, becomes unable to tolerate lung surgery or is unwilling to undergo curative lung resection. Requirements for coverage differ between Medicare and private insurers, with private insurers following the USPSTF guidelines, while Medicare uses age 55 to 77 years with the same smoking history but does not define comorbid conditions. Use of standardized reporting with criteria for lung nodule identification and classification is required by the Center for Medicaid & Medicare Services (CMS) but is only recommended by private insurers. Shared decision-making is also required by Medicare, but it is only recommended by private insurers. Medicare also differs from private

Solitary Pulmonary Nodule
A solitary pulmonary nodule is typically described as a single, well-circumscribed, spherical lesion that is 3 cm or less cm in diameter and completely surrounded by normal aerated lung parenchyma.24 Lung atelectasis, hilar enlargement, and pleural effusion are absent. The majority are detected incidentally on chest radiographs (CXR) or CT scans obtained for some other purpose. About 150,000 solitary nodules are found incidentally each year, with increasing numbers as low-dose computed tomography screening in high-risk populations is adopted. The clinical significance of such a lesion depends on whether or not it represents a malignancy.

The differential diagnosis of a solitary pulmonary nodule should include a broad variety of congenital, neoplastic, inflammatory, vascular, and traumatic disorders. The probability of cancer in a solitary pulmonary nodule increases if the patient has a history of smoking (50% or higher for smokers compared to 20% to 40% in never smokers). It is also more likely to be malignant if it is symptomatic or the patient is older, male, or has had occupational exposures.

Solitary pulmonary nodules were defined by findings on CXR, but with the increased sensitivity of low-dose screening CT, up to 50% of solitary lesions are found to be associated with multiple (one to six) other, usually subcentimeter, nodules. In the Early Lung Cancer Action project, almost 7% of healthy volunteers were found to have between one and three nodules, and 25% had up to six nodules. CT scanning is necessary to characterize nodule number, location, size, margin morphology, calcification pattern, and growth rate.25 Spiral (helical) CT allows continuous scanning as the patient is moved through a scanning gantry, allowing the entire thorax to be imaged during a single breath hold (Fig. 19-14). Compared to conventional CT, this provides a superior image quality, because motion artifacts are eliminated, and improves detection of pulmonary nodules and central airway abnormalities. The shorter acquisition time of spiral CT also allows for consistent contrast filling of the great vessels, resulting in markedly improved visualization of pathologic states and anatomic variation contiguous to vascular structures. In addition, three-dimensional spiral CT images can be reconstructed for enhanced visualization of spatial anatomic relationships. Thin sections (1 to 2 mm collimation) at 1-cm intervals should be used to evaluate pulmonary parenchyma and peripheral bronchi. If the goal is to find any pulmonary metastases, thin sections at intervals of 5 to 7 mm collimation are recommended. For assessing the trachea and central bronchi, collimation of 3 to 5 mm is recommended. Providing accurate clinical history and data is of paramount importance to obtaining appropriate imaging.

CT findings characteristic of benign lesions include small size, calcification within the nodule, and stability over time.

Figure 19-14. Spiral computed tomography scan showing normal transverse chest anatomy at four levels. A. At the level of the tracheal bifurcation, the aorticopulmonary window can be seen. B. The origin of the left pulmonary artery can be seen at a level 1 cm inferior to A. C. The origin and course of the right pulmonary artery can be seen at this next most cephalad level. The left upper lobe bronchus can be seen at its origin from the left main bronchus. D. Cardiac chambers and pulmonary veins are seen in the lower thorax. AA = ascending aorta; APW = aorticopulmonary window; DA = descending aorta; LA = left ventricle; LMB = left main bronchus; LPA = left pulmonary artery; MPA = main pulmonary artery; RA = right atrium; RPA = right pulmonary artery; RV = right ventricle; SVC = superior vena cava; T = trachea.
Four patterns of benign calcification are common: diffuse, solid, central, and laminated or “popcorn.” Granulomatous infections such as tuberculosis can demonstrate the first three patterns, whereas the popcorn pattern is most common in hamartomas. In areas of endemic granulomatous disease, differentiating benign versus malignant can be challenging. Infectious granulomas arising from a variety of organisms account for 70% to 80% of this type of benign solitary nodules; hamartomas are the next most common single cause, accounting for about 10%.

CT findings characteristic of malignancy include growth over time; increasing density on CT scan (40% to 50% of partial solid lesions are malignant compared to only 15% of subcentimeter solid or nonsolid nodules); size >3 cm; irregular, lobulated, or spiculated edges; and the finding of the corona radiata sign (consisting of fine linear strands extending 4 to 5 mm outward and appearing spiculated on radiographs) (Fig. 19-15). Calcification that is stippled, amorphous, or eccentric is usually associated with cancer.

Growth over time is an important characteristic for differentiating benign and malignant lesions. Lung cancers have volume-doubling times from 20 to 400 days; lesions with shorter doubling times are likely due to infection, and longer doubling times suggest benign tumors, but can represent slower-growing lung cancer. Positron emission tomography (PET) scanning can differentiate benign from malignant nodules28; most lung tumors have increased signatures of glucose uptake, as compared with healthy tissues, and thus glucose metabolism can be measured using radio-labeled 18F-fluorodeoxyglucose (FDG). Meta-analysis estimates 97% sensitivity and 78% specificity for predicting malignancy in a nodule. False-negative results can occur (especially in patients who have AIS, MIA, or LPA, carcinoids, and tumors <1 cm in diameter), as well as false-positive results (because of confusion with other infectious or inflammatory processes).

**Metastatic Lesions to the Lung**

The cause of a new pulmonary nodule(s) in a patient with a previous malignancy can be difficult to discern.29 Features suggestive of metastatic disease are multiplicity; smooth, round borders on CT scan; and temporal proximity to the original primary lesion. One must always entertain the possibility that a single new lesion is a primary lung cancer. The probability of a new primary cancer vs. metastasis in patients presenting with solitary lesions depends on the type of initial neoplasm. The highest likelihood of a new primary lung cancer is in patients with a history of uterine (74%), bladder (89%), lung (92%), and head and neck (94%) carcinomas.

Surgical resection of pulmonary metastases has a role in properly selected patients.30 The best data regarding outcomes of resection of pulmonary metastases come from the International Registry of Lung Metastases (IRLM). The registry was established in 1991 by 18 thoracic surgery departments in Europe, the United States, and Canada and included data on 5206 patients. About 88% of patients underwent complete resection. Survival analysis at 5, 10, and 15 years (grouping all primary tumor types) was performed (Table 19-5). Multivariate analysis showed a better prognosis for patients with germ cell tumors, osteosarcomas, a disease-free interval over 36 months, and a single metastasis.31 Depicted in Fig. 19-16, survival after metastasectomy in a variety of cancers is optimal when metastatic disease is resectable, solitary, and identified 36 or more months after initial treatment. When any or all of these optimal characteristics are absent, survival progressively declines.

---

**Figure 19-15.** Computed tomography scan images of solitary pulmonary nodules. A. The corona radiata sign demonstrated by a solitary nodule. Multiple fine striations extend perpendicularly from the surface of the nodule like the spokes of a wheel. B. A biopsy-proven adenocarcinoma demonstrating spiculation. C. A lesion with a scalloped border, an indeterminate finding suggesting an intermediate probability for malignancy.

Figure 19-16. The actuarial survival after metastasectomy is depicted for patients with various tumor types (A-F) further categorized into four groups according to resectability, solitary or multiple, the interval between primary resection and metastasectomy, and a combination of factors known in our work and in others, as follows: (1) resectable, solitary, and disease-free interval (DFI) greater than or equal to 36 months; (2) resectable, solitary, and DFI 36+ months; (3) resectable, multiple metastases, and DFI <36 months; and (4) unresectable. (Reproduced with permission from Pastorino U: The development of an international registry, J Thorac Oncol. 2010 Jun; 5(6 Suppl 2):S196-S197.)

The general principles of patient selection for metastasectomy are listed in Table 19-6. The technical aim of pulmonary metastasectomy is complete resection of all macroscopic tumors. In addition, any involved adjacent structures should be resected en bloc (i.e., chest wall, diaphragm, and pericardium). Multiple lesions and/or hilar lesions may require lobectomy. Pneumonectomy is rarely justified or employed.

Pulmonary metastasectomy can be approached through a thoracotomy or via video-assisted thoracic surgery (VATS) techniques. McCormack and colleagues reported their experience at Memorial Sloan-Kettering in a prospective study of 18 patients who presented with no more than two pulmonary metastatic lesions and underwent VATS resection.32 A thoracotomy was performed during the same operation; if palpation...
identified any additional lesions, they were resected. The study concluded that the probability that a metastatic lesion will be missed by VATS excision is 56%. Patients in the Memorial study were evaluated before the advent of spiral CT scanning, however, and it remains controversial whether metastasis resection should be performed via VATS. Proponents of VATS argue that the resolution of spiral CT scanning is so superior that prior studies using standard CT scanners are no longer relevant. Indeed, a recent study suggested that only 18% of malignant nodules would be missed using a VATS approach in the current era while another study from the United Kingdom found equivalent outcomes with regard to missed lesions and pulmonary progression comparing open and VATS approaches. To date, no prospective study using spiral CT scan has been performed to resolve this clinical dilemma.

**Primary Lung Cancer-Associated Signs and Symptoms**

Lung cancer displays one of the most diverse presentation patterns of all human maladies (Table 19-7). The wide range of symptoms and signs is related to (a) histologic features, which often help determine the anatomic site of origin in the lung; (b) the specific tumor location in the lung and its relationship to surrounding structures; (c) biologic features and the production of a variety of paraneoplastic syndromes; and (d) the presence or absence of metastatic disease. Symptoms related to the local intrathoracic effect of the primary tumor can be conveniently divided into two groups: pulmonary and nonpulmonary thoracic.

**Pulmonary Symptoms.** Pulmonary symptoms result from the direct effect of the tumor on the bronchus or lung tissue. Symptoms (in order of frequency) include cough (secondary to irritation or compression of a bronchus), dyspnea (usually due to central airway obstruction or compression, with or without atelectasis), wheezing (with narrowing of a central airway of >50%), hemoptysis (typically, blood streaking of mucus that is rarely massive; indicates a central airway location), pneumonia (usually due to airway obstruction by the tumor), and lung abscess (due to necrosis and cavitation, with subsequent pneumonia (due to airway obstruction or compression), and lung abscess (due to necrosis and cavitation, with subsequent infection).

**Nonpulmonary Thoracic Symptoms.** Nonpulmonary thoracic symptoms result from invasion of the primary tumor directly into a contiguous structure (e.g., chest wall, diaphragm, pericardium, phrenic nerve, recurrent laryngeal nerve, superior vena cava, and esophagus), or from mechanical compression of a structure (e.g., esophagus or superior vena cava) by enlarged tumor-bearing lymph nodes.

**Table 19-7**

| Clinical presentation of lung cancer |
|---|---|---|
| CATEGORY | SYMPTOM | CAUSE |
| Pulmonary symptoms | Cough | Bronchus irritation or compression |
| | Dyspnea | Airway obstruction or compression |
| | Wheezing | >50% airway obstruction |
| | Hemoptysis | Tumor erosion or irritation |
| | Pneumonia | Airway obstruction |
| Nonpulmonary thoracic symptoms | Pleuritic pain | Parietal pleural irritation or invasion |
| | Local chest wall pain | Rib and/or muscle involvement |
| | Radicular chest pain | Intercostal nerve involvement |
| | Pancoast’s syndrome | Stellate ganglion, chest wall, brachial plexus involvement |
| | Hoarseness | Recurrent laryngeal nerve involvement |
| | Swelling of head and arms | Bulky involved mediastinal lymph nodes |
| | | Medially based right upper lobe tumor |

Peripherally located tumors (often adenocarcinomas) extending through the visceral pleura lead to irritation or growth into the parietal pleura and potentially to continued growth into the chest wall structures. Three types of symptoms, depending on the extent of chest wall involvement, are possible: (a) **pleuritic pain**, from noninvasive contact of the parietal pleura with inflammatory irritation or direct parietal pleural invasion; (b) **localized chest wall pain**, from deeper invasion and involvement of the rib and/or intercostal muscles; and (c) **radicular pain**, from involvement of the intercostal nerve(s). Radicular pain may be mistaken for renal colic in the case of tumors invading the inferoposterior chest wall.

Other specific nonpulmonary thoracic symptoms include:

1. **Pancoast’s syndrome.** Tumors originating in the superior sulcus (posterior apex) elicit: apical chest wall and/or shoulder pain (from involvement of the first rib and chest wall); Horner’s syndrome (unilateral enophthalmos, ptosis, miosis, and facial anhidrosis from invasion of the stellate sympathetic ganglion); and radicular arm pain (from invasion of T1, and occasionally C8, brachial plexus nerve roots).

2. **Phrenic nerve palsy.** The phrenic nerve traverses the hemithorax along the mediastinum, parallel and posterior to the superior vena cava and anterior to the pulmonary hilum. Tumors at the medial lung surface or anterior hilum can directly invade the nerve; symptoms include shoulder pain (referred), hiccups, and dyspnea with exertion because of
diaphragm paralysis. Radiographically, unilateral diaphragm elevation on chest radiograph is present; the diagnosis is confirmed by fluoroscopic examination of the diaphragm with paradoxical motion with breathing and sniffing (the “sniff” test).

3. **Recurrent laryngeal nerve palsy.** Recurrent laryngeal nerve (RLN) involvement most commonly occurs on the left side, given the hilar location of the left RLN as it passes under the aortic arch. Paralysis results from: (a) invasion of the vagus nerve above the aortic arch by a medially based left upper lobe tumor; or (b) direct invasion of the RLN by hilar tumor and/or hilar or aortopulmonary lymph node metastases. Symptoms include voice change, often referred to as hoarseness, but more typically a loss of tone associated with a breathy quality, and coughing, particularly when drinking liquids.

4. **Superior vena cava (SVC) syndrome.** As a result of bulky enlargement of involved mediastinal lymph nodes compressing or a medially based right upper lobe involving the SVC, SVC syndrome symptoms include variable degrees of swelling of the head, neck, and arms; headache; and conjunctival edema. It is seen most commonly with NEC grade IV (small cell) lung cancer.

5. **Pericardial tamponade.** Pericardial effusions (benign or malignant), associated with increasing levels of dyspnea and/or arrhythmias, and pericardial tamponade occur with direct pericardial invasion. Diagnosis requires a high index of suspicion in the setting of a medially based tumor with symptoms of dyspnea and is confirmed by CT scan or echocardiography.

6. **Back pain.** Results from direct invasion of a vertebral body and is often localized and severe. If the neural foramina are involved, radicular pain may also be present.

7. **Other local symptoms.** Dysphagia is usually secondary to external esophageal compression by enlarged lymph nodes involved with metastatic disease, usually with lower lobe tumors. Finally, dyspnea, pleural effusion, or referred shoulder pain can result from invasion of the diaphragm by a tumor at the base of a lower lobe.

**Associated Paraneoplastic Syndromes.** All lung cancer histologies are capable of producing a variety of paraneoplastic syndromes, most often from systemic release of tumor-derived biologically active materials (Table 19-8). Paraneoplastic syndromes may produce symptoms even before any local symptoms are produced by the primary tumor, thereby aiding in early diagnosis. Their presence does not influence resectability or treatment options. Symptoms often abate with successful treatment; paraneoplastic symptom recurrence may herald tumor recurrence. The majority of such syndromes are associated with grade IV NEC (small cell carcinoma), including many endocrinopathies.

**Hypertrichosis lanuginosa acquista** may antedate the diagnosis of cancer by months. Clinically, ankle, feet, forearm, and hand tenderness and swelling are characteristic, resulting from periostitis of the fibula, tibia, radius, metacarpals, and metatarsals. Clubbing of the digits may occur in up to 30% of patients with grade IV NEC (Fig. 19-17). Plain radiographs show periosteal inflammation and elevation, while bone scans demonstrate intense but symmetric uptake in the long bones. Aspirin or nonsteroidal anti-inflammatory agents provide temporary relief; treatment requires successful tumor eradication.

2. **Hypercalcemia.** Up to 10% of patients with lung cancer will have hypercalcemia, most often due to metastatic disease. Ectopic parathyroid hormone secretion by the tumor, most often squamous cell carcinoma, is causative in up to 15%, however, and should be suspected if metastatic bone disease is not present. Symptoms of hypercalcemia include lethargy, depressed level of consciousness, nausea, vomiting,
Figure 19-17. Hypertrophic pulmonary osteoarthropathy associated with small cell carcinoma. A. Painful clubbing of the fingers. B. Painful clubbing of the toes (close-up). C. The arrows point to new bone formation on the femur.

and dehydration. Following complete tumor eradication, the calcium level will normalize. Unfortunately, tumor recurrence is extremely common and may manifest as recurrent hypercalcemia.

3. **Hyponatremia.** Characterized by confusion, lethargy, and possible seizures, hyponatremia can result from the inappropriate secretion of antidiuretic hormone from the tumor into the systemic circulation (syndrome of inappropriate secretion of antidiuretic hormone [SIADH]) in 10% to 45% of patients with grade IV NEC (small cell). It is diagnosed by the presence of hyponatremia, low serum osmolality, and high urinary sodium and osmolality. Another cause of hyponatremia can be the ectopic secretion of atrial natriuretic peptide (ANP).

4. **Cushing’s syndrome.** Autonomous tumor production of an adrenocorticotropic hormone (ACTH)-like molecule leads to rapid serum elevation of ACTH and subsequent severe hypokalemia, metabolic alkalosis, and hyperglycemia. Symptoms are primarily related to the metabolic changes while the physical signs of Cushing’s syndrome (e.g., truncal obesity, buffalo hump, striae) are unusual due to the rapidity of ACTH elevation. Diagnosis is made by demonstrating hypokalemia (<3.0 mmol/L); non-suppressible elevated plasma cortisol levels that lack the normal diurnal variation; elevated blood ACTH levels; or elevated urinary 17-hydroxycorticosteroids, all of which are not suppressible by administration of exogenous dexamethasone. Immunoreactive ACTH is present in nearly all extracts of SCLC, and a high percentage of patients with SCLC have elevated ACTH levels by radioimmunoassay, yet fewer than 5% have symptoms of Cushing’s syndrome.

5. **Peripheral and central neuropathies.** Unlike other paraneoplastic syndromes, which are usually due to ectopic secretion of an active substance, these syndromes are felt to be immune mediated. Cancer cells are thought to secrete antigens normally expressed only by the nervous system, generating antibodies leading either to interference with neurologic function or to immune neurologic destruction. Up to 16% of lung cancer patients have neuromuscular disability, and, of these, half have grade IV NEC (small cell) and 25% have squamous cell carcinomas. In patients with neurologic or muscular symptoms, central nervous system (CNS) metastases must be ruled out with CT or magnetic resonance imaging (MRI) of the head. Other metastatic disease leading to disability must also be excluded.

6. **Lambert-Eaton syndrome.** This myasthenia-like syndrome is caused by tumor secretion of immunoglobulin G (IgG) antibodies targeting voltage-gated calcium channels, which causes a neuromuscular conduction defect by decreasing the amount of acetylcholine released from presynaptic sites at the motor end plate. Symptoms, including gait abnormalities from proximal muscle weakness and impaired coordination, may actually precede radiographic evidence of the tumor. Therapy is directed at the primary tumor with resection, radiation, and/or chemotherapy. Many patients have dramatic improvement after successful therapy. For patients with refractory symptoms, treatment consists of guanidine
hydrochloride, immunosuppressive agents such as predni-
sone and azathioprine, and occasionally plasma exchange.
Unlike with myasthenia gravis patients, neostigmine is usu-
ally ineffective.

**Symptoms Associated with Metastatic Lung Cancer.** Lung
cancer metastasizes most commonly to the CNS, vertebral bod-
ies, bone, liver, adrenal glands, lungs, skin, and soft tissues.
CNS metastases are present at diagnosis in 10% of patients;
another 10% to 15% will develop CNS metastases following
diagnosis. Focal symptoms, including headache, nausea, vom-
iting, seizures, hemiplegia, and dysarthria, are common. Lung
cancer is the most common cause of spinal cord compression,
either by primary tumor invasion of an intervertebral foramen
or direct extension of vertebral metastases. Bony metastases
are identified in 25% of lung cancer patients. They are primar-
ily lytic and produce pain locally; thus, any new and localized
skeletal symptoms must be evaluated radiographically. Liver
metastases and adrenal metastases are typically asymptomatic
and usually discovered by routine CT scan. Adrenal metastasis
may lead to adrenal hypofunction. Skin and soft tissue meta-
tases occur in 8% of patients dying of lung cancer and gen-
erally present as painless subcutaneous or intramuscular masses.
Occasionally, tumor erodes through overlying skin; excision
may then be necessary for both mental and physical palliation.

**Nonspecific Cancer-Related Symptoms.** Lung cancer often
produces a variety of nonspecific symptoms such as anorexia,
weight loss, fatigue, and malaise and their presence raises con-
cern for metastatic disease.

**Lung Cancer Management**

**Role of Histologic Diagnosis and Molecular Testing.**
Establishing a clear histologic diagnosis early in the evalua-
tion and management of lung cancer is critical to effective treat-
ment. Molecular signatures are also key determinants of treat-
ment algorithms for adenocarcinoma and will likely become
important for squamous cell carcinoma as well. Currently,
differentiation between adenocarcinoma and squamous cell
carcinoma in cytologic specimens or small biopsy specimens
is imperative in patients with advanced stage disease, as treat-
ment with pemetrexed or bevacizumab-based chemotherapy is
associated with improved progression-free survival in patients
with adenocarcinoma but not squamous cell cancer. Further-
more, life-threatening hemorrhage has occurred in patients with
squamous cell carcinoma who were treated with bevacizumab.
Finally, *EGFR* mutation predicts response to *EGFR* tumor
kinase inhibitors and is now recommended as first-line therapy in
advanced adenocarcinoma. Because adequate tissue is required
for histologic assessment and molecular testing, each institution
should have a clear, multidisciplinary approach to patient evalu-
ation, tissue acquisition, tissue handling/processing, and tissue
analysis (Fig. 19-18). In many cases, tumor morphology differ-
tentiates adenocarcinoma from the other histologic subtypes. If
no clear morphology can be identified, then additional testing for
one immunohistochemistry marker for adenocarcinoma and one
for squamous cell carcinoma will usually enable differentiation.
Immunohistochemistry for neuroendocrine markers is reserved
for lesions exhibiting neuroendocrine morphology. Additional
molecular testing should be performed on all adenocarcinoma
specimens for known predictive and prognostic tumor mark-
ers (e.g., *EGFR*, *KRAS*, and *EML4-ALK* fusion gene). Ideally,
Figure 19-18. Algorithm for adenocarcinoma diagnosis in small biopsies and/or cytology. Step 1: When positive biopsies (fiberoptic bronchoscopy [FOB], transbronchial [TBBx], core, or surgical lung biopsy [SLBx]) or cytology (effusion, aspirate, washings, and brushings) show clear adenocarcinoma (ADC) or squamous cell carcinoma (SQCC) morphology, the diagnosis can be firmly established. If there is neuroendocrine (NE) morphology, the tumor may be classified as small cell carcinoma (SCLC) or non–small cell lung carcinoma (NSCLC), probably large cell neuroendocrine carcinoma (LCNEC) according to standard criteria (+ = positive, – = negative, and ± = positive or negative). If there is no clear ADC or SQCC morphology, the tumor is regarded as NSCLC—not otherwise specified (NOS). Step 2: NSCLC-NOS can be further classified based on (a) immunohistochemical stains, (b) mucin (DPAS or mucicarmine) stains, or (c) molecular data. If the stains all favor ADC-positive ADC marker(s) (i.e., TTF-1 and/or mucin positive) with negative SQCC markers, then the tumor is classified as NSCLC, favor ADC. If SQCC markers (i.e., p63 and/or CK5/6) are positive with negative ADC markers, the tumor is classified as NSCLC, favor SQCC. If the ADC and SQCC markers are both strongly positive in different populations of tumor cells, the tumor is classified as NSCLC-NOS, with a comment it may represent adenosquamous carcinoma. If all markers are negative, the tumor is classified as NSCLC-NOS. †EGFR mutation testing should be performed in (1) classic ADC, (2) NSCLC, favor ADC, (3) NSCLC-NOS, and (4) NSCLC-NOS, possible adenosquamous carcinoma. In NSCLC-NOS, if EGFR mutation is positive, the tumor is more likely to be ADC than SQCC. Step 3: If clinical management requires a more specific diagnosis than NSCLC-NOS, additional biopsies may be indicated. CD = cluster designation; CK = cytokeratin; DPAS = diastase-periodic acid Schiff; DPAS +ve = periodic-acid Schiff with diastase; EGFR = epidermal growth factor receptor; IHC = immunohistochemistry; NB = of note; TTF-1 = thyroid transcription factor-1; –ve = negative; +ve = positive. (Reproduced with permission from Travis WD, Brambilla E, Noguchi M, et al: Diagnosis of lung cancer in small biopsies and cytology: implications of the 2011 International Association for the Study of Lung Cancer/American Thoracic Society/European Respiratory Society classification, Arch Pathol Lab Med. 2013 May;137(5):668-684.)

Abbreviations: CT = computed tomography; DLCO = carbon monoxide diffusion capacity; FEV₁ = forced expiratory volume in 1 second; FNA = fine-needle aspiration; MRI = magnetic resonance imaging; O₂ = oxygen; PET = positron emission tomography.

Diagnostic tissue from bronchoscopy can be obtained by one of four methods:
1. Brushings and washings for cytology
2. Direct forceps biopsy of a visualized lesion
3. Endobronchial ultrasound-guided fine-needle aspiration (FNA) of an externally compressing lesion without visualized endobronchial tumor
4. Transbronchial biopsy with fluoroscopy to guide forceps to the lesion or electromagnetic navigational bronchoscopy

Electromagnetic navigation bronchoscopy is a recent addition to the surgeon’s armamentarium for transbronchial biopsy of peripheral lung lesions. Using electromagnetic markers that create a three-dimensional image and align the recorded CT images to the patient’s true anatomy, a transbronchial catheter is advanced, and brushings, FNA, cup biopsy, and washings can be performed. Diagnostic yield using electromagnetic navigation bronchoscopy as an adjunct to standard bronchoscopy is reported as high as 80%. The approach can also be used for placement of fiducial markers for subsequent stereotactic body radiation therapy and for tattooing the perilesional region to guide subsequent video-assisted thoracoscopic resection.

Pneumothorax rates are approximately 1% to 3.5%.

For peripheral lesions (roughly the outer half of the lung), transbronchial biopsy is performed first, followed by brushings and washings. This improves diagnostic yield by disrupting the lesion with the biopsy forceps and mobilizing additional cells. For central lesions, direct forceps biopsy is often possible. For central lesions with external airway compression but no visible endobronchial lesions, endobronchial ultrasound (EBUS) is highly accurate and safe for transbronchial biopsies of both the primary tumor (when it abuts the central airways) as well as the mediastinal lymph nodes.

Image-guided transthoracic FNA (ultrasound or CT FNA) biopsy can accurately diagnose appropriately selected peripheral pulmonary lesions in up to 95% of patients. Three biopsy results are possible after image-guided biopsy procedures: malignant, a specific benign process, or indeterminate. Because false-negative rates range from 3% to 29%, further diagnostic efforts are warranted in the absence of a specific benign diagnosis (such as granulomatous inflammation or hamartoma) because malignancy is not ruled out. The primary complication is pneumothorax in as many as 30% of cases. Intrapulmonary bleeding occurs, but it rarely causes clinically significant hemoptysis or respiratory compromise.

Some groups advocate use of video-assisted thoracoscopic biopsy as the first option for diagnosis, citing superior diagnostic accuracy and low surgical risk. With VATS, the nodule can be excised with a wedge or segmental resection, if less than 3 cm, or a core-needle biopsy can be performed under direct vision for larger lesions. VATS can also provide valuable staging information, including sampling/dissection of mediastinal lymph nodes and assessing whether the primary tumor has invaded a contiguous structure (such as the chest wall or mediastinum).

Lesions most suitable for VATS are those that are located in the outer one-third of the lung. The surgeon should avoid direct manipulation of the nodule or violation of the visceral pleura overlying the nodule. In addition, the excised nodule must be extracted from the chest within a bag to prevent seeding of the chest wall. If the patient’s pulmonary reserve is adequate, the surgeon can proceed to lobectomy (either VATS or open) after frozen section diagnosis.
A thoracotomy is occasionally necessary to diagnose and stage a primary tumor. Although this occurs rarely, two circumstances may require such an approach: (a) a deep-seated lesion that yielded an indeterminate needle biopsy result or that could not be biopsied for technical reasons; or (b) inability to determine invasion of a mediastinal structure by any method short of palpation. In the circumstance of a deep-seated lesion without a diagnosis, tissue can be obtained via thoracotomy using FNA, core-needle biopsy, or excisional biopsy. Intraoperative frozen-section analysis is required; if the open biopsy frozen-section result is indeterminate, a lobectomy may be necessary in extremely rare situations. If a pneumonectomy is required to remove the lesion, a tissue diagnosis of cancer must be made before proceeding.

Assessment for Metastatic Disease

Approximately 40% of patients with newly diagnosed lung cancer present with distant metastasis. The presence of lymph node or systemic metastases may imply inoperability. As with the primary tumor, assessment for the presence of metastatic disease should begin with the history and physical examination, focusing on new bone pain, neurologic symptoms, and new skin lesions. In addition, constitutional symptoms (e.g., anorexia, malaise, and unintentional weight loss of >5% of body weight) suggest either a large tumor burden or the presence of metastases. Physical examination focuses on overall appearance, noting any evidence of weight loss such as redundant skin or muscle wasting, and a complete examination of the head and neck, including...
evaluation of cervical and supraclavicular lymph nodes and the oropharynx. This is particularly true for patients with a significant tobacco history. The skin should be thoroughly examined. Routine laboratory studies include serum levels of hepatic enzymes (e.g., serum glutamic oxaloacetic transaminase and alkaline phosphatase), and serum calcium (to detect bone metastases or the ectopic parathyroid syndrome). Elevation of either hepatic enzymes or serum calcium levels typically occurs with extensive metastases.

**Mediastinal Lymph Nodes.** Chest CT scanning facilitates assessment of mediastinal and hilar nodes for enlargement. However, a positive CT result (i.e., nodal diameter >1.0 cm) predicts actual metastatic involvement in only about 70% of lung cancer patients. Thus, up to 30% of such nodes are enlarged from noncancerous reactive causes (e.g., inflammation due to atelectasis or pneumonia secondary to the tumor). Patients should not be denied an attempt at curative resection just because of a positive CT result for mediastinal lymph node enlargement; any CT finding of metastatic nodal involvement must be confirmed histologically. The negative predictive value of normal-appearing lymph nodes by CT (lymph nodes <1.0 cm) is better than the positive predictive value of a suspicious-appearing lymph node, particularly with small squamous cell tumors. With normal-size lymph nodes and a T1 tumor, the false-negative rate is less than 10%, leading many surgeons to omit mediastinoscopy. However, the false-negative rate increases to nearly 30% with centrally located and T3 tumors. It has also been demonstrated that T1 adenocarcinomas or large cell carcinomas have a higher rate of early micrometastasis. Therefore, all such patients should undergo mediastinoscopy.

Mediastinal lymph node staging by PET scanning appears to have greater accuracy than CT scanning. PET staging of mediastinal lymph nodes has been evaluated in two meta-analyses. The overall sensitivity for mediastinal lymph node metastasis was 79% (95% confidence interval [CI] 76%–82%), with a specificity of 91% (95% CI 89%–93%) and an accuracy of 92% (95% CI 90%–94%).

In comparing PET with CT scans in patients who also underwent lymph node biopsies, PET had a sensitivity of 88% and a specificity of 91%, whereas CT scanning had a sensitivity of 63% and a specificity of 76%. Combining CT and PET scanning may lead to even greater accuracy. In one study of CT, PET, and mediastinoscopy in 68 patients with potentially operable NSCLC, CT correctly identified the nodal stage in 40 patients (59%). It understaged the tumor in 12 patients and overstaged it in 16 patients. PET correctly identified the nodal stage in 59 patients (87%). It understaged the tumor in five patients and overstaged it in four. For detecting N2 and N3 disease, the combination of PET and CT scanning yielded a sensitivity, specificity, and accuracy of 93%, 95%, and 94%, respectively. CT scan alone yielded 75%, 63%, and 68%, respectively. Studies examining combined PET-CT consistently show improved accuracy compared to PET or CT alone; accuracy for PET-CT nodal positivity confirmed by mediastinoscopy is approximately 75%, with a negative predictive value of approximately 90%. Right upper lobe lesions were more likely to have occult N2 disease than other lobes of the lung. PET-positive mediastinal lymph nodes require histologic verification of node positivity, either by EBUS-guided FNA or mediastinoscopy, to minimize the risk of undertreatment, assuming node positivity without histologic confirmation relegates the patient to, at a minimum, induction chemotherapy. If there is a suggestion of N3 disease, the patient would be incorrectly staged as having IIIB disease and would not be considered a candidate for potentially curative surgical resection.

It is important for surgeons who are managing patients with lung cancer to have a clear algorithm for invasive mediastinal staging. In general, invasive staging is underutilized, placing many patients at risk for over- or understaging and, thus, inappropriate treatment. An absolute indication for obtaining a tissue diagnosis is mediastinal lymph node enlargement greater than 1.0 cm by CT scan. There are several options for invasive mediastinal staging (Table 19-10):

1. **Endobronchial Ultrasound (EBUS)-guided transbronchial needle aspiration.** Less invasive than mediastinoscopy, EBUS enables image-guided transtracheal and transbronchial FNA cytologic samples from hilar masses and lymph nodes from level 4R and 4L, level 7, level 10, and level 11. Rapid onsite pathologic evaluation with expert cytopathology evaluation greatly increases the diagnostic accuracy of the procedure; importantly, the intraoperative evaluation will confirm whether the target lesion is being sampled and greatly facilitates acquisition of satisfactory samples for determining the morphologic diagnosis as well as sufficient material for cell block for immunohistochemistry

**Indications for invasive mediastinal staging in lung cancer**

1. Radiographically enlarged mediastinal lymph nodes
2. Centrally located tumors
3. N1 nodal enlargement
4. Tumor size >3 cm
5. Peripheral clinical stage I tumor with nonenlarged but FDG-avid mediastinal lymph nodes

**Indications for prethoracotomy/thoracoscopy biopsy of stations 5 and 6 lymph nodes**

1. Criteria for invasive staging met and other mediastinal lymph node stations are negative (assuming patient would have induction therapy if any nodal station positive)
2. Enrollment criteria for induction therapy protocol require pathologic confirmation of N2 disease
3. Computed tomography scan shows evidence of bulky nodal metastasis or extracapsular spread that could prevent complete resection
4. Tissue diagnosis of a hilar mass or of lymph nodes causing recurrent laryngeal nerve paralysis is needed
and molecular testing. EBUS does not allow assessment of level 3, 5, or 6 nodal stations.

2. **Endoscopic ultrasound (EUS).** EUS can accurately visualize mediastinal paratracheal lymph nodes (stations 4R, 7, and 4L), paraesophageal (station 8) and inferior pulmonary ligament (station 9) lymph nodes and visualize primary lung lesions contiguous with or near the esophagus (see Fig. 19-8). Using FNA or core-needle biopsies, samples of lymph nodes or primary lesions can be obtained. Diagnostic yield is improved with intraoperative cytologic evaluation, which can be performed with the cytologist in the operating room. Limitations of EUS include the inability to visualize the anterior (pretracheal) mediastinum; thus, EUS does not replace mediastinoscopy/EBUS for complete mediastinal nodal staging. However, it may not be necessary to perform mediastinoscopy if findings on EUS are positive for N2 nodal disease, particularly if more than one station is found to harbor metastases.

3. **Cervical video-assisted mediastinoscopy.** Mediastinoscopy provides tissue sampling of all paratracheal and subcarinal lymph nodes and permits visual determination of the presence of extracapsular extension of nodal metastasis (Fig. 19-20). With complex hilar or right paratracheal primary tumors, it allows direct biopsies and assessment of invasion into the mediastinum. Mediastinoscopy is recommended for centrally located tumors, T2 and T3 primary tumors, and occasionally for T1 adenocarcinomas or large cell carcinomas (due to their higher rate of metastatic spread). Some surgeons perform mediastinoscopy in all lung cancer patients because of the poor survival associated with surgical resection of N2 disease.

4. It is important to note that EBUS or EUS can be used for initial diagnosis in enlarged lymph nodes, but the predictive value of a negative EBUS in a patient with radiographically suspicious mediastinal disease is not sufficient to accurately guide treatment. At the authors’ institutions, it is standard to begin mediastinal lymph node staging with EBUS-guided FNA of clinically suspicious mediastinal lymphadenopathy. If intraoperative rapid onsite cytologic evaluation is negative, mediastinoscopy is performed in the same operative setting to ensure accurate mediastinal staging. However, if the FNA is positive, mediastinoscopy is not performed, and the patient is referred to medical oncology for induction therapy; avoiding a pretreatment mediastinoscopy in this manner facilitates the safe performance of a postinduction mediastinoscopy for restaging of the mediastinum in patients who respond favorably to induction therapy.

5. Left video-assisted thoracoscopic lung node sampling may be needed for patients with left upper lobe tumors who have localized regional spread to stations 5 and 6 lymph nodes, without mediastinal paratracheal involvement (see Fig. 19-8). If there is a low index of suspicion for nodal metastasis, the patient can be scheduled for VATS biopsy and lobectomy under the same anesthesia; the procedure begins by sampling the level 5 and 6 nodes for frozen section, and if the nodes are negative, the anatomic lung resection is performed. If the index of suspicion is high, the VATS biopsy is performed as a separate procedure. Cervical mediastinoscopy should precede VATS biopsy, even if patients have normal paratracheal lymph nodes. Additional diagnostic evaluation of the lymph nodes in stations 5 and 6 may be unnecessary if the mediastinal lymph nodes are proven to be benign with biopsy during cervical mediastinoscopy and the preoperative CT scan suggests complete resectability of the tumor. There are, however, several indications for prethoracotomy biopsy of stations 5 and 6 lymph nodes, which are listed in Table 19-10. It is particularly important to prove that mediastinal lymph nodes are pathologically involved and not just radiographically suspicious for nodal metastasis prior to deciding that the patient is not a candidate for resection.

**Pleural Effusion.** The presence of pleural effusion on radiographic imaging should not be assumed to be malignant. Pleural effusion may be secondary to atelectasis or consolidation (seen with central tumors), cardiac dysfunction, or may be a reactive effusion. When associated with a peripherally based tumor abutting the visceral or parietal pleural surface, probability of being malignant is higher. If this is the only site concerning for metastatic disease, pathologic confirmation is mandatory. It is reasonable to start with thoracentesis, but cytology reveals malignant cells in only 50% of malignant effusions on initial thoracentesis; negative cytology 5 times is needed to have 95% certainty of a benign process. Thoracoscopy may be needed to rule out pleural metastases in select patients and is usually performed as a separate staging procedure, often with subsequent mediastinoscopy if thoracoscopy is negative for metastasis.

**Distant Metastases.** Currently, chest CT and PET are routine in the evaluation of patients with lung cancer. Integrated PET-CT scanners have become standard and have substantially improved accuracy of detection and localization of lymph node and distant metastases, as compared with independently performed PET and CT scans (Fig. 19-21). This technology overcomes the imprecise information on the exact location of focal abnormalities seen on PET and has become the standard imaging modality for lung cancer. Compared to routine chest or abdominal CT and bone scans, PET scanning detects 10% to 15% more distant metastases, but should be confirmed with MRI and/or biopsies if the patient otherwise has early-stage disease. Brain MRI should be performed when the suspicion or risk of brain metastases is increased, such as in patients with
Figure 19-21. Imaging of non–small cell lung cancer by integrated positron emission tomography (PET)-computed tomography (CT) scan. A. CT of the chest showing a tumor in the left upper lobe. B. PET scan of the chest at the identical cross-sectional level. C. Coregistered PET-CT scan clearly showing tumor invasion (confirmed intraoperatively). (Adapted with permission from Lardinois D, Weder W, Hany TF, et al. Staging of non-small-cell lung cancer with integrated positron-emission tomography and computed tomography, N Engl J Med. 2003 Jun 19;348(25):2500-2507.)

clinical stage III disease. In the absence of neurologic symptoms or signs, the probability of a negative head CT scan is 95%. Liver abnormalities that are not clearly simple cysts or hemangiomas and adrenal enlargement, nodules, or masses are further evaluated by MRI scanning and, occasionally, by needle biopsy. Adrenal adenomas have a high lipid content (secondary to steroid production), but metastases and most primary adrenal malignancies contain little if any lipid; thus, MRI is usually able to distinguish the two.

Tumor, Node, and Metastasis: Lung Cancer Staging

The staging of any tumor is an attempt to estimate the extent of disease and determine the patient’s prognosis; in a given patient, tumors are typically classified into a clinical stage and a pathologic stage. Clinical staging includes history and physical examination, radiographic test results, and diagnostic biopsy information. Therapeutic plans are generated based on clinical stage. After surgical resection of tumor and lymph nodes, postoperative pathologic stage (pTNM) is determined, providing further prognostic information.

The staging of solid epithelial tumors is based on the TNM staging system. The primary tumor “T” status provides information about tumor size and relationship to surrounding structures; the “N” status provides information about regional lymph nodes; and the “M” status provides information about the presence or absence of metastatic disease. The designation of lymph nodes as N1, N2, or N3 requires familiarity with the lymph node mapping system (see Fig. 19-8). Based on clearly delineated anatomic boundaries, accurate and reproducible localization of thoracic lymph nodes is possible, facilitating detailed nodal staging for individual patients and standardization of nodal assessment between surgeons.

Pathologic staging criteria are based on the predicted survival relative to each combination of tumor, node, and metastasis status. In 2018, the AJCC eighth edition incorporated multiple changes into the staging system for NSCLC based on analysis of survival predictors from 77,156 lung cancer patients worldwide. Table 19-11a shows the clinical and pathologic criteria changes implemented and each of the TNM descriptors currently used in staging NSCLC (Table 19-11b) and the overall stage classifications (Table 19-11c). T-staging is markedly changed, including T category designation for each centimeter in size up to 5 cm, as well as size of the invasive component in lepidic growth tumors. Visceral pleural invasion increases T-stage to T2 for patients with tumors ≤3 cm in size, and synchronous primary tumors have an added T suffix (m) in tumor staging. Metastatic disease has also been subdivided into intrathoracic, single-site extrathoracic, and multiple extrathoracic metastasis. In addition to the TNM stage, it is recommended that histologic grade, lymphovascular invasion, adequacy of resection margins and mediastinal dissection, tumor mutation status, treatment, and residual tumor after treatment also be recorded into cancer registries to facilitate evaluation of these potential predictors in future analysis of staging criteria.

Staging for small cell lung cancer (SCLC) is typically based on the extent of disease. SCLC presenting with bulky locoregional disease confined to the ipsilateral hemithorax, with no evidence for distant metastatic disease, is termed “limited” SCLC. Limited disease must be treatable within a tolerable field of radiation. Using AJCC descriptors, this includes any T stage, any N stage, without metastatic disease (M0). The only exception is when multiple lung nodules are widely spread throughout the ipsilateral lung in the same hemithorax; in these patients, the size of the involved area would preclude a “safe” radiation field. In contrast, in “disseminated” disease, tumor is beyond the ipsilateral hemithorax or widely spread within the ipsilateral lung and to distant sites. Metastases to the pleura and pericardium, with resultant effusions, are considered disseminated disease.

Metastases to brain, bone, bone marrow, and the pleural and pericardial spaces are common.

**Assessment of Functional Status** Patients with potentially resectable tumors require careful assessment of their functional status and ability to tolerate either lobectomy or pneumonectomy. The surgeon should first estimate the likelihood of pneumonectomy, lobectomy, or possibly sleeve resection, based on the CT images. A sequential process of evaluation then unfolds.

A patient’s history is the most important tool for gauging risk. Specific questions regarding performance status should be routinely asked. If the patient can walk on a flat surface indefinitely, without oxygen and without having to stop and rest secondary to dyspnea, he will be very likely to tolerate lobectomy. If the patient can walk up two flights of stairs (up two standard levels), without having to stop and rest secondary to dyspnea, she will likely tolerate pneumonectomy. Finally, nearly...
all patients, except those with carbon dioxide (CO₂) retention on arterial blood gas analysis, will be able to tolerate periods of single-lung ventilation and wedge resection. Formal assessment of cardiac fitness is mandatory; use of risk scores such as the Thoracic Revised Cardiac Risk Index developed by Dr. Brunelli and colleagues provides useful prognostic information for postresection survival from early-stage lung cancer.

Current smoking status and sputum production are also pertinent. Current smokers and patients with a greater than 60 pack-year history of smoking have a significantly increased risk of postoperative pulmonary complications; heavy smokers are 2.5 times more likely to develop pulmonary complications and three times more likely to develop pneumonia compared to patients with a ≤60 pack-year history (odds ratio [OR] 2.54; 95% CI 1.28–5.04; \( P = 0.0008 \)). Impaired exchange of CO₂ is also predictive of increased risk, independent of the smoking history. For every 10% decline in percent carbon monoxide diffusion capacity (%DLCO), the risk of any pulmonary complication increased by 42% (OR 1.42; 95% CI 1.16–1.75; \( P = 0.008 \)). Risk reduction requires smoking cessation at least 8 weeks preoperatively, a requirement that is often not feasible in a cancer patient. Nevertheless, abstinence for at least 2 weeks before surgery should be encouraged. Smoking cessation on the day of surgery leads to increased sputum production and potential secretion retention postoperatively, and some authors have reported increased rates of pulmonary complications in this group. Patients with chronic daily sputum production will have more problems postoperatively with retention and atelectasis; they are also at higher risk for pneumonia. Sputum culture, antibiotic administration, and bronchodilators may be warranted preoperatively.

Pulmonary function studies are routinely performed when any resection greater than a wedge resection will be performed. Of all the measurements available, the two most valuable are forced expiratory volume in 1 second (FEV₁) and carbon monoxide diffusion capacity (DLCO). General guidelines for the use of FEV₁ in assessing the patient’s ability to tolerate pulmonary resection are as follows: greater than 2.0 L can tolerate pneumonectomy, and greater than 1.5 L can tolerate lobectomy. It must be emphasized that these are guidelines only. It is also important to note that the raw value is often imprecise because normal values are reported as “percent predicted” based on corrections made for age, height, and gender. For example, a raw FEV₁ value of 1.3 L in a 62-year-old, 75-inch (190-cm) male has a percent predicted value of 30% (because the normal expected value is 4.31 L); in a 62-year-old, 62-inch female, the predicted value is 59% (normal expected value 2.21 L). The male patient is at high risk for lobectomy, while the female could potentially tolerate pneumonectomy.

To calculate the predicted postoperative value for FEV₁ or DLCO, the percent predicted value of FEV₁ or DLCO is multiplied by the fraction of remaining lung after the proposed surgery. For example, with a planned right upper lobectomy, a total of three segments will be removed. Therefore, three of a total 20 segments will leave the patient with \((20 – \frac{3}{20}) \times 100 = 85\%\) of their original lung capacity. In the two patients mentioned earlier, the man will have a predicted postoperative FEV₁ of 30% \(\times 0.85 = 25\%\), whereas the woman will have a predicted postoperative FEV₁ of 50%. Percent predicted value of less than 50% for either FEV₁ or DLCO correlates with risk for postoperative complications, particularly pulmonary complications; the risk of complications increases in a stepwise fashion for each 10% decline. Figure 19-22 shows the relationship between predicted postoperative DLCO and estimated operative mortality.

Quantitative perfusion scanning is used in select circumstances to help estimate the functional contribution of a lobe or whole lung. Such perfusion scanning is most useful when the impact of a tumor on pulmonary physiology is difficult to discern. With complete collapse of a lobe or whole lung, the impact is apparent, and perfusion scanning is usually unnecessary. Figure 19-23 shows a tumor with significant right main stem airway obstruction with associated atelectasis and volume loss of the right lung. At presentation, the patient was dyspneic with ambulation, and the FEV₁ was 1.38 L. Six months prior, this patient could walk up two flights of stairs without dyspnea. The surgeon can anticipate that the patient will tolerate pneumonectomy because the lung is already not functioning due to main stem airway obstruction, and may, in fact, be contributing to a shunt. However, with centrally located tumors associated with partial obstruction of a lobar or main bronchus or of the pulmonary artery, perfusion scanning may be valuable in predicting the postoperative result of resection. For example, if the quantitative perfusion to the right lung is measured to be 21% (normal is 55%) and the patient’s percent predicted FEV₁ is 60%, the predicted postoperative FEV₁ after a right pneumonectomy would be 60% \(\times 0.79 = 47\%\), indicating the ability to tolerate pneumonectomy. If the perfusion value is 55%, the predicted postoperative value would be 27%, and pneumonectomy would pose a significantly higher risk.

It is not uncommon to encounter patients with significant reductions in their percent predicted FEV₁ and DLCO whose history shows a functional status that is inconsistent with the pulmonary function tests. In these circumstances, exercise testing that yields maximal oxygen consumption (\(\dot{V}O_{2 \text{max}}\)) has emerged as a valuable decision-making technique to help patients with abnormal FEV₁ and DLCO (Table 19-12). Values <10 mL/kg/min are associated with a 26% mortality after major pulmonary...
resection compared to only 8.3% with \( \dot{V}_{O_2} \text{max} \geq 10 \text{ mL/kg/min.} \)

Values >15 mL/kg/min generally indicate the patient’s ability to tolerate pneumonectomy.

The risk assessment of a patient is an amalgam of clinical judgment and data that must be integrated with the experienced clinician’s sense of the patient and with the patient’s attitude toward the disease and toward life. Figure 19-24 provides a useful algorithm for determining suitability for lung resection.44

### Lung Cancer Treatment

#### Grade IV NEC (Small Cell) Lung Carcinoma.

In rare circumstances where SCLC presents as an isolated lung lesion, lobectomy followed by chemotherapy is warranted after surgical mediastinal staging has confirmed the absence of N2 disease. Often, ultrasound-guided FNA provides a definitive positive diagnosis and more invasive approaches are not needed. However, less than 5% are stage I, and there is no benefit from surgical resection for more advanced-stage disease; treatment is chemotherapy with or without radiation therapy depending on the extent of disease and the patient performance status.

#### Early-Stage Non–Small Cell Lung Cancer.

Early-stage disease includes T1 and T2 tumors (with or without N1 nodal involvement) and T3 tumors (without N1 nodal involvement). This group represents a small but increasing proportion of the total number of patients diagnosed with lung cancer each year (approximately 16% of an estimated 222,500 patients in 2017).18 Surgical resection is the current standard, ideally accomplished by video-assisted lobectomy or pneumonectomy, depending on the tumor location.

Despite the term “early-stage,” the overall 5-year survival rate for all localized lung cancer is 55% and only 26% when regional metastasis was present between 2004 and 2009.45 Median survival for untreated patients with stage IA NSCLC is 14 months, and 5-year survival rate is 22%.46 After surgical resection of postoperative pathologic stage IA disease, 5-year survival is better than with no treatment, but still only 67%.41 Survival declines with higher stages. Advanced age at diagnosis, male sex, low socioeconomic status, nonsurgical treatment, and poor histologic grade are associated with increased mortality risk on multivariate analysis.45

Depending on tumor size and location, lobectomy, sleeve lobectomy, and occasionally pneumonectomy, with mediastinal lymph node dissection or sampling, are appropriate for patients with clinical early-stage disease. Sleeve resection is performed for tumors located at airway bifurcations when an adequate bronchial...
Figure 19-24. Algorithm for preoperative evaluation of pulmonary function and reserve prior to resectional lung surgery. CPET = cardiopulmonary exercise test; CT = computed tomographic scan; CXR = chest radiograph; DLCO = carbon monoxide diffusion capacity; FEV₁ = forced expiratory volume in 1 second; %ppo = percent predicted postoperative lung function; VO₂max = maximum oxygen consumption. (Modified with permission from Colice GL, Shafazand S, Griffin JP: Physiologic evaluation of the patient with lung cancer being considered for resectional surgery: ACCP evidenced-based clinical practice guidelines (2nd edition), Chest. 2007 Sep;132(3 Suppl):161S-177S.)
margin cannot be obtained by standard lobectomy. Pneumonectomy is rarely performed; primary indications for pneumonectomy in early-stage disease include large central tumors involving the distal main stem bronchus and inability to completely resect involved N1 lymph nodes. The latter circumstance occurs with bulky adenopathy or with extracapsular nodal spread.

Management of Early-Stage Lung Cancer in the High-Risk Patient. Lobectomy may not be an option for some patients with early-stage disease, due to poor cardiopulmonary function or other comorbid illnesses. The ultimate decision that a patient is inoperable, both with regard to the patient’s ability to tolerate surgery and the likelihood of successful resection, should be accepted only after evaluation by an expert surgeon. Surgeons with limited expertise, when faced with a complicated patient, should refer the patient to a high-volume center for further evaluation if they are unable to offer the patient surgical resection in their own center.

Rationale for Limited Resection in Early-Stage Lung Cancer. Limited resection, defined as segmentectomy or wedge resection, is a viable option for achieving local control in high-risk patients. Historically, limited resection with wedge or segmentectomy has been considered a compromise operation due to unacceptably high rates of local recurrence and concerns for worse survival. Subsequent meta-analysis of the literature shows that the difference in death rate is likely negligible (Table 19-13). The high rates of local recurrence demonstrated by Ginsberg and others, however, remain a significant concern and continue to restrict the use of limited resection for early-stage lung cancer to the high-risk patient.

With the recent publication of a 20% reduction in lung cancer mortality with screening CT scans in high-risk populations, the topic of limited resection is again the subject of intensive review. Studies investigating anatomic segmentectomy (or extended wedge resection) with hilar and mediastinal lymph node dissection suggest that close attention to the ratio of surgical margin to tumor diameter and a careful assessment of the lymph nodes substantially reduce local recurrence. Recurrence rates were 6.2%, comparable to rates associated with lobectomy, when the margin-to-tumor diameter ratio exceeded 1, compared to 25% if the margin-to-tumor diameter ratio was less than 1.5. In most centers, this requires use of a thoracotomy, although increasing experience with VATS in high-volume centers shows that limited resection is safe and feasible, with perioperative adverse outcomes that are comparable to lobectomy.

Rationale for Tumor Ablation in the Management of Primary Lung Cancer. Limited resection, by definition, requires that the patient has sufficient cardiopulmonary reserve to undergo a general anesthesia and loss of at least one pulmonary segment. For the high-risk or nonoperable patient, as determined by experience pulmonary surgeons, tumor ablation techniques have been developed for treatment of early-stage lung cancers.

Current limitations of this approach include the absence of nodal staging, lack of tissue for molecular profiling, chemoresistance, or sensitivity testing, concerns about definitions of locoregional recurrence, and a lack of uniformity across centers. Surgeons typically define locoregional recurrence as tumor growth within the operative field, including resectable lymph nodes, whereas local recurrence after ablation is most commonly defined as tumor growth within the field of treatment. Despite the fact that in-transit or lymph node metastases are present in up to 27% of clinically stage I NSCLCs at resection, any tumor growth outside the field of ablative treatment is not be considered treatment failure. Despite these limitations, tumor ablative strategies are increasingly proposed as viable alternatives to surgical resection, even in potentially operable patients. While premature, ablative techniques may ultimately be shown to have efficacy equivalent to lobectomy for the primary treatment of very small peripheral early-stage lung cancers. Multidisciplinary collaboration between thoracic surgery, interventional radiology/pulmonology, and radiation oncology is required to ensure that development of these ablative techniques occurs through properly designed and well-controlled prospective studies and will ensure that patients receive the best available therapy, regardless of whether it is surgical resection or ablative therapy.

The two most commonly applied ablation techniques are radiofrequency ablation and stereotactic body radiotherapy.

1. Radiofrequency ablation. Radiofrequency ablation is performed using either monopolar or bipolar delivery of electrical current to electrodes placed within the tumor tissue. In lung tumors, the electrodes are typically inserted into the tumor mass under CT guidance. An electrical current is delivered; the current is converted by means of friction into heat, which quickly leads to immediate and irreparable tissue destruction in the tissue surrounding the electrode. The efficacy of radiofrequency ablation for controlling the primary tumor and improving survival in poor operative candidates (either due to significant comorbid diseases precluding general anesthesia or poor pulmonary function excluding lung resection) is safe and feasible for peripheral lung nodules. In tumors <3.5 cm, the rate of radiographic resolution of tumor is up to 80%, and cancer-specific survival at 2 years was approximately 90%, indicating excellent local control of the primary site. It has become the preferred modality for small peripheral tumors over standard external-beam radiation in centers where the technique is available.

Radiofrequency ablation is an excellent modality for the patient at risk for adverse outcomes with pulmonary resection or for patients who refuse surgery, and surgeons should have an algorithm for determining which patients are optimal for this modality (see Fig. 19-24). Target lesions larger than 5 cm, tumor abutting the hilum, associated malignant pleural or pericardial effusion, greater than three lesions in one lung, and the presence of pulmonary hypertension are all contraindications to radiofrequency ablation. Proximity to a large vessel is a contraindication not only due to the risk of massive bleeding, but also because large blood vessels act as a heat sink and lethal cellular temperatures are less likely to be achieved. For these patients, stereotactic body radiotherapy may provide local tumor control with less risk of major complications. Combination therapy with either external-beam radiotherapy or stereotactic body radiotherapy is also under investigation.

2. Stereotactic body radiotherapy. Stereotactic body radiotherapy applies highly focused, high-intensity, three-dimensional conformal radiation to the target lesion over a few sessions. Tumor motion quantification and image guidance technologies have significantly improved the delivery of radiation with high levels of precision.

Favours Segmentectomy Favours Lobectomy
to the target lesion. This accuracy is important because the lung is extremely sensitive to radiation injury and the majority of patients with early-stage lung cancer who are currently considered candidates for ablative therapy have marginal lung function; excessive injury to normal surrounding lung tissue is not desirable. Importantly, these techniques allow the safe delivery of up to 66 Gy of radiation to the target tumors without exceeding the maximum-tolerated dose. A phase II North American multicenter study recently demonstrated the safety and efficacy of this approach in 59 nonoperable patients.62

Patients with biopsy-proven, node-negative peripheral NSCLCs less than 5 cm in diameter (T1 or T2) were treated with stereotactic body radiotherapy after they were deemed inoperable, based on coexisting medical conditions, by a thoracic surgeon and/or pulmonologist. Primary tumor control was excellent; at 3 years, 97.6% were deemed to have primary tumor control by the authors, and 90.6% had local control. However, it is important to note that primary tumor failure was defined specifically as at least a 20% increase in the longest diameter of the gross tumor volume by CT scan and evidence of tumor viability either by biopsy confirming carcinoma or by demonstration of FDG avidity on PET scan. For viability to be confirmed with PET scan, the uptake was required to be of similar intensity to the pretreatment staging PET scan. Failure beyond a 1.5- to 2-cm margin around the primary tumor volume was considered local failure. Failure in regional node basins was seen in two patients. When compared to locoregional control rates of approximately 6.5% with limited resection, the 3-year locoregional recurrence was higher at 12.8%.

3. Patient selection for stereotactic body radiotherapy, as with limited resection and radiofrequency ablation, is important. Because the radiation field is so precise, patients with severe emphysema and chronic obstructive pulmonary disease can be safely treated without significant concern for worsening lung function. However, patients with central tumors near the mediastinum and hilum have increased incidence of significant hypoxia, hemoptysis, atelectasis, pneumonitis, and reduced pulmonary function. In the multicenter trial detailed earlier, treated tumors were required to be greater than 2 cm from the proximal bronchial tree in all directions (which they defined as the distal 2 cm of the trachea, carina, and named major lobar bronchi up to their first bifurcation).62

**Rationale for Chemotherapy in the Management of Early-Stage NSCLC.** The role of chemotherapy in early-stage (stages I and II) NSCLC is evolving, with several prospective phase 2 studies having shown a potential benefit. Initial concerns that induction chemotherapy may result in increased perioperative morbidity or mortality appear to be unwarranted, as the incidence of perioperative morbidity and mortality is not different between the two groups, except in patients undergoing right-sided pneumonectomy after induction chemotherapy. As shown in Table 19-14, an absolute survival benefit of 4% to 7% can be realized using induction for all stages of lung cancer, and in situations where use of adjuvant chemotherapy is anticipated, induction chemotherapy is an acceptable alternative.

National Comprehensive Cancer Network guidelines currently recommend observation for T1a (≤1 cm), T1b (>1–2 cm), and T1c (>2–3 cm), node-negative, completely resected NSCLCs (T1abcNOM0). For patients with larger tumors (T2a tumor >3–4 cm; T2b tumor >4–5 cm) that are node-negative, it is recommended that chemotherapy be considered in high-risk patients, ideally in the setting of a clinical trial. High-risk tumor characteristics include poorly differentiated tumors, moderately to poorly differentiated lung neuroendocrine tumors, vascular invasion, resection limited to wedge resection only, tumors >4 cm in size, visceral pleural involvement, and when lymph node sampling at the time of resection was incomplete (Nx).

**Evaluation and Management of Locally Advanced NSCLC.** Five-year relative survival in patients with locoregional disease is 28%, but there is significant heterogeneity within the group. Stage III disease includes patients with small tumors that have metastasized to the mediastinal lymph nodes as well as large tumors (>7 cm), and tumor invading unresectable structures or the major carina with no nodal metastasis at all. Patients with clinically evident N2 disease (i.e., bulky adenopathy present on CT scan or mediastinoscopy, with lymph nodes often replaced by tumor) have a 5-year survival rate of 5% to 10% with surgery alone. In contrast, patients with microscopic N2 disease discovered incidentally in one lymph node station after surgical resection have a 5-year survival rate that may be as high as 30%. As a result, many surgeons and oncologists differentiate between microscopic and bulky N2 lymphadenopathy and the number of involved N2 nodal stations in determining whether to proceed with resection following induction therapy. It is generally accepted that surgical resection is appropriate for patients with a single-station metastasis with a single lymph node smaller than 3 cm, although randomized trials specifically investigating resection following induction therapy for patients with single-station microscopic disease have not yet been performed.

Histologic confirmation of N2 nodal metastases is imperative; false-positive findings on PET scan are unacceptably high, and reliance on this modality will lead to significant undertreatment of patients with earlier stage cancers. This is particularly true in regions with high incidence of granulomatous diseases.
When N2 nodes are found, incidentally, to harbor metastasis at the time of planned anatomic lung resection, the decision to proceed with resection varies depending on surgeon preference; it is acceptable to either proceed with anatomic resection and mediastinal lymph node sampling/dissection or to stop the procedure, refer the patient for induction therapy, and reevaluate for resection after induction therapy is completed.

When histologically confirmed metastases are found during preoperative staging evaluation, patients should be referred for induction chemotherapy; patients in whom the mediastinal nodes are sterilized by induction therapy have a better prognosis, and surgical resection is generally warranted as part of a multimodal approach. As with preinduction evaluation, histologic confirmation of persistent N2 disease after induction therapy is imperative; patients should not be denied surgical resection following induction chemotherapy based on radiographic evidence for N2 disease because the survival for resected NSCLC is significantly better than with definitive chemotherapy.

**Surgery in T4 and Stage IV Disease** Surgery is occasionally appropriate for highly selected patients with tumors invading the SVC, carinal or vertebral body involvement, or satellite nodules in the same lobe (T3, N0-1, M0) or in T4, N0-1 tumors with limited invasion into the mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, diaphragm or carina through direct extension. Surgery generally does not have a role in the care of patients with any tumor with N3 disease or T4 tumors with N2 disease. Survival rates remain extremely low for these patients. Similarly, the treatment of patients with stage IV disease is chemotherapy. However, on occasion, patients with a single site of metastasis are encountered, particularly with adenocarcinomas presenting with a solitary brain metastasis. In this highly select group, 5-year survival rates of 10% to 15% can be achieved with surgical excision of the brain metastasis and the primary tumor, assuming it is early stage.

**Surgery for Management of Pancoast’s Tumor** Carcinoma arising in the extreme apex of the chest with associated arm and shoulder pain, atrophy of the muscles of the hand, and Horner’s syndrome presents a unique challenge to the surgeon. Any tumor of the superior sulcus, including tumors without evidence for involvement of the neurovascular bundle, is now commonly known as Pancoast’s tumors, after Henry Pancoast who described the syndrome in 1932. The designation is reserved for tumors involving the parietal pleura or deeper structures overlying the first rib. Chest wall involvement at or below the second rib is not a Pancoast’s tumor. Treatment is multidisciplinary; due to the location of the tumor and involvement of the neurovascular bundle that supplies the ipsilateral extremity, preserving postoperative function of the extremity is critical. For this reason, resection should only be performed in patients who are proven negative for mediastinal lymph node involvement. Survival with N2 positive nodes is poor, and the morbidity and mortality associated with surgical resection are high. If bulky lymphadenopathy is present, EBUS- or EUS-guided FNA may prove nodal involvement. However, a negative FNA is not sufficient for proving the absence of mediastinal involvement and should be followed by mediastinoscopy to ensure accurate and complete evaluation of the mediastinum.

Because Pancoast’s tumors have high rates of local recurrence and incomplete resection, induction chemoradiotherapy followed by surgery is recommended. This treatment regimen was well tolerated in a study performed by the Southwest Oncology Group, with 95% of patients completing induction treatment. Complete resection was achieved in 76%. Five-year survival was 44% overall and 54% when complete resection was achieved. Disease progression with this regimen was predominantly at distant sites, with the brain being the most common. The current treatment algorithm for Pancoast’s tumors is presented in Fig. 19-25.

Surgical excision is performed via thoracotomy with en bloc resection of the chest wall and vascular structures and anatomic lobectomy. A portion of the lower trunk of the brachial plexus and the stellate ganglion are also typically resected. With chest wall involvement, en bloc chest wall resection, along with lobectomy, is performed, with or without chest wall reconstruction.

For small rib resections or those posterior to the scapula, chest wall reconstruction is usually unnecessary. Larger defects (two rib segments or more) are usually reconstructed with Gore-Tex to provide chest wall contour and stability. En bloc resection is also used for other locally advanced tumors (T3) with direct invasion of the adjacent chest wall, diaphragm, or pericardium. If a large portion of the pericardium is removed, reconstruction with thin Gore-Tex membrane will be required to prevent cardiac herniation and venous obstruction.

**Preoperative (Induction) Chemotherapy for NSCLC** The use of chemotherapy before anatomic surgical resection has a number of potential advantages:

1. The tumor’s blood supply is still intact, allowing better chemotherapy delivery and avoiding tumor cell hypoxia (in any residual microscopic tumor remaining postoperatively), which would increase radioresistance.
2. The primary tumor may be downstaged, enhancing resectability.
3. Patients are better able to tolerate chemotherapy before surgery and are more likely to complete the prescribed regimen than after surgery.
4. It functions as an in vivo test of the primary tumor’s sensitivity to chemotherapy.
5. Response to chemotherapy can be monitored and used to guide decisions about additional therapy.
6. Systemic micrometastases are treated.
7. It identifies patients with progressive disease/nonresponders and spares them a pulmonary resection.

Potential disadvantages include:

1. There is a possible increase in the perioperative complication rate in patients requiring right pneumonectomy after induction chemotherapy.
2. While the patient is receiving chemotherapy, potentially curative resection is delayed; if the patient does not respond, this delay could result in tumor spread.

In stage IIIA N2 disease, the response rates to induction chemotherapy are high, in the range of 70%. The treatment is generally safe, as it does not cause a significant increase in perioperative morbidity. Two randomized trials have now compared surgery alone for patients with N2 disease to preoperative chemotherapy followed by surgery. Both trials were stopped before complete accrual because of a significant increase in survival for the chemotherapy arm.

The initially observed survival differences have been maintained for up to 3 years and beyond (5-year data not shown). Given these results, induction chemotherapy with

cisplatin-based regimen (two to three cycles) has become standard for patients with N2 disease. Table 19-15 summarizes the findings of a systematic review and meta-analysis reporting response rates, progression-free survival, and overall survival after induction chemotherapy followed by surgical resection.

**Postoperative (Adjuvant) Chemotherapy for NSCLC**

Postoperative adjuvant chemotherapy was previously thought to confer no benefit based on multiple prospective randomized trials, in part because patients who had undergone thoracotomy and lung resection had difficulty tolerating the adjuvant regimens. More recently, however, newer, more effective agents have shown promise, and adjuvant therapy is better tolerated after minimally invasive lung resection (i.e., VATS or robotic anatomic resection). Targeted therapies, which have been shown to be beneficial in advanced-stage lung cancer, are of particular interest.

Any patient with nodal metastasis (N1 or N2) or with T3 tumors (defined as tumors >5 to ≤7 cm or separate tumor in same lobe or direct invasion of chest wall [includes parietal pleura and superior sulcus/parietal pericardium/phrenic nerve]) should receive adjuvant chemotherapy if they are able to tolerate the regimen. In the situation where the margins of resection are positive, re-resection is recommended. If not possible, concurrent chemoradiation is recommended for macroscopic residual tumor and sequential chemoradiation for microscopic residual tumor.

**Definitive Nonsurgical Treatment for NSCLC.** Recent advances in targeted therapies have changed the management of advanced NSCLC from a generalized, platinum-based approach to one in which molecular analysis and targeted, personalized therapies are now standard of care. It is now mandatory that the pathologist clearly differentiate between squamous cell carcinoma and adenocarcinoma because the therapeutic options are different and use of bevacizumab, while beneficial in patients with adenocarcinoma, has been found to cause excessive pulmonary hemorrhage in patients with squamous histology. For the surgeon, this requirement translates into a much more aggressive approach to tissue diagnosis. At our institution, the cytopathologist provides onsite rapid assessment of the fine-needle aspirate to determine whether tumor cells are present and confirm that sufficient tumor cells are present to enable molecular testing. This has increased the number of passes performed during an EBUS-guided FNA or during CT-guided aspiration of a pulmonary or intrathoracic lesion; typically, an additional two to three passes are made for cell block material after confirming the presence of tumor cells in the target area. When insufficient cells are obtained for molecular testing, despite having a diagnosis, additional sampling is warranted; this is mandatory in patients with adenocarcinoma and likely to become necessary for other non–small cell histologic types as advances in targeted therapies become available for clinical use. Acquiring adequate tissue for diagnosis may require mediastinoscopy or VATS; close communication between the oncologist, surgeon, pathologist, and patient is needed to ensure that the benefits to the patient clearly outweigh the risks and that results obtained through more aggressive diagnostic measures are needed to direct subsequent care.

Once a treatment plan has been devised, two strategies for delivery are available. “Sequential” chemoradiation involves full-dose systemic chemotherapy (i.e., cisplatin combined with a second agent) followed by standard radiotherapy (approximately 60 Gy). The combination of chemotherapy followed by radiation has improved 5-year survival from 6% with radiotherapy alone to 17%. An alternative approach, referred to as “concurrent chemoradiation,” administers chemotherapy and radiation at the same time. Certain chemotherapeutic agents sensitize tumor cells to radiation and, thus, enhance the radiation effect. The advantages of this approach are improved primary tumor and locoregional lymph node control and elimination of the delay in administering radiotherapy that occurs with sequential treatment. A disadvantage, however, is the necessary reduction in chemotherapy dosage in order to diminish overlapping toxicities; this can potentially lead to undertreatment of systemic micrometastases. Randomized trials have shown a modest 5-year survival benefit as compared with chemotherapy. In a systematic review of 47 trials and six meta-analyses, an absolute survival benefit of 4% at 2 years was seen when concurrent platinum-based chemoradiation was given compared to sequential radiation.

Definitive radiotherapy is predominantly used for palliation of symptoms in patients with poor performance status; cure rates with radiation as a single modality in patients with N2 or N3 disease is less than 7%. Recent improvement has been seen with three-dimensional conformal radiotherapy and altered fractionation. Such poor results for patients with stage III lung cancer reflect the limitations of locoregional treatment in a disease where death results from systemic metastatic spread.

**Options for Thoracic Surgical Approaches**

Thoracic surgical approaches have changed over recent years with advancements in minimally invasive surgery. A surgeon trained in advanced minimally invasive techniques can now perform pleural-based, pulmonary and mediastinal procedures through multiple thoracoscopic ports without the need for a substantial, rib-spreading incision. Subjective measures of quality of life after VATS, such as pain (Fig. 19-26) and perceived functional recovery, consistently and reproducibly favor VATS over thoracotomy. Objective measures such as functional status as measured by 6-minute walk, return to work, and ability to tolerate chemotherapy also favor VATS over thoracotomy. Finally, recovery of respiratory function occurs earlier in VATS patients. These findings are pronounced in patients with chronic obstructive pulmonary disease and in the elderly—populations whose quality of life can be dramatically impacted by changes in their respiratory symptoms and function, thoracic pain, and physical performance. Table 19-16 provides a summary of populations that may benefit from VATS approaches.

**Video-Assisted (VATS)/Robotic-Assisted Thoracoscopic Surgery (RATS).** VATS/RATS has become the recommended approach to diagnosis and treatment of pleural effusions, recurrent pneumothoraces, lung biopsies, lobectomy or segmental resection, resection of bronchogenic and mediastinal cysts, and intrathoracic esophageal mobilization for esophagectomy. These approaches are also utilized for pneumonectomy in some centers of excellence with very high

![Pie chart comparison of pain control at 3 weeks after lobectomy by standard thoracotomy or video-assisted thoracic surgery (VATS). The pie charts show that patients undergoing VATS have significantly less pain (P < .01) as measured by the most potent analgesic still required: severe—schedule II narcotic; moderate—schedule III or lower narcotic; mild—nonsteroidal anti-inflammatory drug (NSAID) or acetaminophen. (Reproduced with permission from Demmy TL, Nwoque C. Is video-assisted thoracic surgery lobectomy better? Quality of life considerations, Ann Thorac Surg. 2008 Feb;85(2):S719-S728.)

volumes of VATS lung resection. VATS is performed via two to four incisions measuring 0.5 to 1.2 cm in length to allow insertion of the thoracoscope and instruments. An access incision, typically in the fourth or fifth intercostal space in the anterior axillary line, is used for dissection of the hilum during lung resection. The incision location varies according to the procedure. With respect to VATS lobectomy, port placement varies according to the lobe being resected and is highly variable among surgeons. The basic principle is to position the ports high enough on the thoracic cage to have access to the hilar structures. Endoscopic staplers are used to divide the major vascular structures and bronchus (Fig. 19-27). Robotic approaches are similarly tailored to the side and lobe undergoing resection, with the entire operation performed using

Figure 19-27. Selected video-assisted thoracic surgery lobectomy maneuvers. All the maneuvers are shown with the patient positioned in the left lateral decubitus position. The same maneuvers can be performed in mirror image for left-sided work. A. Medial viewing and inferior holding of lung to allow dissection through the access incision. Example shows dissection of the apical hilum. B. Medial viewing and access holding of lung to allow stapling of hilar structures from below. Example shows division of the apical pulmonary artery trunk to the right upper lobe (upper lobe branch of vein divided and reflected away). C. Standard viewing and use of working port to dissect and divide structures while lung is retracted through access incision. Example shows use of stapler to divide pulmonary artery to right lower lobe. D. Standard viewing and use of working port to retract lung and access incision to dissect structures. This method is commonly used to dissect the pulmonary artery in the major fissure. Example shows inferior pulmonary vein after the pulmonary ligament was divided using this maneuver. E. Standard viewing and use of access incision to deliver stapler to divide fissures. Example shows division of the posterior fissure between the right lower lobe and the upper lobe.
robotic arms, except for one assistant port through which specimens can be removed and suctioning and stapling performed (in early models; the newest robotic models have robotic staplers, allowing the surgeon to have complete control of the entire operation).

**Open Approaches to Thoracic Surgery.** When a thorascoscopic approach is not possible, an open approach, most frequently the posterolateral thoracotomy, is used to gain access to the intrathoracic space. The posterolateral thoracotomy incision can be used for most pulmonary resections, esophageal operations, and operations in the posterior mediastinum and vertebral column (Fig. 19-28). The anterolateral thoracotomy has traditionally been used in trauma victims. This approach allows quick entry into the chest with the patient supine. In the face of hemodynamic instability, the lateral decubitus position significantly compromises control over the patient’s cardiopulmonary system and resuscitation efforts, whereas the supine position allows the anesthesiologist full access to the patient. A bilateral anterior thoracotomy incision with a transverse sternotomy (“clamshell” thoracotomy) is a standard operative approach to the heart and mediastinum in certain elective circumstances. It is the preferred incision for double-lung transplantation in many centers. A partial median sternotomy can also be added to an anterior thoracotomy (“trap-door” or “hemiclamshell” thoracotomy) for access to mediastinal structures. A hypesthetic nipple is a frequent complication of this approach. The median sternotomy incision allows exposure of anterior mediastinal structures and is principally used for cardiac operations. Although the surgeon has access to both pleural cavities, incision into the pleural cavity can be avoided if entry is unnecessary (Fig. 19-29).

**Postoperative Care**

**Chest Tube Management.** At the conclusion of most thoracic operations, the pleural cavity is drained with a chest tube(s). If the visceral pleura has not been violated and there is no concern
The median sternotomy incision.

**A.** Skin incision from the suprasternal notch to the xiphoid process. **B.** Exposure of the pleural space. a. = artery; v. = vein.

for pneumo- or hemothorax (e.g., after VATS sympathectomy), a chest tube is unnecessary. After chest tube placement, the lung is reexpanded with positive-pressure ventilation. There are two reasons for the use of plural tubes in this setting: first, the tube allows evacuation of air if an air leak is present; second, blood and pleural fluid can be drained, thereby preventing accumulation within the pleural space that would compromise the patient’s respiratory status. The tube is removed when the air leak is resolved and when the volume of drainage decreases below an acceptable level over 24 hours.

Historically, many surgeons have somewhat arbitrarily required less than 150 mL of drainage volume over 24 hours prior to removing a chest tube to minimize risk of reaccumulation. The pleural lymphatics, however, can absorb up to 0.40 mL/kg per hour in a healthy individual, which may be as much as 500 mL over a 24-hour period. In fact, studies have shown that pleural tubes can be removed after VATS lobectomy or thoracotomy with 24-hour drainage volumes as high as 400 mL, without subsequent development of plural effusions.\(^82\)

It is our current practice to remove chest tubes with 24-hour outputs of 400 mL or less after lobectomy or lesser pulmonary resections. In settings where normal pleural fluid dynamics have been altered, such as malignant pleural effusion, pleural space infections or inflammation, and pleurodesis, strict adherence to a volume requirement before tube removal is appropriate (typically 100 to 150 mL over 24 hours).

For operations involving lung resection or parenchymal injury, suction levels of –20 cm H\(_2\)O are routinely used to eradicate residual air spaces and to control postoperative parenchymal air leaks for the first 12 to 24 hours. The following day, however, the decision to continue suction or place the patient to water seal (off suction) must be made. Applying suction to an air leak has been shown to prolong the duration of the air leak and extend the time frame during which tube thoracostomy is needed.\(^83\) The main guidelines for the continued use of suction if an air leak is present depend on the expansion of the remaining lung as determined by CXR. If the lung is well expanded, the chest tube can remain to water seal drainage. If an undrained pneumothorax is present on CXR, the chest tube and its attached tubing should be examined to ensure that the chest tube is patent and the attached tubing is not kinked or mechanically obstructed, such as occurs when the patient is lying on the tube. If the tube is a small caliber tube (pigtail catheter), it should be flushed with sterile saline through a three-way stopcock that has been cleaned with alcohol because these tubes tend to become clogged with fibrin. These catheters are also prone to kinking at the insertion site into the skin. Once the surgeon has confirmed that the chest tube is patent, the patient is asked to voluntarily cough or perform the Valsalva maneuver. This maneuver increases the intrathoracic pressure and will push air that is contained within the hemithorax out of the chest tube. During the voluntary cough, the fluid level in the water seal chamber should move up and down with the cough and with deep respiration, reflecting the pleural pressure changes occurring with these maneuvers. A stationary fluid level implies either a mechanical blockage (e.g., due to external tube compression or to a clot/debris within the tube) or pleurodesis. If bubbles pass through the water seal chamber, an air leak is presumed. If the leak is significant enough to induce atelectasis or collapse of the lung during use of water seal, suction should be used to achieve lung reexpansion.

**Pain Control.** Good pain control after intrathoracic procedures is critical; it permits the patient to actively clear and manage secretions and promotes ambulation and a feeling of well-being. The most common techniques of pain management are epidural, paravertebral, and intravenous. Epidural catheters are commonly used, although we prefer to use paravertebral catheters in our center. Epidural catheters should be inserted at about the T6 level, roughly at the level of the scapular tip. Lower placement risks inadequate pain control, and higher placement may provoke hand and arm numbness. Typically, combinations of fentanyl at 0.3 µg/mL with either bupivacaine (0.125%) or ropivacaine (0.1%) are used. Ropivacaine has less cardiotoxicity than bupivacaine; thus, in the case of inadvertent intravenous injection, the potential for refractory complete heart block is significantly less with ropivacaine. Paravertebral blocks can be placed using the same epidural catheter kit 2.5 cm lateral to the spinous process at T4 to T6. Combinations of narcotic and topical analgesia are then infused as with the epidural catheter.

When properly placed, a well-managed epidural can provide outstanding pain control without significant systemic sedation.\(^84\) Thoracic epidurals do not commonly cause urinary retention, although a low thoracic epidural may block the sensory fibers to the bladder. Motor function, however, remains intact. In some patients who are having difficulty voiding, it...
may be possible to avoid Foley catheterization by simply reminding the patient to void on a regular basis. In male patients with voiding difficulty prior to surgery, urinary catheterization may be required. In addition, the use of local anesthetics may cause sympathetic outflow blockade, leading to vasodilation and hypotension often requiring intravenous vasconstrictors (an α-agonist such as phenylephrine) and/or fluid administration. In such circumstances, fluid administration for hypotension may be undesirable in pulmonary surgery patients, particularly after pneumonectomy. Paravertebral catheters provide equivalent pain control with less effect on hemodynamics.86 Recently, liposomal bupivacaine was introduced and has become the standard approach to pain management after thoracic surgery in several centers. The formulation allows for slow-release of bupivacaine for up to 72 hours after injection. Injected directly into the intercostal spaces immediately prior to chest closure, the formulation has shown great promise in several retrospective reports, with randomized trials not yet completed. One limiting factor in use of the formulation is the cost; future trials are needed, with cost-analysis, to determine whether the benefits in pain, reduction in narcotic use, shorter hospital stay and possibly decreased pulmonary complications justify the cost.

Alternatively, intravenous narcotics via patient-controlled analgesia can be used, often in conjunction with ketorolac, gabapentin, and intravenous Tylenol. Dosing must be titrated to balance the degree of pain relief with the degree of sedation. Oversedated patients are as ominous as patients without adequate pain control because of the significant risk of secretion retention, atelectasis/pneumonia, and pulmonary aspiration, especially in elderly patients who should be carefully assessed for aspiration risk when ordered for dietary advancement. Proper pain control with intravenous narcotics requires a carefully regulated balance of pain relief and sedation to maximize the benefits of pain control while minimizing these very real and potentially life-threatening complications.

Whether on epidural, paravertebral, or intravenous pain control, the patient is typically transitioned to oral pain medication on the third or fourth postoperative day. During both the parenteral and oral phase of pain management, a standardized regimen of stool softeners and laxatives is advisable in order to prevent severe constipation.

Respiratory Care. The best respiratory care is achieved when the patient is able to deliver an effective cough to clear secretions and results from the commitment and proper training of all involved healthcare providers. The process begins preoperatively, with clear instructions on using pillows (or other support techniques) over the wound and then applying pressure.

Postoperatively, proper pain control without oversedation (as outlined earlier) is essential. Daily morning rounds should include a careful assessment of the patient’s pulmonary status, reminders to the patient and family about the importance of coughing and deep breathing, including use of adjunctive respiratory equipment if ordered, and mobilization of the patient. Early transition to a chair and to ambulation is the best respiratory therapy and should be strongly encouraged. When available, physical and/or cardiopulmonary rehabilitation services are vital additional members of the care team.

Postoperative Complications

Postoperative complications after pulmonary resection range from minor to life-threatening. Strict attention to volume status, early and aggressive pulmonary toilet, and good pain control can reduce the risk of most complications, but does not completely eliminate them, even in centers of excellence. The most devastating complication after pulmonary resection is postpneumonectomy pulmonary edema, which occurs in 1% to 5% of patients undergoing pneumonectomy and more often after right compared to left pneumonectomy. Clinically, symptoms of respiratory distress manifest hours to days after surgery. Radiographically, diffuse interstitial infiltration or frank alveolar edema is seen. The pathophysiologic causes are related increased permeability and filtration pressure and decreased lymphatic drainage from the affected lung. Judicious use of intravenous fluids perioperatively, including use of vasopressors rather than fluid boluses for hypotension intra- and postoperatively, is critical to minimizing the risk of this syndrome. Treatment consists of ventilatory support, fluid restriction, and diuretics. Extracorporeal membrane oxygenation may be lifesaving in centers where this option is available. The syndrome reportedly has a nearly 100% mortality rate despite aggressive therapy.

Other postoperative complications include air leak and bronchopleural fistula. Although these are two very different problems, distinguishing between them may be difficult. Postoperative air leaks are common after pulmonary resection, particularly in patients with emphysematous lung, because the fibrosis and destroyed blood supply impairs healing of surface injuries. Prolonged air leaks (i.e., those lasting >5 days) may be treated by diminishing or discontinuing suction (if used), by continuing chest drainage, or by instilling a pleurodesis agent, usually doxycycline or talcum powder, which will cause pleurodesis of the lung within the chest cavity and minimize the possible collapse of the lung due to persistent air leak. This is useful only in patients in whom full lung expansion is achieved, either with suction or on water seal, as patients with a persistent pneumothorax on CXR will not have adequate lung-to-parietal pleural apposition to achieve adequate pleurodesis.

If the leak is moderate to large, a high index of suspicion for bronchopleural fistula from the resected bronchial stump should be maintained, particularly if the patient is immunocompromised or had induction chemo- and/or radiation therapy. If suspected, flexible bronchoscopy is performed to evaluate the bronchial stump. Management options include continued prolonged chest tube drainage, reoperation, and reclosure (with stump reinforcement with intercostal or pedicled serratus muscle flap). If the fistula is very small (<4 mm), bronchoscopic fibrin glue application has been used successfully to seal the hole in some patients. Patients often have concomitant empyema, and open drainage may be necessary.

Spontaneous Pneumothorax

Spontaneous pneumothorax is secondary to intrinsic abnormalities of the lung and can be classified as primary and secondary. Primary spontaneous pneumothorax is defined as a spontaneous pneumothorax without underlying lung disease. The most common cause is rupture of an apical subpleural bleb. The cause of these blebs is unknown, but they occur more frequently in smokers and males, and they tend to predominate in young postadolescent males with a tall thin body habitus. Treatment is generally chest tube insertion with water seal. If a leak is present and persists for greater than 3 days, thoracoscopic management (i.e., bleb resection with pleurodesis by talc or pleural abrasion) is performed. Recurrences or complete lung collapse with the first episode are generally indications for thoracoscopic
Pulmonary Infections

Lung Abscess. A lung abscess is a localized area of pulmonary parenchymal necrosis caused by an infectious organism; tissue destruction results in a solitary or dominant cavity measuring at least 2 cm in diameter. Less often, there may be multiple, smaller cavities (<2 cm). In that case, the infection is typically referred to as a necrotizing pneumonia. An abscess that is present for more than 6 weeks is considered chronic.

Based on the etiology (Table 19-17), lung abscesses are further classified as primary or secondary. A primary lung abscess occurs, for example, in immunocompromised patients, as a result of highly virulent organisms inciting a necrotizing pulmonary infection, or in patients who have a predisposition to aspirate oropharyngeal or gastrointestinal secretions. A secondary lung abscess occurs in patients with an underlying condition such as a partial bronchial obstruction, a lung infarct, or adjacent suppurative infections (subphrenic or hepatic abscesses).

Pathogenesis Lung abscesses result when necrotizing microorganisms infect the lower respiratory tract via inhalation of aerosolized particles, aspiration of oropharyngeal secretions, or hematogenous spread from distant sites. Direct extension from a contiguous site is less frequent. Most primary lung abscesses are suppurative bacterial infections secondary to aspiration. Risk factors for pulmonary aspiration include advanced age, conditions of impaired consciousness, suppressed cough reflex, dysfunctional esophageal motility, laryngopharyngeal reflex dysfunction, and centrally acting neurologic diseases (e.g., stroke). At the time of aspiration, the composition of the oropharyngeal flora determines the etiologic organisms. With increasing use of proton pump inhibitors to suppress acid secretion in the stomach, the oropharyngeal flora has shifted, and the risk of developing bacterial lung infections after an aspiration event has increased.

Secondary lung abscesses occur most often distal to an obstructing bronchial carcinoma. Infected cysts or bullae are not considered true abscesses.

Microbiology Normal oropharyngeal secretions contain many more Streptococcus species and more anaerobes (approximately $1 \times 10^8$ organisms/mL) than aerobes (approximately $1 \times 10^7$ organisms/mL). Pneumonia that follows from aspiration, with or without abscess development, is typically polymicrobial. An average of two to four isolates present in large numbers have been cultured from lung abscesses sampled percutaneously. Overall, at least 50% of these infections are caused by purely anaerobic bacteria, 25% are caused by mixed aerobes and anaerobes, and 25% or fewer are caused by aerobes only. In nosocomial pneumonia, 60% to 70% of the organisms are gram-negative bacteria. Immunocompromised patients may develop abscesses because of the usual pathogens as well as less virulent and opportunistic organisms such as Salmonella species, Legionella species, Pneumocystis carinii, atypical mycobacteria, and fungi.

Clinical Features and Diagnosis The typical presentation may include productive cough, fever (>38.9°C), chills, leukocytosis (>15,000 cells/mm$^3$), weight loss, fatigue, malaise, pleuritic chest pain, and dyspnea. Lung abscesses may also present in a more indolent fashion, with weeks to months of cough, malaise, weight loss, low-grade fever, night sweats, leukocytosis, and anemia. After aspiration pneumonia, 1 to 2 weeks typically elapse before cavitation occurs; 40% to 75% of such patients produce putrid, foul-smelling sputum. Severe complications

such as massive hemoptysis, endobronchial spread to other portions of the lungs, rupture into the pleural space and development of pyopneumothorax, or septic shock and respiratory failure are rare in the modern antibiotic era. The mortality rate is about 5% to 10%, except in the presence of immunosuppression, where rates range from 9% to 28%.

The CXR is the primary tool for diagnosing a lung abscess (Fig. 19-30). Its distinguishing characteristic is a density or mass with a relatively thin-walled cavity. An air-fluid level observed within the abscess indicates communication with the tracheobronchial tree. CT scan of the chest clarifies the diagnosis when CXR is equivocal and identifies endobronchial obstruction and/or an associated mass and other pathologic anomalies. A cavitating lung carcinoma is frequently mistaken for a lung abscess. Differential diagnosis also includes loculated or interlobar empyema, infected lung cysts or bullae, tuberculosis, bronchiectasis, fungal infections, and noninfectious inflammatory conditions (e.g., Wegener’s granulomatosis).

Ideally, the specific etiologic organism is identified before antibiotic administration. Bronchoscopy, which is essential to

Figure 19-30. Lung abscess resulting from emesis and aspiration after an alcoholic binge. A. Chest X-ray showing an abscess cavity in the left upper lobe. B. rule out endobronchial obstruction due to tumor or foreign body, is ideal for obtaining uncontaminated cultures using bronchoalveolar lavage. Culture samples can also be obtained by percutaneous, transthoracic FNA under ultrasound or CT guidance. Routine sputum cultures are often of limited usefulness because of contamination with upper respiratory tract flora.

Actinomycosis and nocardiosis, although rare, are particularly virulent infections associated with lung abscess. Diagnosis can be difficult. Both frequently masquerade as other clinical syndromes; thus, it is important for the surgeon to keep these bacteria in mind when considering the differential diagnosis for cavitary lung lesions. Actinomyces, a normal oropharyngeal bacterium, causes extensive pulmonary damage. Actinomycosis lung infection typically begins as acute pneumonitis after pulmonary aspiration. The symptoms mimic pulmonary tuberculosis, including chronic cough, night sweats, weight loss, and hemoptysis.

Ongoing infection leads to chronic inflammation and fibrosis; cavitation occurs due to destruction of the pulmonary tissues. Without treatment, the infection continues to destroy surrounding structures, resulting in fistula formation to adjacent structures, including the adjacent lung, interlobar fissures, pleural space, chest wall, and mediastinum. Actinomyces israelii is the most common of the species to cause disease. Nocardiosis is also a rare opportunistic infection that usually occurs in an immunocompromised host (HIV or cancer patients) and causes both local and systemic suppurative infections. The most common site is pulmonary, caused by Nocardia asteroides in 90% of cases. Infection is slowly progressive, with weight loss, fatigue, cough, and hemoptysis. An acute pulmonary infection is common, with necrotizing pneumonia and cavitation or slowly enlarging pulmonary nodule. In some cases, empyema also develops.

Management of Lung Abscess Systemic antibiotics directed against the causative organism represent the mainstay of therapy. The duration of antimicrobial therapy varies from 3 to 12 weeks for necrotizing pneumonia and lung abscess. It is likely best to treat until the cavity is resolved or until serial radiographs show significant improvement. Parenteral therapy is generally used until the patient is afebrile and able to demonstrate consistent enteral intake. Oral therapy can then be used to complete the course of therapy. For community-acquired infections secondary to aspiration, likely pathogens are oropharyngeal streptococci and anaerobes. Penicillin G, ampicillin, and amoxicillin are the main therapeutic agents, but a β-lactamase inhibitor or metronidazole should be added to cover the increasing prevalence of gram-negative anaerobes that produce β-lactamase. Clindamycin is also a primary therapeutic agent. For hospital-acquired infections, Staphylococcus aureus and aerobic gram-negative bacilli are common organisms of the oropharyngeal flora. Piperacillin with a β-lactamase inhibitor (or equivalent alternatives) provide better coverage of likely pathogens.

Surgical drainage of lung abscesses is uncommon since drainage usually occurs spontaneously via the tracheobronchial tree. Indications for intervention are listed in Table 19-18. Drainage and resection may be required for actinomycosis and nocardiosis; diagnosis is often delayed because the bacteria are difficult to culture; invasion of the infection into surrounding structures is, therefore, common. Once identified, long-term antibiotics (months to years) are typically required along with drainage, debridement, and resection as needed. While penicillin derivatives are effective against most Actinomyces species, the infections are typically polymicrobial, and broad-spectrum parenteral antibiotics may be required. Nocardia species, in contrast, are highly variable; specific identification of the infecting species with antibiotic sensitivities is needed to direct appropriate therapy. Evaluation for malignant spread, particularly to the brain, is also required in the management of nocardiosis, as systemic dissemination occurs early and frequently.

External drainage may be accomplished with tube thoracostomy, percutaneous drainage, or surgical cavernostomy. The choice between tube thoracostomy versus radiographically guided catheter placement depends on the treating physician’s preference and institutional technical expertise in placing image-guided thoracostomy tubes. Surgical resection is required in fewer than 10% of lung abscess patients. Lobectomy is the preferred intervention for bleeding from a lung abscess or pyopneumothorax. An important intraoperative consideration is to protect the contralateral lung with a double-lumen tube, bronchial blocker, or contralateral main stem intubation. Surgical treatment has a 90% success rate, with associated mortality of 1% to 13%.

Bronchiectasis. Bronchiectasis is defined as a pathologic and permanent dilation of bronchi with bronchial wall thickening. This condition may be localized to certain bronchial segments, or it may be diffuse throughout the bronchial tree, typically affecting the medium-sized airways. Overall, this is a rare clinical entity in the United States with a prevalence of less than 1 in 10,000, although the incidence has increased in recent years and noncystic fibrosis–related bronchiectasis is now thought to affect 27.5 out of every 10,000 persons over age 75.

Pathogenesis Development of bronchiectasis can be attributed to either congenital or acquired causes. The principal congenital diseases that lead to bronchiectasis include cystic fibrosis, primary ciliary dyskinesia, and immunoglobulin deficiencies (e.g., selective IgA deficiency). Congenital causes commonly produce a diffuse pattern of bronchial involvement. Acquired causes are categorized broadly as infectious and inflammatory. Bronchial obstruction from cancer, inhaled objects, extrinsic airway compression, or inspissated sputum promotes localized infection and subsequent medium airway destruction. Diffuse pneumatic processes from pathogens including necrotizing bacterial pneumonia, pertussis and measles pneumonia, severe influenza, or varicella pneumonia can lead to widespread bronchiectasis. Chronic granulomatous disease, immunodeficiency disorders, and hypersensitivity disorders can also lead to diffuse bronchiectasis.

Noninfectious causes of bronchiectasis include inhalation of toxic gases such as ammonia, which results in severe

---
and destructive airway inflammatory responses. Allergic bronchopulmonary aspergillosis, Sjögren’s syndrome, and α1-antitrypsin deficiency are some additional examples of presumed immunologic disorders that may be accompanied by bronchiectasis.

In addition, recent studies have suggested an association between chronic gastroesophageal reflux disease, acid suppression, and nontuberculous mycobacterial infection with bronchiectasis. This interaction is thought to be related to chronic aspiration of colonized gastric secretions in the setting of acid suppression; while not proven to be causative, these findings suggest a role for gastroesophageal reflux disease in the pathogenesis of bronchiectasis.

The process shared by all causes of bronchiectasis is impairment of airway defenses or deficits in immunologic mechanisms, which permit bacterial colonization and chronic infection. Common organisms include Haemophilus species (55%), Pseudomonas species (26%), and Streptococcus pneumoniae (12%). Both the bacterial organisms and the inflammatory cells recruited to thwart the bacteria elaborate proteolytic and oxidative molecules, which progressively destroy the muscular and elastic components of the airway walls; those components are then replaced by fibrous tissue. Thus, chronic airway inflammation is the essential pathologic feature of bronchiectasis. The dilated airways are usually filled with thick purulent material; more distal airways are often occluded by secretions or obliterated by fibrous tissue. Bronchial wall vascularity increases, bronchial arteries become hypertrophied, and abnormal anastomoses form between the bronchial and pulmonary arterial circulation.

There are three principal types of bronchiectasis, based on pathologic morphology: cylindrical—uniformly dilated bronchi; varicose—an irregular or beaded pattern of dilated bronchi; and saccular (cystic)—peripheral balloon-type bronchial dilation. The saccular type is the most common after bronchial obstruction or infection (Fig. 19-31).

**Clinical Manifestations and Diagnosis** Typical symptoms are a daily persistent cough and purulent sputum production; the quantity of daily sputum production (10 mL to >150 mL) correlates with disease extent and severity. Other patients may appear asymptomatic or have a dry nonproductive cough (“dry bronchiectasis”). These patients are prone to have involvement of the upper lobes. The clinical course is characterized by progressive

![Figure 19-31. Multiple cystic-type bronchiectatic cavities can be seen on a cut section of right lower lobe lung.](image-url)
shown either no change or a worsening of pulmonary status and require further study in the non–cystic fibrosis population.

Surgical resection of a localized bronchiectatic segment or lobe, preserving as much functional lung as possible, may benefit patients with refractory symptoms while on maximal medical therapy. Multifocal disease must be excluded before any attempt at surgery; any uncorrectable predisposing factor (e.g., ciliary dyskinesia) must also be excluded. Patients with end-stage lung disease from bronchiectasis may be potential candidates for a bilateral lung transplant. Surgical resection is also indicated in patients with significant hemothysis, although bronchial artery embolization is the preferred first option. Antireflux surgery may also prove beneficial in patients with chronic aspiration, but further studies are required. It is particularly important to recognize that antireflux surgery in patients with severe underlying pulmonary dysfunction has higher risk for perioperative adverse outcomes than in the general population. It should be undertaken only by very experienced surgeons with direct involvement of the pulmonary medicine physicians to minimize postoperative pulmonary compromise.

**Mycobacterial Infections**

**Epidemiology**

Tuberculosis is a widespread problem that affects nearly one-third of the world’s population. It is the ninth leading cause of death worldwide and the leading infectious cause of death. The rate of death from tuberculosis has declined, from 1.7 million in 2000 to 1.3 million among HIV-negative people in 2016. There were 6.3 million new cases of tuberculosis worldwide in 2016 according to the World Health Organization (WHO); 56% are in the countries of India, Indonesia, China, the Philippines, and Pakistan. Treatment success rate was 83%. Only 9257 new cases were reported to the WHO in the United States in 2016. HIV infection is the strongest risk factor for developing active tuberculosis. The elderly, minorities, and recent immigrants are the most common populations to have clinical manifestations of infection, yet no age group, sex, or race is exempt from infection. In most large urban centers, reported cases of tuberculosis are more numerous among the homeless, prisoners, and drug-addicted populations. Immunocompromised patients additionally contribute to an increased incidence of tuberculosis infection, often developing unusual systemic as well as pulmonary manifestations. As compared with past decades, presently surgical intervention is required more frequently in patients with multidrug-resistant or rifampin-resistant (but isoniazid-susceptible) tuberculosis organisms (MDR/RR-TB) who do not respond to medical treatment and in selected patients with nontuberculous mycobacterial infections (NTM).

**Microbiology**

Mycobacterial species are obligate aerobes. They are primarily intracellular parasites with slow growth rates. Their defining characteristic is the property of acid-fastness, which is the ability to withstand decolorization by an acid-alcohol mixture after being stained. *Mycobacterium tuberculosis* is the highly virulent bacillus of this species that produces invasive infection among humans, principally pulmonary tuberculosis.

Infections with *M tuberculosis* are primary when they are the first infection in a previously unsensitized host and secondary or postprimary when reactivation of a previous infection occurs.

Because of improper application of antitubercular drugs and multifactorial interactions, MDR-TB organisms, defined by their resistance to at least two of the first-line antitubercular drugs (isoniazid and rifampin), and rifampicin-resistant (but isoniazid-susceptible) (RR-TB), have emerged. According to the WHO Global Tuberculosis Report 2017, in 2014, there were 108 reported cases of TB from MDR/RR-TB organisms, with 78% of cases successfully treated. In addition, there is another rare variant termed extensively drug-resistant tuberculosis (XDR-TB). These organisms are resistant to isoniazid and rifampin and have also developed resistance to either fluoroquinolones and injectable second-line drugs (e.g., capreomycin, amikacin, kanamycin), the two other classes of medications in the MDR-TB treatment regimen. In 2014, there were 109,680 MDRTB cases globally, with 6777 (6.2%) extensively drug resistant. Successful treatment was achieved in 54% of MDRTB and only 30% of XDR-TB. In 2016, it was estimated that MDR/RR was the responsible organism for more than 4% of new cases and nearly 20% of previously treated cases.

The more important NTM organisms include *Mycobacterium kansasii*, *M avium* and *M intracellulare* complex (MAC), and *M fortuitum*. The highest incidence of *M kansasii* infection is in Midwestern U.S. cities among middle-aged men from good socioeconomic surroundings. MAC organisms are important infections in elderly and immunocompromised patient groups. *M fortuitum* infections are common complications of underlying severe debilitating disease. None of these organisms are as contagious as *M tuberculosis*.

**Pathogenesis and Pathology**

The main route of transmission is via airborne inhalation of viable mycobacteria. Three stages of primary infection have been described. In the first stage, alveolar macrophages become infected through ingesting the bacilli. In the second stage, from days 7 to 21, the patient typically remains asymptomatic while the bacteria multiply within the infected macrophages. The third stage is characterized by the onset of cell-mediated immunity (CD4+ helper T cells) and delayed-type hypersensitivity. Activated macrophages acquire an increased capacity for bacterial killing. Macrophage death increases, resulting in the formation of a granuloma, the characteristic lesion found on pathologic examination.

Tuberculous granulomas are composed of blood-derived macrophages, degenerating macrophages or epithelioid cells, and multinucleated giant cells (fused macrophages with nuclei around the periphery; also known as Langerhans cells). The low oxygen content of this environment inhibits macrophage function and bacillary growth, with subsequent central caseation as macrophage death occurs. A Ghon complex is a single, small lung lesion that is often the only remaining trace of a primary infection. The primary infection is usually located in the peripheral portion of the middle zone of the lungs.

Reactivation tuberculosis may occur after hydrolytic enzymes liquefy the caseum. Typically, the apical and posterior segments of the upper lobes and the superior segments of the lower lobes are involved. Edema, hemorrhage, and mononuclear cell infiltration are also present. The tuberculous cavity may become secondarily infected with other bacteria, fungi, or yeasts, all of which may contribute to enhanced tissue destruction.

The pathologic changes caused by NTM organisms are similar to those produced by *M tuberculosis*. *M intracellulare* complex infections commonly occur, not only in immunocompromised patients but also in patients with previously damaged lungs. Caseous necrosis is uncommon and is characterized by clusters of tissue macrophages filled with mycobacteria. It has a poor granulomatous response and confinement of immune cell infiltration to the interstitium and alveolar walls. Cavitative disease is infrequent, although nodules may be noted.
Clinical Presentation and Diagnosis. The clinical course of infection and the presentation of symptoms are influenced by many factors, including the site of primary infection, the stage of disease, and the degree of cell-mediated immunity. About 80% to 90% of tuberculosis patients present with clinical disease in the lungs. In 85% to 90% of these patients, involution and healing occur, leading to a dormant phase that may last a lifetime. The only evidence of tuberculosis infection may be a positive skin reaction to tuberculin challenge or a Ghon complex observed on CXR. Within the first 2 years of primary infection, reactivation may occur in up to 10% to 15% of infected patients. In 80%, reactivation occurs in the lungs; other reactivation sites include the lymph nodes, pleura, and the musculoskeletal system.

After primary infection, pulmonary tuberculosis is frequently asymptomatic. Systemic symptoms of low-grade fever, malaise, and weight loss are subtle and may go unnoticed. A productive cough may develop, usually after tubercle cavitation. Many radiographic patterns can be identified at this stage, including local exudative lesions, local fibrotic lesions, cavitation, bronchial wall involvement, acute tuberculous pneumonia, bronchiectasis, bronchostenosis, and tuberculous granulomas. Hemoptysis often develops from complications of disease such as bronchiectasis or erosion into vascular malformations associated with cavitation.

Extrapulmonary involvement is due to hematogenous or lymphatic spread from pulmonary lesions. Virtually any organ can become infected, giving rise to the protean manifestations of tuberculosis. The pleura, chest wall, and mediastinal organs may all be involved. More than one-third of immunocompromised patients have disseminated disease, with hepatomegaly, diarrhea, splenomegaly, and abdominal pain.

The definitive diagnosis of tuberculosis requires identification of the mycobacterium in a patient’s bodily fluids or involved tissues. Skin testing using purified protein derivative is important for epidemiologic purposes and can help exclude infection in uncomplicated cases. For pulmonary tuberculosis, sputum examination is inexpensive and has a high diagnostic yield.

Bronchoscopy with alveolar lavage may also be a useful diagnostic adjunct and has high diagnostic accuracy. Chest CT scan can delineate the extent of parenchymal disease.

Management. Medical therapy is the primary treatment of pulmonary tuberculosis and is often initiated before a mycobacterial pathogen is definitively identified. Combinations of two or more drugs are routinely used in order to minimize resistance, which inevitably develops with only single-agent therapy. A current treatment algorithm is outlined in Fig. 19-32. Generally, therapy lasts about 26 weeks (2 months intensive therapy followed by 4 months continuation therapy). A 7-month continuation phase should be considered for patients with cavitary pulmonary TB who remain positive on sputum culture after the 2-month intensive therapy, those patients who did not receive pyrazinamide during the intensive phase, HIV-positive patients who did not receive concomitant antiretroviral therapy, and patients treated with INH and rifapentine once weekly (not recommended) who have persistent positive sputum after 2 months of intensive therapy.

In the United States, surgical intervention is most often required in order to treat patients with MDR/RR-TB organisms whose lungs have been destroyed and who have persistent thick-walled cavitation. The indications for surgery related to mycobacterial pulmonary infections are presented in Table 19-19. The governing principle of mycobacterial surgery is to remove all gross disease while preserving any uninvolved lung tissue. Scattered nodular disease may be left intact, given its low mycobacterial burden. Antimycobacterial medications should be given preoperatively (for about 3 months) and continued postoperatively for 12 to 24 months. Overall, more than 90% of patients who were deemed good surgical candidates are cured when appropriate medical and surgical therapy is used.

Pulmonary Fungal Infections. The incidence of fungal infections has increased significantly, with many new opportunistic fungi emerging. This increase is attributed to the growing population of immunocompromised patients (e.g., organ transplant recipients, cancer patients undergoing chemotherapy, HIV patients, and young and elderly patients) who are more likely to become infected with fungi. Clinically significant examples include species of Aspergillus, Cryptococcus, Candida, and Blastomyces. Other at-risk patient populations include those who are malnourished, severely debilitated, or diabetic or who have hematologic disorders.

Patients receiving high-dose, intensive antibiotic therapies are also susceptible. There are, however, some fungi that are primary or true pathogens, able to cause infections in otherwise healthy patients. Some endemic examples in the United States include species of Histoplasma, Coccidioides, and Blastomyces.

Direct identification of the organism in body exudates or tissues, preferably as growth in culture, provides definitive diagnosis. Serologic testing to identify mycotic-specific antibodies may also be useful. Several new classes of antifungal agents have proven effective against many life-threatening fungi and are less toxic than older agents. In addition, thoracic surgery may be a useful therapeutic adjunct for patients with pulmonary mycoses.

Aspergillus. The genus Aspergillus comprises over 150 species and is the most common cause of mortality due to invasive mycoses in the United States. It is typically acute in onset and life-threatening and occurs in the setting of neutropenia, chronic steroid therapy, or cytotoxic chemotherapy. It can also occur in the general intensive care unit population of critically ill patients, including patients with underlying chronic obstructive pulmonary disease (COPD), postoperative patients, patients with cirrhosis or alcoholism, and postinfluenza patients, without any of these factors present. The species most commonly responsible for clinical disease include A fumigatus, A flavus, A niger, and A terreus. Aspergillus is a saprophytic, filamentous fungus with septate hyphae. Spores (2.5 to 3 µm in diameter) are released and easily inhaled by susceptible patients; because the spores are microns in size, they are able to reach the distal bronchi and alveoli.

Diagnosis of aspergillosis requires one or more cavities on lung imaging, with or without fungal ball or nodules, microscopy or culture positive for Aspergillus, or antibodies (precipitins) to Aspergillus on serum testing. The characteristics must have been present for 3 months. Aspergillus can manifest as one of three clinical syndromes: Aspergillus hypersensitivity lung disease, aspergillosis, or invasive pulmonary aspergillosis. Overlap occurs between these syndromes, depending on the patient’s immune status. Aspergillus hypersensitivity manifests as a productive cough, fever, wheezing, pulmonary infiltrates, eosinophilia, and elevation of IgE antibodies.
Figure 19-32. Treatment algorithm for tuberculosis. Patients in whom tuberculosis is proven or strongly suspected should have treatment initiated with isoniazid (INH), rifampin (RIF), pyrazinamide (PZA), and ethambutol (EMB) for the initial 2 months. A repeat smear and culture should be performed when 2 months of treatment has been completed. If cavities were seen on the initial chest radiograph (CXR) or the acid-fast bacillus (AFB) smear results are positive at completion of 2 months of treatment, the continuation phase of treatment should consist of INH and RIF daily or twice daily for 4 months to complete a total of 6 months of treatment. If cavitation was present on the initial CXR and the culture results at the time of completion of 2 months of therapy are positive, the continuation phase should be lengthened to 7 months (total of 9 months of treatment). If the patient has HIV infection and the CD4+ cell count is <100/µL, the continuation phase should consist of daily or three times weekly INH and RIF. In HIV-uninfected patients with no cavitation on CXR and negative results on AFB smears at completion of 2 months of treatment, the continuation phase may consist of either once weekly INH and rifapentine (RPT) or daily or twice weekly INH and RIF to complete a total of 6 months of treatment (bottom). For patients receiving INH and RPT whose 2-month culture results are positive, treatment should be extended by an additional 3 months (total of 9 months). EMB may be discontinued when results of drug susceptibility testing indicate no drug resistance. PZA may be discontinued after it has been taken for 2 months (56 doses). RPT should not be used in HIV-infected patients with tuberculosis or in patients with extrapulmonary tuberculosis. Therapy should be extended to 9 months if results of 2-month culture are positive. (Reproduced with permission from Blumberg HM, Burman WJ, Chaisson RE, et al. American Thoracic Society/Centers for Disease Control and Prevention/Infectious Diseases Society of America: treatment of tuberculosis, Am J Respir Crit Care Med. 2003 Feb 15;167(4):603-662.)

Table 19-19

Indications for surgery to treat mycobacterial pulmonary infections

1. Complications resulting from previous thoracic surgery to treat tuberculosis
2. Failure of optimized medical therapy (e.g., progressive disease, lung gangrene, or intracavitary aspergillosis superinfection)
3. Need for tissue acquisition for definitive diagnosis
4. Complications of pulmonary scarring (e.g., massive hemoptysis, cavernomas, bronchiectasis, or bronchostenosis)
5. Extrapulmonary thoracic involvement
6. Pleural tuberculosis
7. Nontuberculous mycobacterial infection

to Aspergillus, whereas aspergilloma (fungal ball) is a matted sphere of hyphae, fibrin, and inflammatory cells that tends to colonize preexisting intrapulmonary cavities. Grossly, aspergilloma appears as a round or oval, friable, gray (or red, brown, or even yellow), necrotic-looking mass (Fig. 19-33). This form is the most common presentation of noninvasive pulmonary aspergillosis. The most common symptoms are hemoptysis, chronic and productive cough, clubbing, malaise, or weight loss. CXR can suggest the diagnosis by the finding of a crescentic radiolucency above a rounded radiopaque lesion (Monad sign).

The natural history varies greatly between patients and, therefore, treatment is individualized. Factors associated with poor prognosis include severe underlying pulmonary disease, growth in the number or size of the aspergilloma(s) during observation, immunosuppression or HIV infection, history of lung transplantation, chronic pulmonary sarcoidosis, and increasing Aspergillus-specific IgG titers.
Asymptomatic patients can be observed without any additional therapy. Antifungals have limited utility due to the poor blood supply to the aspergilloma. Oral triazole therapy is now considered the standard of care for chronic, cavitary pulmonary aspergillosis. Hemoptysis is a harbinger of erosion of the disease into adjacent bronchial arteries and typically requires intervention. In the setting of very mild hemoptysis (e.g., blood-streaked sputum), cough suppression is warranted while further therapeutic evaluation is performed.

Bronchial artery embolization is the first-line therapy for massive hemoptysis and may be definitive therapy.\textsuperscript{105} This is particularly important to consider for patients with severely impaired pulmonary function who may not have sufficient reserve to tolerate even a very small pulmonary resection. Operative intervention may be required for recurrent hemoptysis, particularly after bronchial artery embolization, chronic cough with systemic symptoms, progressive infiltrate around the mycetoma, and a pulmonary mass of unknown cause.\textsuperscript{106}

When operative intervention is indicated, the surgeon must remain cognizant of the goals of the procedure. In the setting of simple aspergilloma, VATs wedge resection is preferred. As this disease typically occurs in patients with significantly impaired pulmonary function, attempts should be made to excise all diseased tissue with as limited a resection as possible. Once resection is completed, the postresection space in the hemithorax should be obliterated with a pleural tent, pneumoperitoneum, decortication of the remaining lung, intrathoracic rotation of a muscle or omental flap, or thoracoplasty. If completely resected for single aspergilloma, antifungal therapy is not needed. If multiple nodules are present or the disease is incompletely resected, however, antifungal therapy should be considered. Long-term follow-up is necessary, given that the recurrence rate after surgery is about 7%. 

\textbf{Figure 19-33.} Pulmonary aspergilloma. \textbf{A.} The chest X-ray shows a solid mass within a cavity surrounded by a rim of air between the mass and cavity wall (Monad sign, arrows). \textbf{B.} A cut section shows the “fungus ball” occupying an old, fibrotic cavity. \textbf{C.} Histologic stain reveals characteristic \textit{Aspergillus} hyphae invading the wall of the cavity.
Invasive pulmonary aspergillosis typically affects immunocompromised patients who have dysfunctional cellular immunity, namely defective polymorphonuclear leukocytes. Invasion of pulmonary parenchyma and blood vessels by a necrotizing bronchopneumonia may be complicated by thrombosis, hemorrhage, and then dissemination. Patients present with fever that is nonresponsive to antibiotic therapy in the setting of neutropenia. They may also have pleuritic chest pain, cough, dyspnea, or hemoptysis. Characteristic signs on CT scan include the halo sign and cavitary lesions. Treatment with voriconazole must be prompt and aggressive, including reversal of neutropenia, if there is to be any chance for recovery. Mortality ranges from 93% to 100% in bone marrow transplant recipients, to approximately 38% in kidney transplant recipients, although this improves to approximately 60% at 12 weeks with antifungal therapy. Several other advances in diagnosis and treatment, including CT scans in high-risk populations and development of additional triazoles and echinocandins, have improved the early identification and response to therapy in this patient population. Additional treatment considerations include the use of hematopoietic growth factors to minimize the neutropenic period, which contributes to uncontrolled disease. Surgical removal of the infectious nidus is advocated by some groups because medical treatment has such poor outcomes. Treatment continues until microbiologic clearance is achieved and clinical signs and radiographic imaging indicate resolution of disease. In addition, the patient should no longer be immunosuppressed. If continuation of immunosuppressive medications is required, antifungal therapy should also continue to prevent recurrence of invasive disease.

Cryptococcosis

Cryptococcosis is a subacute or chronic infection caused by Cryptococcus neoformans, a round, budding yeast (5 to 20 μm in diameter) that is sometimes surrounded by a characteristic wide gelatinous capsule. Cryptococci are typically present in soil and dust contaminated by pigeon droppings. When inhaled, such droppings can cause a nonfatal disease primarily affecting the pulmonary and central nervous systems. At present, cryptococcosis is one of the most common opportunistic infections in patients with HIV infection, affecting ~3% of that population. Four basic pathologic patterns are seen in the lungs of infected patients: granulomas; granulomatous pneumonia; diffuse alveolar or interstitial involvement; and proliferation of fungi in alveoli and lung vasculature. Symptoms are nonspecific, as are the radiographic findings. Cryptococcus neoformans may be isolated from sputum, bronchial washings, percutaneous needle aspiration of the lung, or cerebrospinal fluid. If disease is suspected, serum cryptococcal antigen tilters should be obtained; if positive or if the patient has persistent fever, evidence of progression, physiologic compromise, or dissemination, treatment should be promptly initiated. According to the CDC, multiple antifungal agents are effective against C neoformans; asymptomatic infections, such as those identified through targeted screening, should be treated with fluconazole while severe lung infections require amphotericin B combined with flucytosine followed by fluconazole for an extended length of time. Duration of therapy is longer in patients who are immunocompromised.

Candidiasis

Candida organisms are oval, budding cells (with or without mycelial elements) that colonize the oropharynx of many healthy individuals. The fungi of this genus are common hospital and laboratory contaminants. Usually, Candida albicans causes disease in the oral or bronchial mucosa, among other anatomic sites. Approximately 95% of all invasive Candida infections are caused by five species: C albicans, C tropicalis, C parapsilosis, C glabrata, and C krusei. The specific pathogen varies between patient populations and geographic regions. Non-C albicans infections now constitute nearly 70% of all cases in the United States, with C glabrata leading the list. Resistance to fluconazole is common in the non-C albicans species, either natural or developed in response to antifungal therapy, and the shift is likely related to the widespread use of this antifungal agent.

The incidence of Candida infections has increased and is no longer confined to immunocompromised patients. Increasing incidence of infection has been identified in patients with any of the following risk factors: critical illness of long duration; use of long-term antibiotics, particularly multiple; indwelling urinary or vascular catheter; gastrointestinal perforation; or burn wounds. With respect to the thorax, such patients commonly have candidial pneumonia, pulmonary abscess, esophagitis, and mediastinitis. Pulmonary candidal infections typically result in an acute or chronic granulomatous reaction. Because Candida can invade blood vessel walls and a variety of tissues, systemic or disseminated infections can occur, but are less common.

Treatment for candidal infection includes both fungicidal and fungistatic agents. The fungicidal medications include polyenes (amphotericin B deoxycholate [AmB-D] and various lipid-associated amphotericin B preparations) and the echinocandins (caspofungin, micafungin, and anidulafungin). Fungistatic drugs include the triazoles (fluconazole, itraconazole, voriconazole, and posaconazole). The availability of multiple effective therapies allows for specific tailoring of treatment, including combination regimens, based on the patient’s ability to tolerate associated toxicities, the microbiologic information for the specific candidal species, and the route of administration. While demonstrated efficacy is similar, the triazoles and echinocandins appear to have fewer side effects and are better tolerated than the other classes of antifungal drugs. The current initial recommended regimen for adults with invasive candidiasis is an echinocandin.

In addition to prompt institution of antifungal therapy, it is advisable to remove all central venous catheters as soon as can be safely achieved. For fungemia, an eye examination should be performed. Treatment should continue for at least 2 weeks after the last positive blood culture. For patients with Candida mediastinitis (which has a mortality rate of >50%), surgical intervention to debride all infected tissues is required, in addition to prolonged administration of antifungal drugs.

Mucormycosis

The Mucor species, rare members of the class Zygomycetes, are responsible for rapidly fatal disease in immunocompromised patients. Other disease-causing species of the class Zygomycetes include Absidia, Rhizopus, and Mortierella. Characteristic of these fungi are nonseptate, branching hyphae that are difficult to culture. Infection occurs via inhalation of spores. Immunocompromised patients, including patients with neutropenia, acidosis, diabetes, and hematologic malignancy all predispose to clinical susceptibility. In the lungs, disease consists of blood vessel invasion, thrombosis, and infarction of infected organs.

Tissue destruction is significant, along with cavitation and abscess formation. Initial treatment is to correct underlying risk factors and administer antifungal therapies, although
the optimal duration and optimal total dose are unknown. Lipid formulations of amphotericin B are recommended at this time. Surgical resection of any localized disease should be performed after initial medical treatment attempts fail.

**Primary Fungal Pathogens**

*Histoplasma capsulatum* is a dimorphic fungus existing in mycelial form in soil contaminated by fowl or bat excreta and in yeast form in human hosts. The most common of all fungal pulmonary infections, histoplasmosis, primarily affects the respiratory system after spores are inhaled. It is endemic in the Midwest and Mississippi River Valley of the United States, where about 500,000 new cases arise each year. In immunocompromised patients, the infection becomes systemic and more virulent; because cell-mediated immunity is impaired, uninhibited fungal proliferation occurs within pulmonary macrophages and then spreads. Acute forms of the disease present as primary or disseminated pulmonary histoplasmosis; chronic forms present as pulmonary granulomas (*histoplasmosis*), chronic cavitary histoplasmosis, mediastinal granulomas, fibrosing mediastinitis, or bronchiolithiasis. Histoplasmosis is definitively diagnosed by fungal smear, culture, direct biopsy of infected tissues, or serologic testing.

The clinical presentation depends on the inoculum size and on host factors.

Symptoms of acute pulmonary histoplasmosis are fever, chills, headache, chest pain, musculoskeletal pain, and nonproductive cough. CXRs may be normal or may show mediastinal lymphadenopathy and patchy parenchymal infiltrates. Most patients improve in a few weeks; mild to moderate disease can be treated with itraconazole. Amphotericin B is the treatment of choice if moderate symptoms persist for 2 to 4 weeks or if the illness is extensive, including dyspnea and hypoxia, and if patients are immunosuppressed.110

As the pulmonary infiltrates from acute histoplasmosis heal, consolidation into an asymptomatic solitary nodule or histoplasmosma may occur and is usually seen incidentally on radiographs as a coin-shaped lesion. Central and concentric calcification may occur; if so, no further treatment is required. Noncalcification of the lesion requires further diagnostic workup including chest CT scan, needle biopsy, or surgical excision to rule out a malignancy. Figure 19-34 demonstrates the differences in pathologic findings between infections in normal and immunocompromised hosts.111

When lymph nodes and pulmonary granulomas calcify over time, pressure atrophy on the bronchial wall may result in erosion and migration of the granulomatous mass into the bronchus, causing bronchiolithiasis. Typical symptoms include cough, hemoptysis, and dyspnea. Life-threatening complications include massive hemoptysis or bronchoesophageal fistula. In addition to radiography, bronchoscopy should be performed to aid in diagnosis. Definitive treatment requires surgical excision of the bronchial mass and repair of the airway and contiguous structures. Endobronchial debridement is not advised as this can result in massive, fatal bleeding.

Fibrosing mediastinitis is an uncommon manifestation of histoplasmosis but can be fatal due to progressive distortion and compression of the major vessels and central airways.

Diagnosis can be difficult, and symptoms may be present for extended periods, even years, before the diagnosis is made. The differential diagnosis for the disease process includes granulomatous mediastinitis related to recent infection, malignancy, and chronic pulmonary thromboembolism. A trial of itraconazole is worthwhile, although it is not proven to be effective. In cases where radiographic or physiologic improvement is achieved after a trial of 12 week of therapy, continuation of therapy is considered for a full 12 months. In the majority of patients, however, antifungal therapy has not been proven. There is no role for corticosteroids at this time or for antifibrotics. Occasionally, intravascular stents have been helpful for severe vascular compromise. Balloon dilatation and endobronchial silicone stents may be needed for airway compromise, although this should be directed by a surgeon with expertise in mediastinal and airway disease management.

Chronic pulmonary histoplasmosis occurs in about 10% of patients who become symptomatic after infection. Most such patients have preexisting lung pathology, particularly emphysema, which becomes colonized, and subsequent pneumonitis and necrosis, cavity enlargement, new cavity formation, and pulmonary dissemination occur. Nonspecific symptoms, such as cough, sputum production, fever, weight loss, weakness, and hemoptysis are common. Chest radiography may reveal intrapulmonary cavitation and scarring. Occasionally, partial resolution of the inflammatory changes may be observed. Itraconazole provides effective therapy, but must be given for 12 to 24 months. It is superior to ketoconazole and fluconazole; these should only be used if itraconazole is not tolerated. Voriconazole and posaconazole have been found to be useful for salvage therapy. Serum itraconazole levels should be monitored to ensure the drug is being absorbed. Occasionally, lipid-associated amphotericin B is necessary for more severe infections. Surgical excision should be considered in patients patients with adequate pulmonary reserve and localized, thick-walled cavities that have been unresponsive to antifungal therapy.

Disseminated histoplasmosis occurs most frequently in patients who are severely immunocompromised, such as posttransplantation patients, patients with HIV, and patients using immunosuppressive medications. Presentation ranges from nonspecific signs of fever, weight loss, and malaise, to shock, respiratory distress, and multiorgan failure. Diagnosis can be made with a combination of *Histoplasma* urine antigen, serologic assay, and fungal culture and should be suspected in patients with the above symptoms in any endemic area, particularly if the patient is immunosuppressed.112 Any of the antifungal therapies can be used in treatment of disseminated histoplasmosis. Use of amphotericin B has decreased the mortality rate to less than 25% in this type of serious infection.

*Coccidioides immitis* is an endemic fungus found in soil and dust of the southwestern United States. Agricultural workers, military personnel, and other occupations with extensive exposure to soil, especially in areas of endemic growth, are at highest risk, as are immunocompromised individuals.113 Spores (arthroconidia) are inhaled, swell into spherules, and subdivide into endospores, and subsequent infection develops. Diagnosis can be achieved through serum analysis for antecoccidioidal antibody, spherule identification in tissue, or by isolating the fungus in cultures from sputum, other body fluid, or tissue.

Inhalation of the fungus causes pulmonary involvement in 95% of patients with symptomatic disease. Three main categories of pulmonary involvement, based on the associated signs and symptoms, are possible: primary, complicated, and residual pulmonary coccidioidomycosis. Primary pulmonary
Figure 19-34. Pathologic findings of infection in normal and immunocompromised hosts. Histopathologic preparations are shown contrast- ing acute diffuse pulmonary involvement in a lung segment of a normal host with a probable primary infection (A through D) with pulmonary granulomas from an immunocompromised patient who had an opportunistic reinfection with *Histoplasma capsulatum* (E, F). A. Diffuse interstitial pneumonitis in an adult (normal host) with recent heavy environmental exposure and subsequent development of progressive pulmonary disease. There is an inflammatory cell infiltrate primarily involving the interalveolar interstitial spaces but present within many alveolar spaces as well. The exudate consists mostly of mononuclear phagocytes, lymphocytes, and occasional plasma cells. Many of the alveolar walls are markedly thickened (hematoxylin and eosin stain [H&E], ×50). B. Another area from the same lung as in A showing focal vasculitis with an infiltrate of lymphocytes and macrophages (H&E, ×25). C. Relatively large alveolar macrophages packed with single and budding yeasts 2 to 4 µm in diameter (same lung as in A and B). The basophilic cytoplasm of these yeasts is retracted from their thin outer cell walls, leaving halo-like clear areas that can be confused with capsules (H&E, ×500). D. Intracellular and extracellular yeasts, 2 to 4 µm in diameter, some of which are single, budding, or in short chains (Gomori methenamine silver stain, ×500). E. Nonnecrotizing (sometimes called epithelioid cell or noncaseating) granuloma from a patient who had recently received chemotherapy for a germ cell tumor (different patient than in A through D). This lesion consists of a focal collection of macrophages (sometimes referred to as histiocytes or epithelioid cells) plus lymphocytes and occasional plasma cells. A few multinucleated macrophages are present. A thin layer of fibroblasts circumscribes the lesion. Yeasts of *H capsulatum*, probably present within macrophages of this lesion at an earlier stage, were not identified in this granuloma or in any of several other nonnecrotizing granulomas within the specimen. Lesions of this type often undergo necrosis to become necrotizing granulomas (H&E, ×50). F. Necrotizing (sometimes referred to as caseating) granuloma from the same lung as in E. This lesion has a necrotic center surrounded by macrophages, encapsulating fibroblasts, fibrous connective tissue in the periphery, and scattered lymphocytes. A prominent giant cell is present in the lower left of the granuloma (at approximately 8 o’clock). Microorganisms are usually present only in relatively small numbers in these types of lesions. They are most frequently detected within the most central necrotic material in these granulomas (H&E, ×25). (Reproduced with permission from Hage CA, Wheat LJ, Loyd J, et al: Pulmonary histoplasmosis, Semin Respir Crit Care Med. 2008 Apr;29(2):151-165.)
coccidioidomycosis occurs in about 40% of people who inhale spores. The other 60% will remain asymptomatic and develop life-long immunity. The constellation of symptoms of “valley fever,” including fever, chills, headache, erythema multiforme, erythema nodosum, polyarthralgias, nonproductive cough, and chest pain, and a CXR showing hiliar and paratracheal adenopathy are highly suggestive of pulmonary coccidioidomycosis. In many patients, initial diagnosis is community-acquired pneumonia, and it is only when the patient fails to respond to appropriate antibiotic therapy that pulmonary coccidioidomycosis is considered. The disease is self-limited in the majority of patients, and treatment is not required in these cases.

Therapy should be considered for (a) patients with impaired cellular immunity; (b) comorbid illnesses that are adversely impacted by the infection, including chronic pulmonary dysfunction, renal failure, and congestive heart failure; and (c) when symptoms and radiographic findings persist for more than 6 to 8 weeks, at which time the disease is considered to be persistent coccidioidal pneumonia and occurs in approximately 1% of patients. Progression to caseous nodules, cavities, and calcified, fibrotic, or ossified lesions indicates complicated or residual stages of coccidioidomycosis.

There are several relative indications for surgery in pulmonary coccidioidomycosis. A rapidly expanding (>4 cm) cavity that is close to the visceral pleura is a high risk for rupture into the pleural space and subsequent empyema. Other indications for operative intervention include life-threatening hemoptysis; hemoptysis that is persistent despite medical therapy; symptomatic fungus ball; bronchopleural fistula; cavitory lesions with persistent positive sputum; and pulmonary nodules that degenerate over time. Finally, any nodule with signs that are concerning for malignancy should undergo further evaluation, including biopsy or resection, to determine the underlying etiology.

Diagnosis of coccidioidomycosis is confirmed by histopathologic, mycologic, and serologic evaluation. Extrapulmonary disease may develop in approximately 0.5% of infected patients, with involvement of meninges, bones, joints, skin, or soft tissues. Immunocompromised patients are especially susceptible to disseminated coccidioidomycosis, which carries a mortality rate over 40%. Treatment options for this disease vary depending on the severity of the disease as well as the stage. Amphotericin B deoxycholate or the triazoles continue to be the primary antifungal medications. If meningeal involvement is identified, flucytosine or itraconazole therapy is required for the remainder of the patient’s life. Intrathecal amphotericin B can also be administered in some cases.

*Blastomyces dermatitidis* Blastomyces dermatitidis is a round, single-budding yeast with a characteristic thick, refractile cell wall. It resides in the soil as a nonmotive spore called conidia. Exposure occurs when contaminated soil is disturbed and the conidia are aerosolized. The spore is inhaled and transforms into a yeast phase at body temperature. Infection is typically self-limited. A small minority of patients will develop chronic pulmonary infection or disseminated disease, including cutaneous, osteoarticular, and genitourinary involvement. *B dermatitidis* has a worldwide distribution; in the United States, it is endemic in the central states. With chronic infection, the organism induces a granulomatous and pyogenic reaction with microabscesses and giant cells; caseation, cavitation, and fibrosis may also occur. Symptoms are nonspecific and consistent with chronic pneumonia in 60% to 90% of patients. They include cough, mucoid sputum production, chest pain, fever, malaise, weight loss, and, uncommonly, hemoptysis. In acute disease, radiographs are either completely negative or have nonspecific findings; in chronic disease, fibronodular lesions (with or without cavitation) similar to tuberculosis are noted. Pulmonary parenchymal abnormalities in the upper lobe(s) may be noted. Mass lesions similar to carcinoma are frequent, and lung biopsy is frequently used. Over 50% of patients with chronic blastomycosis also have extrapulmonary manifestations, but less than 10% of patients present with severe clinical manifestation.

Once a patient manifests symptoms of chronic blastomycosis, antifungal treatment is required to achieve resolution. Mortality approaches 60% if untreated. While controversial, a short course of triazole therapy (oral itraconazole 200 mg daily) for 6 months is the treatment of choice for most patients with mild to moderate forms of the disease. Because itraconazole has poor CNS penetration, the most common site of recurrence after apparently successful therapy is in the CNS. In the absence of therapy, close follow-up is warranted for evidence of progression to chronic or extrapulmonary disease. Amphotericin B is warranted for patients with severe or life-threatening disease, CNS involvement, disseminated disease, or extensive lung involvement and in immunocompromised patients. After adequate drug therapy, surgical resection of known cavitary lesions should be considered because viable organisms are known to persist in such lesions.

**Massive Hemoptysis**

Massive hemoptysis is generally defined as expectoration of over 600 mL of blood within a 24-hour period. It is a medical emergency associated with a mortality rate of 30% to 50%. Most clinicians would agree that losing over a liter of blood via the airway within 1 day is significant, yet use of an absolute volume criterion presents difficulties. First, it is difficult for the patient or caregivers to quantify the volume of blood being lost. Second, and most relevant, the rate of bleeding necessary to incite respiratory compromise is highly dependent on the individual’s prior respiratory status. For example, the loss of 100 mL of blood over 24 hours is significant, yet use of an absolute volume criterion presents difficulties. First, it is difficult for the patient or caregivers to quantify the volume of blood being lost. Second, and most relevant, the rate of bleeding necessary to incite respiratory compromise is highly dependent on the individual’s prior respiratory status.

Anatomy. The lungs have two sources of blood supply: the pulmonary and bronchial arterial systems. The pulmonary system is a high-compliance, low-pressure system, and the walls of the pulmonary arteries are very thin and delicate. The bronchial arteries, part of the systemic circulation, have systemic pressures and thick walls; most branches originate from the proximal thoracic aorta. Most cases of massive hemoptysis involve bleeding from the bronchial artery circulation or from the pulmonary circulation pathologically exposed to the high pressures of the bronchial circulation. In many cases of hemoptysis, particularly those due to inflammatory disorders, the bronchial arterial tree becomes hyperplastic and tortuous. The systemic pressures within these arteries, combined with a disease process within the airway and erosion, lead to bleeding.

**Causes.** Significant hemoptysis has many causes, most commonly including pulmonary, extrapulmonary, and iatrogenic. Table 19-20 summarizes the most common causes of hemoptysis. Most are secondary to inflammatory processes. Aneurysms

of the pulmonary artery (referred to as Rasmussen’s aneurysm) can develop within pulmonary cavities and can result in massive bleeding. Hemoptysis due to lung cancer is usually mild, resulting in blood-streaked sputum. Massive hemoptysis in patients with lung cancer is typically caused by malignant invasion of pulmonary artery vessels by large central tumors. Although rare, it is often a terminal event.

**Management.** Life-threatening hemoptysis is best managed by a multidisciplinary team of intensive care physicians, interventional radiologists, and thoracic surgeons. Treatment priorities begin with respiratory stabilization; intubation with isolation of the bleeding lung may be required to prevent asphyxiation. This can be done with main-stem intubation into the nonbleeding lung, endobronchial blockers into the bleeding lung, or double-lumen endotracheal intubation, depending on the urgency of the situation and the expertise of the providers. Once adequate ventilation has been achieved, the bleeding site should be localized; bronchoscopy can often provide direct visualization of blood coming from a specific area of the tracheobronchial anatomy. Control of the hemorrhage is then achieved endobronchially with laser or bronchial occlusion, endovascularly with bronchial and/or pulmonary artery embolization, or surgically with resection of the involved area. The order of priorities in management is detailed in Table 19-21.

The clinically pragmatic definition of massive hemoptysis is a degree of bleeding that threatens respiratory stability. Therefore, clinical judgment of respiratory compromise is the first step in evaluating a patient. Two scenarios are possible: (a) bleeding is significant and persistent, but its rate allows a rapid but sequential diagnostic and therapeutic approach, and (b) bleeding is so rapid that emergency airway control and therapy are necessary.

**Scenario 1: Significant, Persistent, but Nonmassive Bleeding**

Although bleeding is brisk in scenario 1, the patient may be able to maintain clearance of the blood and secretions with his or her own respiratory reflexes. Immediate measures are admission to an intensive care unit; strict bed rest; Trendelenburg positioning with the affected side down (if known); administration of humidified oxygen; cough suppression; monitoring of oxygen saturation and arterial blood gases; and insertion of large-bore intravenous catheters. Strict bed rest with sedation may lead to slowing or cessation of bleeding, and the judicious use of intravenous narcotics or other relaxants to mildly sedate the patient and diminish some of the reflexive airway activity is often necessary. Also recommended are administration of aerosolized adrenaline, intravenous antibiotic therapy if needed, and correction of abnormal blood coagulation study results. Finally, unless contraindicated, intravenous vasopressin (20 U over 15 minutes, followed by an infusion of 0.2 U/min) can be given.

A CXR is the first test and often proves to be the most revealing. Localized lesions may be seen, but the effects of blood soiling of other areas of the lungs may predominate, obscuring the area of pathology. Chest CT scan provides more detail and is nearly always performed if the patient is stable. Pathologic areas may be obscured by blood soiling.

Flexible bronchoscopy is the next step in evaluating the patient’s condition. Some clinicians argue that rigid bronchoscopy should always be performed. However, if the patient is clinically stable and the ongoing bleeding is not imminently threatening, flexible bronchoscopy is appropriate. It allows diagnosis of airway abnormalities and will usually permit
localization of the bleeding site to either a lobe or even a segment. The person performing the bronchoscopy must be prepared with excellent suction and must be able to perform saline lavage with a dilute solution of epinephrine.

Most cases of massive hemoptysis arise from the bronchial arterial tree; therefore, the next therapeutic option frequently is selective bronchial arteriography and embolization.

Prearteriogram bronchoscopy is extremely useful to direct the angiographer. However, if bronchoscopy fails to localize the bleeding site, then bilateral bronchial arteriograms can be performed. More recently, use of multidetector CT angiography in patients with hemoptysis that is not immediately life-threatening has been shown to facilitate endovascular intervention; reformatting of the images in multiple projections allows clear delineation of the pulmonary vascular anatomy. With this approach, abnormal bronchial and nonbronchial arteries can be visualized and subsequently targeted for therapeutic arterial embolization. Once the targeted arterial system has been embolized, immediate control and cessation of the hemoptysis is achieved in more than 80% of patients. If bleeding persists after bronchial artery embolization, a pulmonary artery source should be suspected and a pulmonary angiogram performed at the same setting.

Recurrence is seen in 30% to 60% of cases and is very common in the setting of invasive fungal infections such as aspergilloma. Recurrence after bronchial artery embolization is less common in the setting of malignancy and active tuberculosis but does occur and can ultimately result in patient death. Repeat embolization can be effective and is warranted for initial management of recurrent hemoptysis, but early surgical intervention should be considered, particularly in the setting of aspergilloma or other cavitary lesions.

If respiratory compromise is impending, orotracheal intubation should be performed. After intubation, flexible bronchoscopy should be performed to clear blood and secretions and to attempt localization of the bleeding site. Depending on the possible causes of the bleeding, bronchial artery embolization or (if appropriate) surgery can be considered.

**Scenario 2: Significant, Persistent, and Massive Bleeding**

Life-threatening bleeding requires emergency airway control and preparation for potential surgery. Such patients are best cared for in an operating room equipped with rigid bronchoscopy. Immediate orotracheal intubation may be necessary to gain control of ventilation and suctioning. However, rapid transport to the operating room with rigid bronchoscopy should be facilitated. Rigid bronchoscopy allows adequate suctioning of bleeding with visualization of the bleeding site; the nonbleeding side can be cannulated with the rigid scope and the patient ventilated. After stabilization, ice-saline lavage of the bleeding site can then be performed (up to 1 L in 50-mL aliquots); bleeding stops in up to 90% of patients.

Alternatively, blockade of the main stem bronchus of the affected side can be accomplished with a double-lumen endotracheal tube, with a bronchial blocker, or by intubation of the nonaffected side by an uncut standard endotracheal tube. Placement of a double-lumen endotracheal tube is challenging in these circumstances, given the bleeding and secretions.

Proper placement and suctioning may be difficult, and attempts could compromise the patient’s ventilation. The best option is to place a bronchial blocker in the affected bronchus with inflation. Endovascular embolization can be performed to stop the bleeding after control has been achieved with the bronchial blocker. The blocker is left in place for 24 hours; after 24 hours, the area is reexamined bronchoscopically.

**Surgical Intervention.** In most patients, bleeding can be stopped, recovery can occur, and plans to definitively treat the underlying cause can be made. In scenario 1 (significant, persistent, but nonmassive bleeding), the patient may undergo further evaluation as an inpatient or outpatient. A chest CT scan and pulmonary function studies should be obtained preoperatively. In scenario 2 (patients with significant, persistent, and massive bleeding), surgery, if appropriate, will usually be performed during the same hospitalization as the rigid bronchoscopy or main stem bronchus blockade. In a small number of patients (<10%), immediate surgery will be necessary due to the extent of bleeding. The bleeding site in these patients is localized using rigid bronchoscopy with immediate thoracotomy or sternotomy to follow.

Surgical treatment is individualized according to the source of bleeding and the patient’s medical condition, prognosis, and pulmonary reserve. General indications for urgent surgery are presented in Table 19-22. In patients with significant cavitary disease or with fungus balls, the walls of the cavities are eroded and necrotic; rebleeding will likely ensue. In addition, bleeding from cavitary lesions may be due to pulmonary artery erosion, which requires surgery for control.

**End-Stage Lung Disease**

**Lung Volume Reduction Surgery.** The ideal patient for lung volume reduction surgery (LVRS) has heterogeneous emphysema with apical predominance, meaning the worst emphysematous changes are in the apex (seen on chest CT scan) of the lungs. The physiologic lack of function of these areas is demonstrated by quantitative perfusion scan, which shows minimal or no perfusion. By surgically excising these nonfunctional areas, the volume of the lung is reduced, theoretically restoring respiratory mechanics. Diaphragm position and function are improved, and there may be an improvement in the dynamic small airway collapse in the remaining lung.

Operative mortality in the initial experience was 16.9%, with a 1-year mortality of 23%. In response, the National Emphysema Treatment Trial (NETT) performed a randomized trial of 1218 patients in a noncrossover design to medical versus surgical management after a 10-week pretreatment pulmonary rehabilitation program. Subgroup analysis demonstrated that in patients with the anatomic changes delineated by Cooper and colleagues, LVRS significantly improved exercise capacity, lung function, quality of life, and dyspnea compared to medical therapy. After 2 years, functional improvements began to decline toward baseline. Similar parameters in medically treated patients steadily decline below baseline. LVRS was associated with increased short-term morbidity and mortality and did not confer a survival benefit over medical therapy.

Lung Transplantation. The most common indications for lung transplant are COPD and idiopathic pulmonary fibrosis (IPF). Most patients with IPF and older patients with COPD are offered a single-lung transplant. Younger COPD patients and patients with α1-antitrypsin deficiency and severe hyperinflation of the native lungs are offered a bilateral-lung transplant. Most patients with primary pulmonary hypertension and almost all patients with cystic fibrosis are treated with a bilateral-lung transplant. A heart-lung transplant is reserved for patients with irreversible ventricular failure or uncorrectable congenital cardiac disease.

Patients with COPD are considered for placement on the transplant waiting list when their FEV₁ has fallen to below 25% of its predicted value. Patients with significant pulmonary hypertension should be listed earlier. IPF patients should be referred when their forced vital capacity has fallen to less than 60% or their DLCO has fallen to less than 50% of their predicted values.

In the past, patients with primary pulmonary hypertension and New York Heart Association (NYHA) class III or IV symptoms were listed for a lung transplant. However, treatment of such patients with intravenous prostacyclin and other pulmonary vasodilators has now markedly altered that strategy. Virtually all patients with primary pulmonary hypertension are now treated with intravenous epoprostenol. Several of these patients have experienced a marked improvement in their symptoms associated with a decrease in their pulmonary arterial pressures and an increase in exercise capacity. Listing of these patients is deferred until they develop NYHA class III or IV symptoms or until their mean pulmonary artery pressure rises above 75 mmHg.

Medium-term and bronchiolitis obliterans syndrome (BOS)—free survival rates of patients who underwent a lung transplant at the University of Minnesota are shown in Figs. 19-35 and 19-36. The mortality of patients while waiting for transplants is about 10%. In an effort to expand the number of lung donors, many transplant groups have liberalized their criteria for donor selection. Still, the partial pressure of arterial oxygen (Pao₂) should be greater than 300 mmHg on a fraction of inspired oxygen (Fio₂) of 100%. In special circumstances, lungs may be used from donors with a smoking history; from donors older than 50 years of age; and from donors with positive Gram stains or infiltrates on CXR. The use of two living donors, each donating a single lower lobe, is another strategy for increasing the donor pool. Recipient outcomes are similar to those with cadaver donors in carefully selected patients.

Most of the early mortality after lung transplant is related to primary graft failure resulting from a severe ischemia-reperfusion injury to the lung(s) (Fig. 19-37). Reperfusion injury is characterized radiographically by interstitial and alveolar edema and clinically by hypoxia and ventilation-perfusion mismatch. Donor neutrophils and recipient lymphocytes probably play an important role in the pathogenesis of reperfusion injury. The most important impediment to longer-term survival after a lung transplant is the development of BOS, a manifestation of chronic rejection. Episodes of acute rejection are the major risk factors for developing BOS. Other injuries to the lung (including early reperfusion injury and chronic gastroesophageal reflux disease) may also adversely affect long-term outcomes of patients.

CHEST WALL

Chest Wall Mass

Clinical Approach. Surgeons confronted with a patient with a chest wall mass must be cognizant that their approach to diagnosis and treatment has significant impact on the patient’s chances.
for long-term survival. All chest wall tumors should be considered malignant until proven otherwise. It is critically important that the surgeon(s) be mindful of this tenet and well versed in the diagnostic and treatment principles for chest wall malignancies. These tenets must be applied from the initial biopsy, as the placement of the incision can impact significantly on the successful complete resection and reconstruction of the chest wall. Complete resection is imperative if there is any hope for cure and/or long-term survival. A general approach is outlined in Figs. 19-38 and 19-39.

Patients with chest wall tumors, regardless of etiology, typically complain of a slowly enlarging palpable mass (50% to 70%), chest wall pain (25% to 50%), or both. Interestingly, growing masses are often not noticed by the patient until they suffer a trauma to the area. Pain from a chest wall mass is typically localized to the area of the tumor; it occurs more often and more intensely with malignant tumors, but it can also be present in up to one-third of patients with benign tumors. With Ewing’s sarcoma, fever and malaise may also be present. Benign chest wall tumors tend to occur in younger patients (average age 26 years), whereas malignant tumors tend to be found in older patients (average age 40 years). Overall, between 50% and 80% of chest wall tumors are malignant.

**Evaluation and Management.** Laboratory evaluations are useful in assessing chest wall masses for the following:

1. **Plasmacytoma.** Serum protein electrophoresis demonstrates a single monoclonal spike, which is measuring the overproduction of one immunoglobulin from the malignant plasma cell clone.

2. **Osteosarcoma.** Alkaline phosphatase levels may be elevated.

3. **Ewing’s sarcoma.** Erythrocyte sedimentation rates may be elevated.

**Radiography** CXR may reveal rib destruction, calcification within the lesion, and if old films are available, a clue to growth rate. CT scanning, however, is necessary to determine the relationship of the chest wall mass to contiguous structures (e.g., mediastinum, lung, soft tissues, and other skeletal elements), evaluate for pulmonary metastases, and assess for extraosseous bone formation and bone destruction, both typically seen with osteosarcoma.

Because MRI provides multiple planes of imaging (coronal, sagittal, and oblique), better definition of the relationship between tumor and muscle, and tumor and contiguous or nearby neurovascular structures or the spine, it is an important radiographic adjunct for preoperative planning. Compared to CT scan alone, MRI may further delineate tissue abnormalities, potentially enhancing the ability to distinguish benign from malignant sarcoma.

**Biopsy** The first step in the management of all chest wall tumors is to obtain a tissue diagnosis. Inappropriate or misguided attempts at tissue diagnosis through casual open biopsy techniques have the potential (if the lesion is a sarcoma) to seed surrounding tissues and contiguous body cavities (e.g., the pleural space) with tumor cells, potentially compromising local

---

**Figure 19-38.** Systematic approach for evaluating a chest wall mass when the clinical scenario is uncomplicated and initial imaging studies suggest a clear diagnosis. CT = computed tomography; MRI = magnetic resonance imaging.

**Figure 19-39.** Systematic approach for evaluating a chest wall mass for which the diagnosis is not unequivocal. A tissue diagnosis is critical for effective management of chest wall masses. CT = computed tomography; MRI = magnetic resonance imaging; PNET = primitive neuroectodermal tumor.
tumor control and patient survival. Tissue diagnosis is accomplished using one of three methods: needle biopsy (typically CT-guided, FNA, or a core biopsy), incisional biopsy, or excisional biopsy in limited and specific situations.

1. Needle biopsy. Pathologists experienced with sarcomas can accurately diagnose approximately 90% of patients using FNA cytology. A needle biopsy (FNA or core) has the advantage of avoiding wound and body cavity contamination (a potential complication with an incisional biopsy).

2. Incisional biopsy. If a needle biopsy is nondiagnostic, an incisional biopsy may be performed, with caveats. First, the skin incision must be placed directly over the mass and oriented to allow subsequent scar excision and skin flaps, and drains should be avoided. If the surgeon believes a hematoma is likely to develop, a drain is useful for limiting soft tissue contamination by tumor cells. At the time of definitive surgical resection, the en bloc resection includes the biopsy scar and the drain tract along with the tumor.

3. Excisional biopsy. Any lesion less than 2.0 cm can be excised as long as the resulting wound is small enough to close primarily. Otherwise, excisional biopsy is performed only when the initial diagnosis (based on radiographic evaluation) indicates that the lesion is benign or when the lesion has the classic appearance of a chondrosarcoma (in which case, definitive surgical resection can be undertaken).

**Benign Chest Wall Neoplasms**

1. Chondroma. Chondromas, seen primarily in children and young adults, are one of the more common benign tumors of the chest wall. They usually occur at the costochondral junction anteriorly and may be confused with costochondritis, except that a painless mass is present. Radiographically, the lesion is lobulated and radiodense; it may have diffuse or focal calcifications; and it may displace the bony cortex without penetration. Chondromas may grow to huge sizes if left untreated. Treatment is surgical resection with a 2-cm margin. Large chondromas may harbor well-differentiated chondrosarcoma and should be managed with a 4-cm margin to prevent local recurrence.

2. Fibrous dysplasia. As with chondromas, fibrous dysplasia most frequently occurs in young adults and may be associated with trauma. Pain is an infrequent complaint, and the lesion is typically located in the posterolateral aspect of the rib cage. Radiographically, an expansile mass is present, with cortical thinning and no calcification. Local excision with a 2-cm margin is curative.

3. Osteochondroma. Osteochondromas, often found incidentally as a solitary lesion on radiograph, are the most common benign bone tumor. Osteochondromas occur in the first two decades of life, and they arise at or near the growth plate of bones. Osteochondromas in the thorax arise from the rib cortex. They are one of several components to the autosomal dominant syndrome, hereditary multiple exostoses. When part of this syndrome, osteochondromas have a high rate of degeneration into chondrosarcomas. Any patient with hereditary multiple exostoses syndrome who develops new pain at the site of an osteochondroma or who notes gradual growth in the mass over time should be carefully evaluated for osteosarcoma. Local excision of a benign osteochondroma is sufficient. If malignancy is determined, wide excision is performed with a 4-cm margin.

4. Eosinophilic granuloma. Eosinophilic granulomas are benign osteolytic lesions. Eosinophilic granulomas of the ribs can occur as solitary lesions or as part of a more generalized disease process of the lymphoreticular system termed Langerhans cell histiocytosis (LCH). In LCH, the involved tissue is infiltrated with large numbers of histiocytes (similar to Langerhans cells seen in skin and other epithelia), which are often organized as granulomas. The cause is unknown. Of all LCH bone lesions, 79% are solitary eosinophilic granulomas, 7% involve multiple eosinophilic granulomas, and 14% belong to other forms of more systemic LCH. Isolated single eosinophilic granulomas can occur in the ribs or skull, pelvis, mandible, humerus, and other sites. They are diagnosed primarily in children between the ages of 5 and 15 years. Because of the associated pain and tenderness, they may be confused with Ewing’s sarcoma or with an inflammatory process such as osteomyelitis. Healing may occur spontaneously, but the typical treatment is limited surgical resection with a 2-cm margin.

5. Desmoid tumors. Soft tissue neoplasms arising from fascial or musculopaponeurotic structures, desmoid tumors consist of proliferations of benign-appearing fibroblastic cells, abundant collagen, and few mitoses. Desmoid tumors possess alterations in the adenomatous polyposis coli (APC)/β-catenin pathway. Cyclin D1 dysregulation is thought to play a significant role in their pathogenesis. Associations with other diseases and conditions are well documented, especially those with similar alterations in the APC pathway, such as familial adenomatous polyposis (Gardner’s syndrome). Other conditions with increased risk of desmoid tumor formation include increased estrogen states (pregnancy) and trauma. Surgical incisions (abdominal and thorax) have been the site of desmoid development, either in or near the scar.

Clinically, patients are usually in the third to fourth decade of life and have pain, a chest wall mass, or both. The tumor is usually fixed to the chest wall, but not to the overlying skin. There are no typical radiographic findings, but MRI may delineate muscle or soft tissue infiltration. Desmoid tumors do not metastasize, but they have a significant propensity to recur locally, with rates as high as 5% to 50%, sometimes despite complete initial resection with histologically negative margins. Such locally aggressive behavior is secondary to microscopic tumor infiltration of muscle and surrounding soft tissues and prompts some to consider them a low-grade form of fibrosarcoma.

Because the lesions have low cellularity and poor yield with FNA, an open incisional biopsy for lesions over 3 to 4 cm is often necessary, following the caveats listed earlier (see biopsy section). Surgery consists of wide local excision with a 2- to 4-cm margin and intraoperative frozen section assessment of resection margins. Typically, chest wall resection, including the involved rib(s) and one rib above and below the tumor with a 4- to 5-cm margin of rib, is required. A margin of less than 1 cm results in much higher local recurrence rates. If a major neurovascular structure would have to be sacrificed, leading to high morbidity, then a margin of less than 1 cm would have to suffice. Survival after wide local excision with negative margins is 90% at 10 years.
Primary Malignant Chest Wall Tumors

Malignant tumors of the chest wall are either metastatic lesions from another primary tumor or sarcoma. Soft tissue sarcomas of the chest wall include fibrosarcomas, liposarcomas, malignant fibrous histiocytomas (MFHs), rhabdomyosarcomas, angiosarcomas, and other extremely rare lesions (Fig. 19-40). Despite the prevalence of localized disease, soft tissue sarcomas of the chest wall have significantly worse survival than similar tumors located on the extremities or the head and neck region. The factors impacting on risk of death from soft tissue sarcomas of the chest wall are presented in Table 19-23. All sarcomas have a propensity to spread to the lungs.

While many varieties of sarcoma exist, the primary features affecting prognosis are histologic grade and responsiveness to chemotherapy (Table 19-24). Preoperative (neoadjuvant) chemotherapy offers the ability to (a) assess tumor chemosensitivity by the degree of tumor size reduction and microscopic necrosis; (b) determine tumor sensitivity to specific chemotherapeutic agents; and (c) improve resectability by reducing tumor size. Patients whose tumors are responsive to preoperative chemotherapy have a much better prognosis than those with a poor response. Information about tumor response to chemotherapy, the patient’s physiologic state and capacity to receive treatment, and metastatic disease status is used to determine optimal therapy. The initial treatment is either (a) preoperative chemotherapy (for patients with osteosarcoma, rhabdomyosarcoma, primitive neuroectodermal tumor, or Ewing’s sarcoma) followed by surgery and postoperative chemotherapy; (b) primary surgical resection and reconstruction (for patients with nonmetastatic MFH, fibrosarcoma, liposarcoma, or synovial sarcoma); or (c) preoperative chemotherapy followed by surgical resection if indicated in patients presenting with metastatic soft tissue sarcomas. Contiguous involvement of underlying lung or other soft tissues or the presence of pulmonary metastases does not preclude successful surgery. In fact, patients receiving surgical intervention have significantly better overall survival. Median survival with surgical resection is 25 months compared to 8 months without resection. Additional prognostic variables that are important for long-term survival include tumor size, grade, stage, and negative re-resection margin. With the exception of rhabdomyosarcomas, the primary treatment of these lesions is wide surgical resection with 4-cm margins and reconstruction.

The following is an overview of several chest wall sarcomas.

1. **Chondrosarcoma.** Chondrosarcomas are the most common primary chest wall malignancy. As with chondromas, they usually arise anteriorly from the costochondral arches. CT scan shows a radiolucent lesion often with stippled calcifications pathognomonic for chondrosarcomas (Fig. 19-41). The involved bony structures are also destroyed. Most chondrosarcomas are slow-growing, low-grade tumors; these often painful masses can reach massive proportions. For this reason, any lesion in the anterior chest wall likely to be a low-grade chondrosarcoma should be treated with wide (4-cm) resection after metastatic disease to the lungs or bones is ruled out.

   Chondrosarcomas are not sensitive to radiation or chemotherapy. Prognosis is determined by tumor grade and extent of resection. With a low-grade tumor and wide resection, patient survival at 5 to 10 years can be as high as 60% to 80%.

2. **Osteosarcoma.** While osteosarcomas are the most common bone malignancy, they represent only 10% to 15% of all malignant chest wall tumors. They primarily occur in young adults as rapidly enlarging, painful masses; however, osteosarcomas can occur in older patients as well.

sometimes in association with previous radiation, Paget’s disease, or chemotherapy. Radiographically, the typical appearance consists of spicules of new periosteal bone formation producing a sunburst appearance. Osteosarcomas have a propensity to spread to the lungs, and up to one-third of patients present with metastatic disease. Osteosarcomas are potentially sensitive to chemotherapy. Currently, pre-operative chemotherapy is common. After chemotherapy, complete resection is performed with wide (4-cm) margins, followed by reconstruction. In patients presenting with lung metastases that are potentially amenable to surgical resection, induction chemotherapy may be given, followed by surgical resection of the primary tumor and of the pulmonary metastases. Following surgical treatment of known disease, additional maintenance chemotherapy is usually recommended.
3. **Malignant fibrous histiocytoma.** Originally thought to derive from histiocytes because of the microscopic appearance of cultured tumor cells, these tumors likely originate from the fibroblast. MFHs are generally the most common soft tissue sarcoma of late adult life, although they are rare on the chest wall. The typical age at presentation is between age 50 and 70 years. Presentation is pain, with or without a palpable mass. Radiographically, a mass is usually evident, with destruction of surrounding tissue and bone. Treatment is wide resection with a margin of 4 cm or more and reconstruction. Over two-thirds of patients suffer from distant metastasis or local recurrence.

4. **Liposarcoma.** Liposarcomas make up 15% of chest wall sarcomas. Most liposarcomas are low-grade tumors that have a propensity to recur locally, given their infiltrative nature. They typically present as a painless mass. Treatment is wide resection and reconstruction. Intraoperative margins should be evaluated (as with all sarcomas) and resection continued, if feasible, until margins are negative. Local recurrence can be treated with reexcision, with occasional use of radiotherapy.

5. **Fibrosarcoma.** Often presenting as a large, painful mass, these lesions are visible on plain radiograph or CT, with surrounding tissue destruction. Treatment is wide local excision with intraoperative frozen-section analysis of margins, followed by reconstruction. Local and systemic recurrence is frequent. Patient survival at 5 years is about 50% to 60%.

6. **Rhabdomyosarcoma.** Rhabdomyosarcomas are rare tumors of the chest wall. Microscopically, they are a spindle cell tumor. The diagnosis often depends on immunohistochemical staining for muscle markers. Rhabdomyosarcomas are sensitive to chemotherapy. Treatment consists of preoperative chemotherapy with subsequent surgical resection.

**Other Tumors of the Chest Wall**

1. **Primitive neuroectodermal tumors (PNETs) and Ewing’s sarcoma.** PNETs (neuroblastomas, ganglioneuroblastomas, and ganglioneuromas) derive from primordial neural crest cells that migrate from the mantle layer of the developing spinal cord. Histologically, PNETs and Ewing’s sarcomas are small, round cell tumors; both possess a translocation between the long arms of chromosomes 11 and 22 within their genetic makeup. They also share a consistent pattern of proto-oncogene expression and have been found to express the product of the *MIC2* gene.

   Ewing’s sarcoma occurs in adolescents and young adults who present with progressive chest wall pain, but without the presence of a mass. Systemic symptoms of malaise and fever are often present. Laboratory studies reveal an elevated erythrocyte sedimentation rate and mild white blood cell elevation. Radiographically, the characteristic onion peel appearance is produced by multiple layers of periosteum in the bone formation. Evidence of bony destruction is also common. The diagnosis can be made by a percutaneous needle biopsy or an incisional biopsy.

   These tumors have a strong propensity to metastasize to the lungs and skeleton; patient survival rates are thus only 50% or less at 3 years. Increasing tumor size is associated with decreasing survival. Treatment has improved significantly and now consists of multiagent chemotherapy, radiation therapy, and surgery. Patients are typically treated preoperatively with chemotherapy and reevaluated with radiologic imaging. When residual disease is identified, surgical resection and reconstruction are performed followed by maintenance chemotherapy.

2. **Plasmacytoma.** Solitary plasmacytomas of the chest wall are very rare, with approximately 25 to 30 cases per year in the United States. The typical presentation is pain without a palpable mass. Plain radiographs show an osteolytic lesion in the region of the pain. As with other chest wall tumors, a needle biopsy under CT guidance is performed for diagnosis. Histologically, the lesion is identical to multiple myeloma, with sheets of plasma cells. It occurs at an average age of 55 years. Evaluation for systemic myeloma is performed with bone marrow aspiration, testing of calcium levels, and measurement of urinary Bence Jones proteins. If the results of these studies are negative, then a solitary
plasmacytoma is diagnosed. Surgery is usually limited to a biopsy only, which may be excisional.\textsuperscript{134} Treatment consists of radiation with doses of 4000 to 5000 cGy. Up to 75\% of patients develop systemic multiple myeloma with 10-year survival of approximately 20\%.

**Chest Wall Reconstruction**

The primary determinant of long-term freedom from recurrence and overall survival is margin status; therefore, adequate margins of normal tissue must be included in the en bloc resection. En bloc resection should include involved ribs, sternum, superior sulcus, or spine if necessary; invasion of these structures should not be considered a contraindication to surgery in an otherwise fit patient. The resection should include at least one normal adjacent rib above and below the tumor, with all intervening intercostal muscles and pleura. In addition, an en bloc resection of overlying chest wall muscles is often necessary, such as of the pectoralis minor or major, serratus anterior, or latissimus dorsi. When the periphery of the lung is involved with the neoplasm, it is appropriate to resect the adjacent part of the pulmonary lobe in continuity (Fig. 19-42). Involvement of the sternum by a malignant tumor requires total resection of the sternum with the adjacent cartilage. Techniques for postoperative respiratory support are now good enough that resection should not be compromised because of any concern about the patient’s ability to be adequately ventilated in the early postoperative period.

The extent of resection depends on the tumor’s location and on any involvement of contiguous structures. Laterally based lesions often require simple wide excision, with resection of any contiguously involved lung, pleura, muscle, or skin. Anteriorly based lesions contiguous with the sternum require partial sternectomy. Primary malignant tumors of the sternum may require complete sternectomy. Posterior lesions involving the rib heads over their articulations with the vertebral bodies may, depending on the extent of rib involvement, require partial en bloc vertebrectomy.

Optimal management of larger tumors includes careful preoperative planning and execution of the surgery by the thoracic surgeon and an experienced plastic surgeon in order to ensure optimal physiologic and cosmetic results. With these measures, reconstruction at the same operation can be accomplished.\textsuperscript{135} Reconstruction of a large defect in the chest wall requires the use of some type of material to prevent lung herniation and to provide stability for the chest wall (see Fig. 19-42). Mild degrees of paradoxical motion are often well tolerated if the area of instability is relatively small. Historically, a wide variety of materials have been used to reestablish chest wall stability, including rib autografts, steel struts, acrylic plates, and numerous synthetic meshes. The current preference is either a 2-mm polytetrafluoroethylene (Gore-Tex) patch or a double-layer polypropylene (Marlex) mesh sandwiched with methylmethacrylate. There are several properties that make Gore-Tex an excellent material for use in chest wall reconstruction: (a) it is impervious to fluid, which prevents pleural fluid from entering the chest wall and minimizes the formation of seromas, which can compromise the myocutaneous flap viability and provide a nidus for infection; and (b) it provides excellent rigidity and stability when secured taut to the surrounding bony structure and, as a result, provides a firm platform for myocutaneous flap reconstruction. Except for smaller lesions, tissue coverage requires the use of myocutaneous flaps (latissimus dorsi, serratus anterior, rectus abdominis, or pectoralis major muscles).\textsuperscript{136,137}

**MEDIASTINUM**

**Anatomy and Pathologic Entities**

The mediastinum can be divided into compartments for classification of anatomic components and disease processes, which, despite substantial overlap, facilitates understanding of general concepts of surgical interest. Several classification schemes exist, but for the purposes of this chapter, the three-compartment model is used (Fig. 19-43). The anterior compartment lies between the sternum and the anterior surface of the heart and great vessels. The visceral or middle compartment is located between the great vessels and the trachea. As the name implies, the posterior compartment lies posterior and includes the paravertebral sulci, bilaterally, and the paraesophageal area.

**Figure 19-42.** Principles of reconstruction after resection of a chest wall tumor (osteogenic sarcoma) are shown. A. En bloc resection of the involved chest wall, including normal ribs above and below the tumor as well as pulmonary parenchyma, must be performed. The resected specimen is shown. B. A prosthesis has been sewn in place. In the lower third of the prosthesis, the line of diaphragm reattachment is seen. The skin defect was closed with a myocutaneous flap from the ipsilateral rectus muscle.

Middle mediastinum

Figure 19-43. Anatomic division of the mediastinum.

The normal content of the anterior compartment includes the thymus gland or its remnant, the internal mammary artery and vein, lymph nodes, and fat. The thymus gland is large during childhood, occupying the entire anterior mediastinum (Fig. 19-44) but decreases in both thickness and length after adolescence and takes on a more fatty content, with only residual islands of thymic cellular components (Fig. 19-45). The middle mediastinal compartment contains the pericardium and its contents, the ascending and transverse aorta, the superior and inferior venae cavae, the brachiocephalic artery and vein, the phrenic and upper vagus nerves, the trachea and main bronchi and corresponding lymph nodes, and the central portions of the pulmonary arteries and veins. The posterior compartment contains the descending aorta, esophagus, thoracic duct, azygos and hemiazygos veins, and lymph nodes. Numerous pathologic variants may be present in the various compartments, with much overlap. Table 19-25 includes the most common pathologic entities listed by compartment.138,139

History and Physical Examination
Mediastinal pathology varies significantly by patient age. In children, neurogenic tumors of the posterior mediastinum are most common, followed by lymphoma, which is usually located in the anterior or middle compartment. Thymoma in childhood is rare (Table 19-26). In adults, the most common tumors include neurogenic tumors of the posterior compartment, benign cysts occurring in any compartment, and thymomas of the anterior mediastinum (Table 19-27). In both age groups, about 25% of mediastinal tumors are malignant. Pediatric tumors will be discussed in Chapter 39.

Up to two-thirds of mediastinal tumors in adults are discovered as asymptomatic abnormalities on radiologic studies ordered for other problems, particularly now that screening CT examinations are more prevalent. When symptomatic, these tumors are significantly more likely to be malignant. Characteristics such as size, location, rate of growth, and associated inflammation are important factors that correlate with symptoms. Large, bulky tumors, expanding cysts, and teratomas can cause compression of mediastinal structures, in particular the trachea, and lead to cough, dyspnea on exertion, or stridor. Chest pain or dyspnea may be reported secondary to associated pleural effusions, cardiac tamponade, or phrenic nerve involvement. Occasionally, a mediastinal mass near the aortopulmonary window may be identified in a workup for hoarseness because of left recurrent laryngeal nerve involvement. The patient in Fig. 19-46 presented with hoarseness due to nodal compression of the left recurrent laryngeal nerve from a primary lung cancer with metastases to the level 5 and 6 lymph nodes in the region of the aortopulmonary window.

The history and physical examination in conjunction with the imaging findings may suggest a specific diagnosis (Table 19-28). In one series, systemic symptoms were present in 50% of patients with a mediastinal mass and a lymphoproliferative disorder, as compared with only 29% of patients with other masses (such as thymic or neurogenic). Laboratory signs of inflammation were also noted; the erythrocyte sedimentation rate and C-reactive protein levels were elevated and leukocytosis was present in 86% of patients with a lymphoproliferative disorder, as compared with only 58% of patients with other types of mediastinal masses.

Imaging and Serum Markers
Chest CT or MRI is required to fully delineate the anatomy.140 A contrast-enhanced CT scan enables clear delineation of the

Figure 19-44. Normal appearance of the thymus gland in childhood. Ao = aorta; PA = pulmonary artery; VC = vena cava.
soft tissue structures from the vasculature and is preferred over noncontrast studies. If there is concern for invasion of vascular structures or spinal involvement, MRI is more accurate than CT scan and provides important information regarding respectability.

If an endocrine origin is suspected, several other imaging modalities are available (Table 19-29). Single-photon emission CT (SPECT) technology may be used to improve image contrast and give information on three-dimensional localization, largely replacing conventional two-dimensional nuclear imaging studies. If a thyroid origin is suspected, a thyroid scan using $^{131}$I or $^{123}$I can identify most intrathoracic goiters and identify the extent of functioning thyroid tissue. If indicated, the thyroid scan should precede other scans requiring iodine-containing contrast agents because they would subsequently interfere with iodine tracer uptake by thyroid tissue. If a pheochromocytoma or neuroblastoma is suspected, the octreotide scan or $^{123}$I-metaiodobenzylguanidine (MIBG) scans are helpful in diagnosis and localization. The sestamibi scan may be useful for diagnosing and localizing a mediastinal parathyroid gland. PET is useful for distinguishing malignant from benign tumors and may help detect distant metastases in some patients. However, the role of routine PET imaging for staging surgically resectable lesions of the mediastinum has not been established.

The use of serum markers to evaluate a mediastinal mass can be invaluable in some patients. For example, nonseminomatous and seminomatous germ cell tumors can frequently be diagnosed and often distinguished from one another by the levels of α-fetoprotein (AFP) and human chorionic gonadotropin (hCG). In over 90% of nonseminomatous germ cell tumors, either the AFP or the hCG level will be elevated. Results are close to 100% specific if the level of either AFP or hCG is greater than 500 ng/mL. Some centers institute chemotherapy based on this result alone, without biopsy confirmation of the diagnosis. In contrast, the AFP level in patients with mediastinal seminoma is always normal; only 10% will have elevated hCG, which is usually less than 100 ng/mL. Other serum markers, such as intact parathyroid hormone level for ectopic parathyroid

adenomas, may be useful for diagnosing and also for intraoperatively confirming complete resection. After successful resection of a parathyroid adenoma, this hormone level should rapidly normalize.

**Diagnostic Nonsurgical Biopsies of the Mediastinum**

The treatment of up to 60% of patients with anterior mediastinal masses is ultimately nonsurgical, so it is essential to understand all options for obtaining adequate tissue for a definitive diagnosis using the least invasive approach. CT-guided needle biopsy, EBUS- and EUS-guided FNA, and even core-needle biopsy (either CT-guided and EUS-guided) have proven most useful for cytologic and tissue diagnosis of mediastinal masses and lymphadenopathy.

When FNA and core-needle biopsy were combined, the accuracy was 98%, compared to 79% for each modality independently. In addition, core-needle biopsy changed the diagnosis in nine cases that had been missed by FNA due to inadequate specimens. Finally, core-needle biopsy was better at diagnosis for benign diseases compared to FNA. Accessible nodal stations include subcarinal (level 7), aortopulmonary (level 5), paraeosophageal (level 8), and inferior pulmonary ligament (level 9) as well as paratracheal (level 4). Technical expertise in these modalities should be pursued by thoracic and general surgeons.

Historically, needle biopsies of anterior mediastinal masses were reportedly sensitive and specific for most carcinomatous tumors, but there were questions regarding accuracy for diagnosing lymphomas. However, advances in cytopathology as well as needle biopsy technology have substantially improved diagnostic accuracy such that most centers are reporting yields ranging from 75% to 80% for the diagnosis of lymphoma as well.

To achieve maximal diagnostic yield for mediastinal masses suggestive of a lymphoma, it is necessary to obtain multiple fine-needle aspirates, preferably with immediate onsite rapid cytologic analysis to confirm sampling of the target tissue and adequate cellularity. This also facilitates processing of the sample to ensure that proper studies for lymphoma, including flow cytometry, are obtained. If the needle biopsy is inconclusive, surgical biopsy can be performed. If the lesion is accessible by CT-guided or EUS-guided core-needle biopsy, intraoperative frozen section or immediate cytologic smear of a core biopsy can also be performed. Currently, core-needle biopsy with EBUS is not possible. The authors perform their own endobronchial, endoscopic, and CT-guided transbronchial and transthoracic biopsies, and in our experience, lack of cellularity in the aspirate is readily apparent.

In general, plans to proceed with surgical biopsy are made in combination with the image-guided aspiration and, as such, are performed in the same setting. This enables the authors to avoid a more invasive surgical procedure when FNA or core-needle biopsy is sufficient without contributing to delays in diagnosis by having multiple attempts from multiple providers (such as interventional radiology and pulmonology) before involvement of the surgeon in the diagnostic workup.
**Surgical Biopsies and Resection of Mediastinal Masses**

For tumors of the mediastinum that are not amenable to an endoscopic or CT-guided needle biopsy or that do not yield sufficient tissue for diagnosis, a surgical biopsy is indicated. The definitive approach to a surgical biopsy of the anterior mediastinum is through a median sternotomy. At the time of sternotomy, if the lesion is easily resectable, it should be completely removed. Given the invasiveness of the procedure and the inability in some patients to obtain a definitive diagnosis by frozen section, less invasive procedures are preferable if the lesion is large or if the CT scan or history suggests that surgery is not the best definitive treatment.

Masses in the paratracheal region are easily biopsied by mediastinoscopy. For tumors of the anterior or posterior mediastinum, a left or right VATS approach often allows safe and adequate surgical biopsies. In some patients, an anterior mediastinotomy (i.e., Chamberlain procedure) may be ideal for an anterior tumor or a tumor with significant parasternal extension. Before a surgical biopsy is pursued, a discussion should be held with the pathologist regarding routine histologic assessment, special stains and markers, and requirements for lymphoma workup.

Surgical resection using minimally invasive approaches, including video-assisted and robotic thoracoscopic surgery and transcervical, are now routine for the vast majority of middle and posterior tumors and for moderate sized (<5 to 6 cm) anterior mediastinal tumors. Outcomes comparing VATS to open thymectomy in patients with myasthenia gravis without thymoma were prospectively evaluated by Chang and colleagues in 2005, and no differences were seen in terms of response to therapy and recurrence of symptoms. Pain scores were significantly better in the VATS approach. These reports and others support application of VATS for the majority of anterior mediastinal masses.

Other minimally invasive approaches are under study. For example, good results have been reported using a cervical incision with a sternal retractor for thymus removal. The upward lift allows the surgeon reasonable access to the anterior mediastinum and has proven adequate in some centers for definitive resection of the thymus gland for myasthenia gravis. For larger anterior mediastinal masses or in centers where expertise in thoracoscopy is not available, median sternotomy and thoracotomy remain excellent options for resection of anterior mediastinal masses. Occasionally, a lateral thoracotomy with sternal extension (hemi-clamshell) provides excellent exposure for extensive mediastinal tumors that have a lateral component.

Most surgeons would agree that if a larger anterior mediastinal tumor is seen or malignancy is suspected, a median sternotomy with a more radical resection should be performed.

** Mediastinal Neoplasms**

**Thymic Hyperplasia.** Diffuse thymic hyperplasia was first described in children after successful chemotherapy for lymphoma. It has now been described in adults and is referred to as “rebound thymic hyperplasia.” It is most frequently reported after chemotherapy for lymphoma or germ cell tumors. Initially, atrophy of the thymic gland is seen with subsequent thymic gland enlargement, which can be dramatic. The usual time course for thymic hyperplasia is about 9 months after cessation of chemotherapy (range 2 weeks to 12 months). Benign hyperplasia must be clearly distinguished from recurrent lymphoma or germ cell tumors, which may be difficult since thymic hyperplasia is dramatic in some patients; careful follow-up with serial CT scans is the minimum requirement. The role of PET scanning is unclear. Thymic hyperplasia is a known cause of false-positive PET scans; in many patients, CT scan will show a triangular soft tissue density in the retrosternal space that has a characteristic bilobed anatomic appearance consistent with thymus gland. In addition, a low standardized uptake value of tracer on PET scan suggests a benign tumor. Biopsies may be required if the clinical index of suspicion is high.
**Thymoma.** While it is the most frequently encountered neoplasm of the anterior mediastinum in adults (seen most frequently between 40 and 60 years of age), thymoma is rare in children. Between 10% and 50% of patients with thymoma will have symptoms suggestive of myasthenia gravis or have circulating antibodies to acetylcholine receptor, but less than 10% of patients with myasthenia gravis have a thymoma. Most patients with thymoma are asymptomatic. Thymectomy leads to improvement or resolution of symptoms of myasthenia gravis in only about 25% of patients with thymomas. In contrast, in patients with myasthenia gravis and no thymoma, thymectomy results are superior: up to 50% of patients have a complete remission, and 90% improve. In 5% of patients with thymomas, other paraneoplastic syndromes, including red cell aplasia, hypogammaglobulinemia, systemic lupus erythematosus, Cushing’s syndrome, or SIADH, may be present. Large thymic tumors may present with symptoms related to a mass effect, which may include cough, chest pain, dyspnea, or SVC syndrome.

The diagnosis may be suspected based on CT scan and history, but imaging alone is not diagnostic. In most centers, the diagnosis is made after surgical resection because of the relative difficulty of obtaining a needle biopsy and the likelihood that removal will ultimately be recommended. Biopsy should be avoided in cases where imaging is highly suggestive of thymoma. In most patients, the distinction between lymphomas and thymomas can be made on CT scan since most lymphomas have marked lymphadenopathy and thymomas most frequently appear as a solitary encapsulated mass. PET scan may have a role in differentiating thymic cancer from thymoma, as thymic cancer tends to be very FDG avid.153 In addition, PET scan may facilitate identification of low-risk and minimally invasive thymoma; a standardized uptake value (SUV) <5 was associated with Masaoka stage I or II thymoma, whereas invasive thymoma and mediastinal lymphoma were more likely when the SUV was >5.154 In cases where the diagnosis is unclear, transmediastinal, not transpleural, CT-guided FNA biopsy has a diagnostic sensitivity of 87% and a specificity of 95% in specialized centers.

The most commonly accepted staging system for thymoma is that of Masaoka.155 It is based on the presence or absence of gross or microscopic invasion of the capsule and of surrounding structures, as well as on the presence or absence of metastases (Table 19-30). Histologically, thymomas are characterized by a mixture of epithelial cells and mature lymphocytes. Grossly, many thymomas remain well encapsulated. Even those with capsular invasion often lack histologic features of malignancy; they appear cytologically benign and identical to early-stage tumors. This lack of classic cellular features of malignancy is why most pathologists use the term “thymoma” or “invasive thymoma” rather than “malignant thymoma.” Thymic tumors with malignant cytopathic features are classified separately and referred to as “thymic carcinoma.”

The definitive treatment for thymoma is complete surgical removal; local recurrence rates and survival vary according to stage (Fig. 19-47). In centers with significant experience with VATS procedures, thymoma is not a contraindication to VATS approach, provided the principles of resection are adhered to, such as a complete resection without disrupting the capsule.156 Otherwise, resection is generally accomplished by median sternotomy with extension to hemi-clamshell in more advanced cases. Even advanced tumors with local invasion of resectable structures such as the pericardium, SVC, or innominate vessels should be considered for resection with reconstruction.

A multidisciplinary approach to nonresectable and more advanced lesions (stage ≥II) is mandatory to optimize patient care. The goal for surgical resection should be complete excision of the mass with total thymectomy. All contiguous and noncontiguous disease is removed at the same setting; this may include resection of the pericardium or pleura, adjacent adherent lung, phrenic nerve, major vascular structures, and pleural metastasis. Bilateral phrenic nerve resection should be avoided, however, due to the major respiratory morbidity associated with bilateral paralyzed hemidiaphragms.

The role of adjuvant or neoadjuvant therapies for advanced-stage tumors remains unclear. Traditionally, stage II thymomas have been treated by complete surgical resection followed by mediastinal radiation, but randomized trials have not been done. A recent retrospective review of a single-institution series of stage II thymoma patients showed no difference in survival or local recurrence after complete surgical resection alone, as compared with surgical resection with radiotherapy. Advanced thymomas have been shown to respond to platinum-based chemotherapy and to corticosteroids.157158 One summary of chemotherapy trials showed an overall response rate of about 70%. Cisplatin/doxorubicin-based regimens appear to yield the best results. The combination radiotherapy and chemotherapy for local progression appears to prolong survival in some small series.158 Radiation therapy in surgically resected stage III thymoma is likely beneficial in extending disease-specific survival; an analysis of the Surveillance, Epidemiology, and End Results (SEER) database identified 476 patients with stage III thymoma treated with primary surgery. Postoperative radiation was given

Figure 19-47. Stage-specific survival for thymomas.
to 322 patients with a significant improvement in survival (127 months compared to 105 months, \( P = .038 \)) despite the fact that these patients were more likely to have had debulking rather than curative resection. In multivariate analysis, disease-specific survival was better in the adjuvant radiation group.\(^\text{156}\) Therefore, it is imperative that all patients with thymomas undergo a thorough evaluation for potential resection. Current guidelines recommend radiation for patients with unresectable thymoma who have failed induction chemotherapy or for patients with incompletely resected invasive thymoma or thymic cancer. Planning the radiation ports requires input from the surgeon; it is important for the surgeon to carefully document areas of adherence between the thymoma and adjacent structures during the operation, with clips or other radiopaque markers placed to guide radiation therapy postoperatively. Extracapsular extension and positive surgical margins should be noted by the pathologist and correlated anatomically so that the surgeon and radiation oncologist can ensure appropriate radiation treatment.

**Thymic Carcinoma.** Thymic carcinomas are unequivocally malignant at the microscopic level. Suster and Rosai classified thymic carcinomas into low-grade and high-grade tumors.\(^\text{160}\) Low-grade tumors are well differentiated with squamous cell, mucoepidermoid, or basaloid features. High-grade thymic carcinomas include those with lymphoepithelial, small cell neuroendocrine, sarcomatoid, clear cell, and undifferentiated or anaplastic features. Care must be taken to differentiate thymic carcinoma from lung cancer metastatic to the thymus gland as the histologic features can be similar between the two. Compared with thymomas, they are a more heterogeneous group of malignancies with a propensity for early local invasion and widespread metastases. Malignant pleural and pericardial effusions occur frequently.

Five-year survival rates are between 30% and 50%. Complete resection is occasionally curative and leads to improved survival, but most thymic carcinomas will recur and are refractory to chemotherapy.\(^\text{157}\) Management, therefore, depends on the completeness of the resection. Postoperative care includes radiation therapy, guided by residual gross disease or microscopically positive margins from the resection specimen. Chemotherapy may also be given, with carboplatin/paclitaxel recommended based on the best response rates with the least toxicity in clinical trials. The prognosis of patients with thymic cancer remains poor.

**Thymolipoma.** Thymolipomas are rare benign tumors that may grow to a very large size prior to diagnosis. On CT scan, their appearance can be dramatic, with a characteristic fat density dotted by islands of soft tissue density representing islands of thymic tissue (Fig. 19-48). Thymolipomas are generally well-encapsulated, soft, and pliable masses that do not invade surrounding structures. Resection is recommended for large masses.

**Neurogenic Tumors.** Most neurogenic tumors of the mediastinum arise from the cells of the nerve sheath, from ganglion cells, or from the paraganglionic system (Table 19-31). The incidence, cell types, and risk of malignancy strongly correlate with patient age. Tumors of nerve sheath origin predominate in adults. Most present as asymptomatic incidental findings, and most are benign. In children and young adults, tumors of the autonomic ganglia predominate, with up to two-thirds being malignant.\(^\text{161}\)

**Nerve Sheath Tumors.** Nerve sheath tumors account for 20% of all mediastinal tumors. More than 95% of nerve sheath tumors are benign neurilemomas or neurofibromas. Malignant neurosarcomas are much less common.

**Neurilemoma.** Neurilemomas, also called schwannomas, arise from Schwann cells in intercostal nerves. They are firm, well encapsulated, and generally benign. Two characteristic histologic components are referred to as Antoni type A and Antoni type B regions. Antoni type A regions contain compact spindle

---

**Figure 19-48.** Massive thymolipoma that was asymptomatic in an 18-year-old female.
cells with twisted nuclei and nuclear palisading. Antoni type B regions contain loose and myxoid connective tissue with hap hazard cellular arrangement. These characteristics distinguish neurilemoma from malignant fibrosarcomatous tumors, which lack encapsulation and have no Antoni features. If routine CT scan suggests extension of a neurilemoma into the intervertebral foramen, MRI is used to evaluate the extent of this “dumbbell” configuration (Fig. 19-49). Such a configuration may lead to cord compression and paralysis and requires a more complex surgical approach. Resection is recommended; VATS has been established as safe and effective for simple and, in experienced centers, even the more complex operations.\textsuperscript{162} It is reasonable to follow small, asymptomatic paravertebral tumors in older patients or in patients at high risk for surgery. In children, ganglioneuroblastomas or neuroblastomas are more common; therefore, all neurogenic tumors should be completely resected.

**Neurofibroma.** Neurofibromas consist of both nerve sheath and nerve cells and account for up to 25% of nerve sheath tumors. Up to 40% of patients with mediastinal fibromas have generalized neurofibromatosis (von Recklinghausen’s disease). About 70% of neurofibromas are benign, but malignant degeneration to neurofibrosarcoma occurs in 25% to 30% of patients.\textsuperscript{163} The risk of malignant degeneration increases with advancing age, von Recklinghausen’s disease, and exposure to previous radiation. Neurofibrosarcomas carry a poor prognosis because of rapid growth and aggressive local invasion along nerve bundles. Complete surgical resection is the mainstay of treatment. Adjuvant radiotherapy or chemotherapy does not confer a significant benefit, but may be added if complete resection is not possible.\textsuperscript{164} The 5-year survival rate is 53%, but it drops to 16% in patients with neurofibromatosis or with large tumors (>5 cm).

**Ganglion Cell Tumors** Ganglion cell tumors (ganglioneuromas, ganglioneuroblastomas, and neuroblastomas) arise from the sympathetic chain or from the adrenal medulla.

1. **Ganglioneuroma.** Well-differentiated, benign tumors characterized histologically by well-differentiated ganglion cells with a background of Schwann cells, these are most often found incidentally in asymptomatic young adults. Diarrhea related to secretion of a vasoactive intestinal peptide has been described in some patients. These tumors have a propensity for intraspinal canal extension, although they remain well-encapsulated; complete resection is curative, with a low risk of local recurrence.

2. **Ganglioneuroblastoma.** Ganglioneuroblastomas contain a mixture of benign ganglion cells and malignant neuroblasts. The distribution of these cells within the tumor is predictive of the clinical course. The nodular pattern has a high incidence of metastatic disease, whereas the diffuse pattern rarely metastasizes. Gross examination typically reveals encapsulated tumor; histologically, there are focal calcifications around regions of neuroblasts. Ganglioneuroblastomas arise most frequently in infants and children <3 years old. The majority are resectable, with 80% 5-year survival.

3. **Neuroblastoma.** Highly malignant, neuroblastomas are the most common extracranial solid malignancy of childhood. The primary site is intrathoracic malignancy in 14%; extension into the spinal canal and osseous invasion commonly present. These thoracic tumors are not as recalcitrant to chemotherapy and surgical resection as other chest malignancies; they are more likely to be resectable, with less invasion of surrounding organs. More than half occur in children under 2 years old; 90% arise within the first decade of life, and thus, these malignancies are discussed in more detail in Chapter 39.

**Paraganglionic Tumors.** Paraganglionic tumors arising in the thoracic cavity include chemodectomas and pheochromocytomas. Only 10% of all pheochromocytomas are located in an extra-adrenal site. Intrathoracic pheochromocytomas are one of the rarest tumors. Approximately 10% of thoracic pheochromocytomas are malignant, a rate similar to that of adrenal tumors. The most common thoracic location is within the costovertebral sulcus, but paraganglionic tumors also arise within the visceral compartment of the mediastinum. These catecholamine-producing lesions can lead to life-threatening hemodynamic problems, so complete removal is important. Diagnosis is generally confirmed by measuring elevated levels of urinary catecholamines and their metabolites. Localization is by CT scan, aided by MIBG scintigraphy. Preoperative care includes α- and β-adrenergic blockade to prevent intraoperative malignant hypertension and arrhythmias. These tumors tend to be highly vascular and should be approached with care. Chemodectomas are rare tumors that may be located around the aortic arch, vagus nerves, or aortic syphymathetics. They rarely secrete catecholamines and are malignant in up to 30% of patients.

**Lymphoma.** Overall, lymphomas are the most common malignancy of the mediastinum. In about 50% of patients who have both Hodgkin’s and non-Hodgkin’s lymphoma, the mediastinum may be the primary site. The anterior compartment is most commonly involved, with occasional involvement of the middle compartment and hilar nodes. The posterior compartment is rarely involved. Chemotherapy and/or radiation results in a cure rate of up to 90% for patients with early-stage Hodgkin’s disease and up to 60% with more advanced stages.

**Mediastinal Germ Cell Tumors.** Germ cell tumors are uncommon neoplasms, but they are the most common malignancy in young men 15 to 35 years of age. Most germ cell tumors are gonadal in origin; primary mediastinal germ cell tumors comprise less than 5% of all germ cell tumors and less than 1% of all mediastinal tumors (usually occurring in the anterior compartment). If a malignant mediastinal germ cell tumor is found, it is important to exclude a gonadal primary tumor. Primary mediastinal germ cell tumors (including teratomas, seminomas, and nonseminomatous malignant germ cell tumors) are a heterogeneous group of benign and malignant neoplasms thought to originate from primitive pluripotent germ cells “misplaced” in the mediastinum during embryonic development. Previously, most mediastinal germ cell tumors were thought to be metastatic. However, two lines of evidence suggest that many mediastinal germ cell tumors are primary, developing from pluripotent primordial germ cells in the mediastinum: (a) several autopsy series showed that patients with extragonadal sites of germ cell tumors, presumed previously to have originated from the gonads, had no evidence of an occult primary tumor or of any residual scar of the gonads, even after an exhaustive search; and (b) patients treated by surgery or radiation for their mediastinal germ cell tumors had long-term survival with no late testicular recurrences.

About one-third of all primary mediastinal germ cell tumors are seminomas. Two-thirds are nonseminomatous tumors or teratomas. Treatment and prognosis vary considerably within these two groups. Mature teratomas are benign and can generally be diagnosed by the characteristic CT findings of multilocular cystic tumors, encapsulated with combinations of fluid, soft tissue, calcium, and/or fat attenuation in the anterior compartment. FNA biopsy alone may be diagnostic for seminomas, usually with normal serum markers, including hCG and AFP. In 10% of seminomas, hCG levels may be slightly elevated. FNA findings, along with high hCG and AFP levels, can accurately diagnose nonseminomatous tumors. If the diagnosis remains uncertain after assessment of FNA findings and serum marker levels, then core-needle biopsies or surgical biopsies may be required. Thoracoscopy is the most frequent diagnostic surgical approach.

1. **Seminoma.** Most patients with seminomas have advanced disease at the time of diagnosis and present with symptoms of local compression, including SVC syndrome, dyspnea, or chest discomfort. With advanced disease, the preferred treatment is combination cisplatin-based chemotherapy regimens with bleomycin and either etoposide or vindesine. Complete responses have been reported in over 75% of patients treated with these regimens. Surgical resection may be curative for small asymptomatic seminomas that are found incidentally with screening CT scans. Surgical resection of residual masses after chemotherapy may be indicated.

2. **Nonseminomatous germ cell tumors.** Nonseminomatous germ cell tumors include embryonal cell carcinomas, choriocarcinomas, endodermal sinus tumors, and mixed types. They are often bulky, irregular tumors of the anterior mediastinum with areas of low attenuation on CT scan because of necrosis, hemorrhage, or cyst formation. Frequently, adjacent structures have been involved, with metastases to regional lymph nodes, pleura, and lungs. Lactate dehydrogenase (LDH), AFP, and hCG levels are frequently elevated. Chemotherapy is the preferred treatment and includes combination therapy with cisplatin, bleomycin, and etoposide, followed by surgical resection of residual disease. With this regimen, survival is 67% at 2 years and 60% at 5 years. Surgical resection of residual masses is indicated, as it may guide further therapy. Up to 20% of residual masses contain additional tumors; in another 40%, mature teratomas; and the remaining 40%, fibrotic tissue.
It is important to note that oxygen toxicity can occur in patients who have been exposed to bleomycin; high levels of oxygen supplementation in the perioperative setting should be avoided in these patients as respiratory failure and death can ensue.\textsuperscript{166} Factors independently predictive of survival after induction chemotherapy followed by resection are elevated serum tumor markers after resection, postchemotherapy pathologic findings (complete necrosis vs. teratoma), and persistent germ cell or non-germ cell cancer in the pathologic specimen.\textsuperscript{166}

3. **Teratoma.** Teratomas are the most common type of mediastinal germ cell tumors, accounting for 60% to 70% of mediastinal germ cell tumors. They contain two or three embryonic layers that may include teeth, skin, and hair (ectodermal), cartilage and bone (mesodermal), or bronchial, intestinal, or pancreatic tissue (endodermal). Therapy for mature, benign teratomas is surgical resection, which confers an excellent prognosis. Rarely, teratomas may contain a focus of carcinoma; these malignant teratomas (or teratocarcinomas) are locally aggressive. Often diagnosed at an unresectable stage, they respond poorly to chemotherapy and in a limited manner to radiotherapy; prognosis is uniformly poor.

**Mediastinal Cysts**

Benign cysts account for up to 25% of mediastinal masses and are the most frequently occurring mass in the middle mediastinal compartment. A CT scan showing characteristic features of near water density in a typical location is virtually 100% diagnostic.\textsuperscript{167}

1. **Pericardial cyst.** Usually asymptomatic and detected incidentally in the right costophrenic angle, pericardial cysts typically contain a clear fluid and are lined with a single layer of mesothelial cells. For most simple, asymptomatic pericardial cysts, observation alone is recommended. Surgical resection or aspiration may be indicated for complex cysts or large symptomatic cysts.

2. **Bronchogenic cyst.** Developmental anomalies that occur during embryogenesis and occur as an abnormal budding of the foregut or tracheobronchial tree, bronchogenic cysts arise most often in the mediastinum just posterior to the carina or main stem bronchus. Approximately 15% occur within the pulmonary parenchyma. Thin-walled and lined with respiratory epithelium, they contain a protein-rich mucoid material and varying amounts of seromucous glands, smooth muscle, and cartilage. They may communicate with the tracheobronchial tree. In adults, over half of all bronchogenic cysts are found incidentally during workup for an unrelated problem or during screening. The natural history of an incidentally diagnosed, asymptomatic bronchogenic cyst is unknown, but it is clear that many such cysts do not lead to clinical problems. In one study of young military personnel, 78% of all bronchogenic cysts found on routine CXRs were asymptomatic. However, in other reports with more comprehensive follow-up, up to 67% of adults with incidentally found bronchogenic cysts eventually became symptomatic. Symptoms include chest pain, cough, dyspnea, and fever. If large (>6 cm) or symptomatic, resection is generally recommended since serious complications may occur if the cyst becomes larger or infected.

Complications include airway obstruction, infection, rupture, and, rarely, malignant transformation.\textsuperscript{168,169}

Traditionally, complete removal of the cyst wall has been via posterolateral thoracotomy.\textsuperscript{170} Resection of infected cysts may be quite difficult because of dense adhesions; elective removal is often recommended before infection has a chance to occur. Thoracoscopic exploration and resection are possible for small cysts with minimal adhesions. With increasing experience using video-assisted or robotic-assisted thoracoscopy, a greater proportion of these lesions are amenable to minimally invasive resection.

3. **Enteric cyst.** Generally asymptomatic, thymic cysts are often discovered incidentally. Simple cysts are of no consequence; however, the occasional cystic neoplasm must be ruled out. Cystic components occasionally are seen in patients with thymoma and Hodgkin’s disease.

4. **Thymic cyst.** Generally asymptomatic, thymic cysts are often discovered incidentally. Simple cysts are of no consequence; however, the occasional cystic neoplasm must be ruled out. Cystic components occasionally are seen in patients with thymoma and Hodgkin’s disease.

5. **Ectopic endocrine glands.** Up to 5% of all mediastinal masses are of thyroid origin; most are simple extensions of thyroid masses. Usually nontoxic, over 95% can be completely resected through a cervical approach. True ectopic thyroid tissue of the mediastinum is rare. About 10% to 20% of abnormal parathyroid glands are found in the mediastinum; most can be removed during exploration from a cervical incision. In cases of true mediastinal parathyroid glands, thoracoscopic or open resection may be indicated. Location can generally be pinpointed by a combination of CT scan and Sestamibi scans.

**Mediastinitis**

**Acute Mediastinitis.** Acute mediastinitis is a fulminating infectious process that spreads rapidly along the continuous fascial planes connecting the cervical and mediastinal compartments. Infections originate most commonly from esophageal perforations, sternal infections, and oropharyngeal or neck infections, but a number of less common etiologic factors can lead to this deadly process (Table 19-32). Clinical signs and symptoms include fever, chest pain, dysphagia, respiratory distress, and cervical and upper thoracic subcutaneous crepitus. In severe cases, the clinical course can rapidly deteriorate to florid sepsis, hemodynamic instability, and death. Thus, a high index of suspicion is required in the context of any infection with access to the mediastinal compartments.

A chest CT scan illuminates the extent of spread and guides selection of the best approach to surgical drainage. Acute mediastinitis is a true surgical emergency; treatment must be instituted immediately and aimed at correcting the primary problem, such as the esophageal perforation or oropharyngeal abscess, and debridement and drainage of the spreading infectious process within the mediastinum, neck, pleura, and other tissue planes. Antibiotics, fluid resuscitation, and other supportive measures are also important.
Debridement may need to be repeated and other planes and cavities explored depending on the patient’s clinical status. Blood cell counts and serial CT scans may also be required. Persistent sepsis or collections on CT scan may require further radical surgical debridement.

**Chronic Mediastinitis.** Sclerosing or fibrosing mediastinitis results from chronic mediastinal inflammation that originates in the lymph nodes, most frequently from granulomatous infections such as histoplasmosis or tuberculosis. Chronic, low-grade inflammation leads to fibrosis and scarring, which can, in some patients, result in entrapment and compression of the low-pressure veins (including the SVC and innominate and azygos veins), the esophagus, and pulmonary arteries. There is no definitive treatment. Surgery is indicated only for diagnosis or in specific patients to relieve airway or esophageal obstruction or to achieve vascular reconstruction. Reports of palliative success with less invasive procedures (such as dilation and stenting of airways, the esophagus, or the SVC) are promising. In one series of 22 patients, ketoconazole was effective in controlling progression. In another series of 71 patients, 30% died from disease-associated complications during long-term follow-up. Chronic mediastinitis is similar to retroperitoneal fibrosis, sclerosing cholangitis, and Riedel’s thyroiditis.

**PLEURA AND PLEURAL SPACE**

**Anatomy**

Each hemithorax has a mesothelial lining that invaginates at the hilum of each lung and continues on to cover each lung. The portion lining the bony rib cage, mediastinum, and diaphragm is called the parietal pleura, whereas the portion encasing the lung is known as the visceral pleura. Between these two surfaces is the potential pleural space, which is normally occupied by a thin layer of lubricating pleural fluid. A network of somatic, sympathetic, and parasympathetic fibers innervates the parietal pleura. Irritation of the parietal surface by inflammation, tumor invasion, trauma, and other processes can lead to a sensation of chest wall pain. The visceral pleura have no somatic innervation.

**Pleural Effusion**

Pleural effusion refers to any significant collection of fluid within the pleural space. Normally, between 5 and 10 L of fluid enters the pleural space each day by filtration through microvessels supplying the parietal pleura (located mainly in the less dependent regions of the cavity). The net balance of pressures in these capillaries leads to fluid flow from the parietal pleural surface into the pleural space, and the net balance of forces in the pulmonary circulation leads to absorption through the visceral pleura. Normally, 15 to 20 mL of pleural fluid is present at any given time. Any disturbance in these forces can lead to imbalance and accumulation of pleural fluid. Common pathologic conditions in North America that lead to pleural effusion include congestive heart failure, bacterial pneumonia, malignancy, and pulmonary emboli (Table 19-33).

**Access and Drainage of Pleural Fluid Collections**

Most patients with pleural effusions of unknown cause should undergo thoracentesis with the following exceptions: effusions in the setting of congestive heart failure, hepatic failure or renal failure, or small effusions associated with an improving pneumonia. If the clinical history suggests congestive heart failure as a cause, particularly in the setting of bilateral effusions, a trial of diuresis may be indicated (rather than thoracentesis). Up to 75% of effusions due to congestive heart failure resolve within 48 hours with diuresis alone. Similarly, thoracentesis can be avoided in patients with small effusions associated with resolving pneumonia. These patients typically present with cough, fever, leukocytosis, and unilateral infiltrate, and the effusion is usually a result of a reactive, parapneumonic process. If the effusion is small and the patient responds to antibiotics, a diagnostic thoracentesis may be unnecessary. If the effusion is large and compromising respiratory efforts, or if the patient has a persistent white blood cell count despite improving signs of pneumonia, an empyema of the pleural space must be considered. In these patients, early and aggressive drainage with chest tubes is required, possibly with surgical intervention.

Once the decision is made to access a pleural effusion, the next step is to determine if a sample of the fluid or complete drainage of the pleural space is desired. This step is influenced by the clinical history, the type and amount of fluid present, the
nature of the collection (such as free-flowing or loculated), the cause, and the likelihood of recurrence. For small, free-flowing effusions, an outpatient diagnostic and/or therapeutic thoracentesis with a relatively small-bore needle or catheter (14- to 16-gauge) can be performed (Fig. 19-50). The appearance of the fluid is informative: clear straw-colored fluid is often transudative; turbid or bloody fluid is often exudative.

The site of entry for drainage of a pleural effusion or pneumothorax may be based on the CXR alone if the effusion is demonstrated to be free-flowing. For free-flowing effusions, a low approach at the eighth or ninth intercostal space in the posterior midclavicular line facilitates complete drainage. If the effusion is loculated, CT- or ultrasound-guided drainage may be indicated. If the goal is complete drainage, a small-bore pigtail catheter is inserted and connected to a closed drainage system with applied suction (typically \(-20 \text{ cm } \text{H}_2\text{O}\)). In general, the smallest-bore drainage catheter that will effectively drain the pleural space should be chosen. Smaller-diameter catheters significantly decrease the pain associated with the placement of chest tubes but are more prone to clogging and twisting.\textsuperscript{174,175} For clinical situations requiring biopsy or for potential interventions such as adhesiolysis or pleurodesis, minimally invasive surgery may be indicated, using a VATS approach.

Complications of Pleural Drainage. The most common complications of invasive pleural procedures are inadvertent injury to adjacent organs, including lung, with air leakage and pneumothorax; subdiaphragmatic entry and damage to the liver, spleen, or other intra-abdominal viscera; intercostal vessel injury with subsequent bleeding or larger vessel injury; and even cardiac puncture. Sometimes, bleeding may be the result of an underlying coagulopathy or anticoagulant therapy. Other technical complications include loss of a catheter, guidewire, or fragment in the pleural space and infections. Occasionally, rapid drainage of a large effusion can be followed by shortness of breath, clinical instability, and a phenomenon referred to as postexpansion pulmonary edema. For this reason, it is recommended to drain only up to 1500 mL initially. Most complications can be avoided by consulting with a clinician experienced in pleural drainage techniques.

Pleural Fluid Analysis. Pleural fluid collections are generally classified as transudates and exudates (Table 19-34). Transudates are protein-poor ultrafiltrates of plasma that result from alterations in the systemic hydrostatic pressures or colloid...
osmotic pressures (for example, with congestive heart failure or cirrhosis). On gross visual inspection, a transudative effusion is generally clear or straw-colored. Exudates are protein-rich pleural fluid collections that generally result from inflammation or pleural invasion by tumor. Grossly, they are often turbid, bloody, or purulent. Absent trauma, grossly bloody effusions are frequently malignant, but they may also occur in the setting of a pulmonary embolism or pneumonia.

Transudates and exudates can be differentiated using Light’s criteria. An effusion is exudative if the pleural fluid-to-serum ratio of protein is greater than 0.5 and the LDH ratio is greater than 0.6 or the absolute pleural LDH level is greater than two-thirds of the normal upper limit for serum. If criteria suggest a transudate, a careful evaluation for congestive heart failure, cirrhosis, or conditions associated with transudates is undertaken. If criteria suggest an exudate, further diagnostic studies may be helpful. If total and differential cell counts reveal a predominance of neutrophils (>50% of cells), the effusion is likely associated with an acute inflammatory process (such as a parapneumonic effusion or empyema, pulmonary embolus, or pancreatitis). A predominance of mononuclear cells suggests a more chronic inflammatory process (such as cancer or tuberculosis). Gram stains and cultures should be obtained if possible, with inoculation into culture bottles at the bedside. Pleural fluid glucose levels are frequently decreased (<60 mg/dL) with complex parapneumonic effusions or malignant effusions. It is important to note that while the distinction between transudate and exudate can be diagnostically useful, the ultimate decision for prolonged chest tube drainage or surgery depends on the effusion size and adequacy of drainage, presence of loculations, adequacy of lung reexpansion after drainage, and recurrence after initial drainage.

A pleural effusion occurring in association with pleuritic chest pain, hemoptysis, or dyspnea out of proportion to the size of the effusion should raise concern for pulmonary embolism. These effusions may be transudative, but if an associated infarct near the pleural surface occurs, an exudate may be seen. If a pulmonary embolism is suspected in a postoperative patient, most clinicians would obtain a spiral CT scan. Alternatively, duplex ultrasonography of the lower extremities may yield a diagnosis of deep vein thrombosis, thereby indicating anticoagulant therapy and precluding the need for a specific diagnosis of pulmonary embolism. In some patients, a blood test for levels of D-dimer may be helpful; if a sensitive D-dimer blood test is negative, pulmonary embolism may be ruled out.

### Malignant Pleural Effusion

Malignant pleural effusions may occur in association with a number of different malignancies, most commonly lung cancer, breast cancer, and lymphomas, depending on the patient’s age and gender (Tables 19-35 and 19-36). Cytologic testing should be done on exudative effusions to rule out an associated malignancy; accuracy is 70% when associated with adenocarcinomas, but it is less sensitive for mesotheliomas (≤10%), squamous cell carcinomas (20%), or lymphomas (25% to 50%). If the diagnosis remains uncertain after drainage and fluid analysis, thoracoscopy and direct biopsies are indicated. Malignant effusions are exudative and often tinged with blood. An effusion in the setting of a malignancy means a more advanced stage; mean survival ranges from 3 to 11 months, depending on the primary tumor location.

Occasionally, effusions associated with a bronchogenic NSCLC are benign, and surgical resection may still be indicated.

Effusion size and degree of associated dyspnea influence management. Symptomatic, moderate to large effusions should be drained by tunneled indwelling pleural catheter, tube thoracostomy (chest tube or pigtail catheter) with subsequent instillation of a sclerosing agent, or VATS with talc instillation. Management is based on patient preference, degree of known or anticipated lung reexpansion, and patient tolerance for operative intervention. Lung entrapment by tumor or adhesions limits reexpansion and generally predicts a poor result with pleurodesis; it is the primary indication for placement of indwelling pleural catheters. Patient preference is also considered, as is their life expectancy. Tunneled indwelling pleural catheters have dramatically changed the management of end-stage cancer treatment.
because they substantially shorten the amount of time patients spend in the hospital during their final weeks of life. If the lung is expected to fully expand and the patient has a longer life expectancy (e.g., malignant effusions in the setting of breast cancer), drainage with sclerosis is the preferred option. The choice of sclerosant includes mechanical pleurodesis or pleurectomy, talc, bleomycin, or doxycycline. Success rates range from 60% to 90% and are highest with talc. Typically, talc is administered as an aerosolized powder during video-assisted thoracoscopy, whereas doxycycline or a talc slurry is infused at the bedside through a previously placed pigtail catheter or larger bore chest tube. Figure 19-51 presents a decision algorithm for the management of malignant pleural effusion.

Empyema
Thoracic empyema is defined by a purulent pleural effusion. Patients of all ages can develop empyema, but the frequency is increased in older or debilitated patients. Common associated conditions include a pneumonic process in patients with pulmonary disorders and neoplasms, cardiac problems, diabetes mellitus, drug and alcohol abuse, neurologic impairments, postthoracotomy problems, and immunologic impairments. The mortality of empyema frequently depends on the degree of severity of the comorbidity; it may range from as low as 1% to over 40% in immunocompromised patients.

Pathophysiology. The most common causes are parapneumonic, but postsurgical, posttraumatic, and GI-associated (e.g., subphrenic or hepatic abscess, perforation of esophagus or other viscus) empyema is also common (Table 19-37). The spectrum of organisms involved in pneumonic processes that progress to empyema is changing. Pneumococci and staphylococci continue to be the most common, but gram-negative aerobic bacteria and anaerobes are becoming more prevalent. Cases involving mycobacteria or fungi are rare. Multiple organisms may be found in up to 50% of patients. Cultures may be sterile, however, if antibiotics were initiated before the culture or if the culture process was not efficient. It is also fairly common for Pneumococcus to grow in blood cultures but not to grow in the pleural fluid cultures. The choice of antibiotics, therefore, is guided by the clinical scenario and not just the organisms found on culture. Broad-spectrum coverage may be required even when cultures do not grow out an organism or if a single organism is grown when the clinical picture is more consistent with a multiorganism process. For example, a polymicrobial gram stain, particularly including yeast, is strongly suggestive of esophageal perforation. Common gram-negative organisms include Escherichia coli, Klebsiella, Pseudomonas, and Enterobacteriaceae. Anaerobic organisms may be fastidious and difficult to document by culture and are associated with periodontal diseases (especially Streptococcus species), aspiration syndromes, alcoholism, general anesthesia, drug abuse, or other functional associations with gastroesophageal reflux.

Organisms gain entry into the pleural cavity through contiguous spread from pneumonia, lung abscess, liver abscess, or another, adjacent infectious processes. Organisms may also enter the pleural cavity by direct contamination from thoracentesis, thoracic surgical procedures, esophageal injuries,
or trauma. As organisms enter the pleural space, an influx of polymorphonuclear cells and fluid occurs, with subsequent release of inflammatory mediators and toxic oxygen radicals. These mechanisms lead to variable degrees of endothelial injury and capillary instability. This process overwhelms the normal pleural lymphatic drainage. This early effusion is watery and free-flowing in the pleural cavity. Thoracentesis at this stage yields fluid with a pH typically above 7.3, a glucose level greater than 60 mg/dL, and a low LDH level (<500 U/L). At this stage, the decision to use antibiotics alone or perform a repeat thoracentesis, chest tube drainage, thoracoscopy, or open thoracotomy depends on the amount of pleural fluid, its consistency, the clinical status of the patient, the degree of expansion of the lung after drainage, and the presence of loculated fluid in the pleural space (vs. free-flowing purulent fluid). Early in the parapneumonic process, when the purulent fluid is relatively thin, complete drainage with simple large-bore thoracentesis is possible. If complete lung expansion is obtained and the pneumatic process is responding to antibiotics, no further drainage may be necessary. Pleural fluid with a pH lower than 7.2 and with a glucose level of less than 40 mg/dL means that a more aggressive approach to drainage should be pursued.

The pleural fluid may become thick and loculated over the course of hours to days and may be associated with fibrinous adhesions (the fibrinopurulent stage). At this stage, chest tube insertion with closed-system drainage or drainage with thoracoscopy may be necessary to remove the fluid and adhesions and facilitate complete lung expansion. Further progression of the inflammatory process leads to the formation of a pleural peel, which may be flimsy and easy to remove early on. However, as the process progresses, a thick pleural rind may develop, leaving a trapped lung; complete lung decortication by either thoracoscopic or thoracotomy would then be necessary.

The use of intrapleural fibrinolytic therapy for management of empyema has been investigated in several large prospective trials. Intrapleural infusion of tissue plasminogen activator (t-PA) alone did not improve outcomes, whereas combined intrapleural t-PA and DNase was associated with a reduction in hospital stay of nearly 7 days, 77% fewer referrals for surgical intervention at 3 months, and more than double the reduction in the infected pleural fluid collection by CXR imaging. In this trial, the medications were given twice daily by intrapleural injection; the dose was 5 mg for the DNase and 10 mg for t-PA. The chest drain was clamped for 1 hour after injection and released. This study suggests that the combination of fibrinolysis (t-PA) and cleavage of uncoiled DNA by DNase reduces fluid viscosity and facilitates pleural clearance.

Management. If there is a residual space, persistent pleural infection is likely to occur. A persistent pleural space may be secondary to contracted, but intact, underlying lung; or it may be secondary to surgical lung resection. If the space is small and well drained by a chest tube, a conservative approach may be possible. This requires leaving the chest tubes in place and attached to closed-system drainage until symphysis of the visceral and parietal surfaces takes place. At this point, the chest tubes can be removed from suction; if the residual pleural space remains stable, the tubes can be cut and advanced out of the chest over the course of several weeks. If the patient is stable, tube removal can frequently be done in the outpatient setting, guided by the degree of drainage and the size of the residual space visualized on serial CT scans. Larger spaces may require open thoracotomy and decortication in an attempt to reexpand the lung to fill this residual space. If reexpansion has failed or appears too high risk, then open drainage, rib resection, and prolonged packing may be required, with delayed closure with muscle flaps or thoracoplasty. Most chronic pleural space problems can be avoided by early specialized thoracic surgical consultation and complete drainage of empyema, allowing space obliteration by the reinflected lung.

**Chylothorax**

Chylothorax develops most commonly after surgical trauma to the thoracic duct or a major branch, but may be also associated with a number of other conditions (Table 19-38). It is generally unilateral; for example, it may occur after dissection of the distal esophagus where the duct lies in close proximity to the esophagus as it enters the right chest from its origin in the

abdomen at the cisterna chyli (Fig. 19-52). If the mediastinal pleura are disrupted on both sides, bilateral chylothoraces may occur. Left-sided chylothoraces may develop after a left-sided neck dissection, especially in the region of the confluence of the subclavian and internal jugular veins. Chylothorax may also follow nonsurgical trauma, including penetrating or blunt injuries to the chest or neck area, central line placements, and other surgical misadventures. It may be seen in association with a variety of benign and malignant diseases that generally involve the lymphatic system of the mediastinum or neck.

Pathophysiology. Most commonly, the thoracic duct originates in the abdomen from the cisterna chyli, which is located in the midline, near the level of the second lumbar vertebra. From this origin, the thoracic duct ascends into the chest through the aortic hiatus at the level of T10 to T12, and courses just to the right of the aorta (see Fig. 19-52). As the thoracic duct courses cephalad above the diaphragm, it most commonly remains in the right chest, lying just behind the esophagus, between the aorta and aygos vein. The duct continues superiorly, lying just to the right of the vertebral column. Then, at the fourth thoracic vertebra, it crosses behind the aorta and the aortic arch into the left posterior mediastinum and travels superiorly, staying near the esophagus and mediastinal pleura as it exits the thoracic inlet. As it exits the thoracic inlet, it passes to the left, just behind the carotid sheath and anterior to the inferior thyroid and vertebral bodies. Just medial to the anterior scalene muscle, it courses inferiorly and drains into the union of the internal jugular and subclavian veins. Given the extreme variability in the main duct and its branches, accumulation of chyle in the chest or flow from penetrating wounds may be seen after a variety of traumatic and medical conditions.

The main function of the duct is to transport fat absorbed from the digestive system along with variable amounts of protein and lymphatic material (Table 19-39). Given the high volume of chyle that flows through the thoracic duct, significant injuries can cause leaks in excess of 2 L per day; if left untreated, protein, lymphocyte, and volume depletion can lead to serious metabolic effects and death. Thoracentesis is usually grossly suggestive, revealing milky, nonpurulent pleural fluid. However, if the patient is taking nothing by mouth, the pleural fluid may not be grossly abnormal. Laboratory analysis of the pleural fluid shows the presence of chylomicrons, a high lymphocyte count and high triglyceride levels. If the triglyceride level is greater than 110 mg/100 mL, a chylothorax is almost certainly present (a 99% accuracy rate). If the triglyceride level is less than 50 mg/mL, there is only a 5% chance of chylothorax. In many clinical situations, the accumulation of chyle may be slow because of minimal digestive fat flowing through the gastrointestinal tract after major trauma or surgery, so the diagnosis may be more difficult to establish.

Management. The treatment plan for any chylothorax depends on its cause, the amount of drainage, and the patient’s clinical status (Fig. 19-53). In general, most patients are treated with a short period of chest tube drainage, nothing by mouth (NPO) orders, total parenteral nutrition (TPN), and observation. In centers with interventional radiology expertise, thoracic duct embolization as soon as possible after diagnosis should be considered.

Chest cavity drainage must be adequate to allow complete lung reexpansion. Somatostatin has been advocated by some authors, with variable results. If significant chyle drainage (>500 mL per day in an adult, >100 mL in an infant) continues despite TPN and good lung expansion, early surgical duct ligation or embolization is recommended (within 4–7 days following diagnosis). Ligation can be approached best by right thoracotomy, and in some experienced centers, by right thoracoscopy. Chylothoraces due to malignant conditions often respond to radiation and/or chemotherapy and less commonly require surgical ligation. Significant nutritional and immunologic depletion results from untreated chylothorax; associated mortality is in excess of 50%. With early recognition and aggressive medical management as well as early surgical ligation or embolization for persistent leaks, the mortality rate of chylothorax is now less than 10%.

**Tumors of the Pleura**

Malignant mesothelioma is the most common type of primary tumor of the pleura, with approximately 3000 cases per year in the United States. Other, less common tumors include benign and malignant fibrous tumors of the pleura, lipomas, and cysts.

**Malignant Mesothelioma.** The only known risk factor for mesothelioma is exposure to asbestos, identified in over 50% of cases. Exposure is typically work-related in industries using asbestos in the manufacturing process, such as shipbuilding and brake pad linings. The risk extends to family members who are
exposed to the dust of the clothing or to the work environment. Asbestos exposure and smoking synergistically increase the risk for lung cancer, but smoking does not increase risk for malignant mesotheliomas. Male predominance is 2:1, and it occurs most commonly after the age of 40.

Risk of developing mesothelioma after asbestos exposure differs depending on the physical characteristics of the asbestos and similar fibers (either serpentine or amphibole). The serpentine fibers are large and curly and are generally not able to travel beyond larger airways. However, the narrow, straight amphibole fibers, in particular the crocidolite fibers, may navigate distally into the pulmonary parenchyma and are most clearly associated with mesotheliomas. Like many carcinogens, the latency period between asbestos exposure and the development of mesothelioma is at least 20 years. The tumor generally is multicentric, with multiple pleural-based nodules coalescing to form sheets of tumor. This process initially involves the parietal pleura, generally with early spread to the visceral surfaces and with a variable degree of invasion of surrounding structures. Autopsy studies have shown that most patients have distant metastases, but the natural history of the disease in untreated patients culminates in death due to local extension and effective stranulation of the lung.

Clinical Presentation Most patients present with dyspnea and chest pain. Over 90% have a pleural effusion, but thoracentesis is diagnostic in less than 10% of patients. Frequently, a thoracoscopy or open pleural biopsy with special stains is required to differentiate mesotheliomas from adenocarcinomas (Table 19-40). Epithelial subtypes are associated with a more favorable prognosis, and long-term survival may be seen in rare patients with no treatment. Sarcomatous and mixed tumors share a more aggressive course.

Management The treatment of malignant mesotheliomas remains controversial. Treatment options include supportive care only, surgical resection, and multimodality approaches (using a combination of surgery, chemotherapy, and radiation therapy). Surgical approaches range from extrapleural pneumonectomy (removal of the lung, entire parietal pleural, ipsilateral pericardium, and hemidiaphragm with patch reconstruction), pleurectomy and decortication (removal of the visceral and parietal pleura only), and palliative procedures such as talc pleurodesis and insertion of long-term tunneled indwelling pleural catheters.

**Fibrous Tumors of the Pleura.** Fibrous tumors of the pleura are unrelated to asbestos exposure or malignant mesotheliomas. They generally occur as a single pedunculated mass arising from the visceral pleura but can occasionally arise from the parietal pleura. They can grow to be quite large, with most ranging from 5 to 10 cm and 100 to 400 g in size by the time they are discovered. Architecturally, the most common microscopic feature is the “patternless pattern.” This is characterized by randomly situated areas of hypercellularity, containing spindle cells with bland, vesicular, ovoidal nuclei and scarce cytoplasm, and hypocellularity, with fibrous connective tissue, hemorrhage, myxoid, or necrosis. They can also have an hemangiopericytoma-like appearance. The neoplastic cells are immunoreactive for CD34 and CD99 but negative for cytokeratins and desmin. Immunoreactivity for Bcl-2 is variably positive. They are frequently discovered incidentally on routine CXRs, without an associated pleural effusion. They occur with equal frequency in males and females and are most common in the sixth to seventh decade of life. Fibrous tumors of the pleura may be benign or malignant. Symptoms such as cough, chest pain, and dyspnea occur in 30% to 40% of patients but are found in 75% of patients with malignant tumors. Malignant tumors are differentiated from benign tumors based on high cellularity, more than four mitotic figures per 10 high-power fields, nuclear pleomorphism, tumor necrosis, and hemorrhage. They are more likely to arise from the parietal pleura of the chest wall, diaphragm, or mediastinum, or in the fissures or invading into the lung parenchyma. Hypoglycemia, associated pleural effusion, and hypertrophic pulmonary osteoarthropathy (clubbed digits, long bone ossifying periostitis, and arthritis) are associated with these lesions in approximately 25% of patients. Less common are fever and hemoptysis. Symptoms resolve with surgical resection. Given the well-circumscribed and often pedunculated nature of fibrous tumors of the pleura, all benign lesions and approximately 50% of malignant lesions are cured by complete surgical resection. Incompletely resected malignant tumors may recur locally or metastasize, and more than 50% of patients with malignant tumors will die from the disease; frequently, they are fatal within 2 to 5 years.

INTRODUCTION

Congenital heart surgery is a dynamic and evolving field. The last 20 years have brought about rapid developments in technology, emphasis on a multidisciplinary approach to treatment, and a more thorough understanding of both the anatomy and pathophysiology of congenital heart disease, leading to the improved care of these challenging patients.

These advancements have created a sustained paradigm shift in the field of congenital heart surgery. The traditional strategy of initial palliation followed by definitive correction at a later age, which had pervaded the thinking of most surgeons, began to evolve into emphasizing early repair. Defects such as hypoplastic left heart syndrome (HLHS) are now successfully managed with staged palliation, resulting in excellent survival outcomes for these children.

The goal in most cases of congenital heart disease (CHD) is appropriate timing of complete repair. Rather than subdividing lesions into cyanotic or noncyanotic lesions, a more appropriate classification divides defects into three categories based on the feasibility of achieving complete repair: (a) defects that have no reasonable palliation and for which repair is the only option; (b) defects for which repair is not possible and for which palliation is the only option; and (c) defects that can either be repaired or palliated in infancy. It bears mentioning that all defects in the second category are those in which the appropriate anatomic components either are not present, as in hypoplastic left heart syndrome, or cannot be created from existing structures, i.e., unguarded tricuspid orifice.

Eight out of every 1000 live births will have some form of CHD, most of which, however, are mild.1 In the United States nearly 40,000 infants are affected each year.2 As of 2010, it is estimated that there are about 2 million people living with CHD in the United States, and as of 2011 there are more adults (>18) than children.3 CHD is the most common birth defect and the most common cause of infant death related to birth defects, accounting for 28% of deaths due to birth defects in the first month of life. There are currently 127 centers in North America that perform congenital heart surgery. The Society for Thoracic Surgeons (STS) reports an overall national mortality of 3.1%.3

DEFECTS AMENABLE TO COMPLETE REPAIR

Atrial Septal Defect

An atrial septal defect (ASD) is defined as discontinuity of the interatrial septum that permits direct mixing of blood between the systemic venous and pulmonary venous circulations.

Embryology. The atrial and ventricular septa form between the third and sixth weeks of fetal development. After the paired heart tubes fuse into a single tube folded onto itself, the distal portion of the tube indents to form the roof of the common atrium. Near this portion of the roof, the septum primum originates and descends in a crescentic formation toward the atrioventricular (AV) junction. The ostium primum is situated superiorly to the crux of the heart at the atrioventricular junction. Prior to completion of endocardial cushion fusion with the septum primum, a sequence of fenestrations appear that coalesce into the
ostium secundum. During this coalescence, the septum secundum grows downward from the roof of the atrium, parallel to and to the right of the septum primum. The septum primum does not fuse, but creates an oblique pathway, called the foramen ovale, within the interatrial septum. After birth, the increase in left atrial pressure associated with an increase in systemic vascular resistance (SVR) typically closes this pathway in approximately 80% of the population, obliterating the interatrial communication.

**Anatomy.** ASDs can be classified into three different types (Fig. 20-1): (a) ostium secundum type defect (Fig. 20-1B,C) (deficiency of septum primum), which are the most prevalent subtype, comprising 80% of all ASDs; (b) ostium primum defects (Fig. 20-1A), which may also be described as partial or transitional AV canal defect; and (c) sinus venosus type defects, comprising approximately 5% to 10% of all ASDs.4

**Pathophysiology.** ASDs result in an increase in pulmonary blood flow secondary to primarily left-to-right shunting through the defect. The direction of the intracardiac shunt is predominantly determined by the compliance of the respective ventricles. In utero, the distensibility, or compliance, of the right and left ventricles is equal, but postnatally the left ventricle (LV) becomes less compliant than the right ventricle (RV). This shift occurs because the resistance of the downstream vascular beds changes after birth. The pulmonary vascular resistance falls with the infant’s first breath, decreasing RV pressure, whereas the systemic vascular resistance rises dramatically, increasing LV pressure. The increase in LV pressure promotes hypertrophy with a thicker muscle mass, which offers a greater resistance to diastolic filling than does the RV; thus, the majority of flow through the ASD occurs from left to right. The greater volume of blood returning to the right atrium causes volume overload in the RV, but because of its lower muscle mass and low-resistance output, it easily distends to accommodate the increased volume.

The long-term consequences of RV volume overload include hypertrophy with elevated RV end-diastolic pressure and a relative pulmonary stenosis across the pulmonary valve because it cannot accommodate the increased RV flow. Compliance gradually decreases as the right ventricular pressure approaches systemic pressure, and the size of the left-to-right shunt decreases. Patients at this stage have a balanced circulation and may deceptively appear less symptomatic.
Patients with large ASDs gradually develop progressive pulmonary vascular changes as a result of chronic overcirculation. The increased pulmonary vascular resistance in these patients leads to an equalization of left and right ventricular pressures, and their ratio of pulmonary (Qp) to systemic flow (Qs), Qp to Qs, will approach 1.\(^5\) This does not mean, however, that there is no intracardiac shunting, only that the ratio between the left-to-right component and the right-to-left component is equal.

The ability of the RV to recover normal function is related to the duration of chronic overload because those undergoing ASD closure before age 10 years have a better likelihood of achieving normal RV volumes and function in the postoperative period.\(^6\)

The physiology of sinus venosus ASDs is similar to that discussed earlier, except that these are frequently accompanied by anomalous pulmonary venous drainage. This often results in significant hemodynamic derangements that accelerate the clinical course of these infants.

The same increase in symptoms is true for those with ostium primum defects because the associated mitral insufficiency from the “cleft” mitral valve can lead to more atrial volume load and increased atrial level shunting.

**Diagnosis.** Patients with ASDs upon auscultation may reveal prominence of the first heart sound with fixed splitting of the second heart sound. This results from the relatively fixed left-to-right shunt throughout all phases of the cardiac cycle. A diastolic flow murmur indicating increased flow across the tricuspid valve may be discerned, and frequently, an ejection flow murmur can be heard across the pulmonary valve. A right ventricular heave and increased intensity of the pulmonary component of the second heart sound indicates pulmonary hypertension.

Chest radiographs in the patient with an ASD demonstrate increased pulmonary vascularity, with prominent hilar markings and cardiomegaly. The electrocardiogram shows right axis deviation with an incomplete bundle-branch block. When right bundle-branch block is associated with a leftward or superior axis, an AV canal defect should be strongly suspected.

Diagnosis is clarified by two-dimensional echocardiography (Fig. 20-1A,C), and use of color-flow mapping facilitates an understanding of the physiologic derangements created by the defects. Older children and adults with unrepaired ASDs may present with stroke or systemic embolism from paradoxical embolism or atrial arrhythmias from dilatation of the right atrium.

Echocardiography also enables the clinician to estimate the amount of intracardiac shunting, and it can demonstrate the degree of mitral regurgitation in patients with ostium primum defects. With the addition of an agitated saline injection (bubble study), it can also assist in the detection of sinus venosus defects.

The advent of two-dimensional echocardiography with color-flow Doppler has largely superseded the use of cardiac catheterization because the ASD can be well defined by echocardiography alone. However, in cases where the right ventricular systolic pressure is elevated, or patient is older than age 40 years, catheterization can quantify the degree of pulmonary hypertension because those with a fixed pulmonary vascular resistance greater than 12 U/mL may be considered inoperable.\(^7\)

Cardiac catheterization also can be useful in that it provides data that enable the calculation of Qp and Qs so that the magnitude of the intracardiac shunt can be determined. The ratio (Qp to Qs) can then be used to determine whether closure is indicated in equivocal cases, because a ratio of Qp to Qs greater than 1.5:1

---

**Figure 20-1.** A. Echocardiogram of a patient with primum type atrial septal defect (‘*’ points to the atrial septal defect). B. Echocardiogram of a large secundum type ASD (‘*’ points to the defect). C. Intra-operative picture during repair of atrial septal defect. A large fenestrated atrial septum is seen. Bicaval venous cannulation has been performed and a right atriotomy provides exposure to the atrial septum.
is generally accepted as the threshold for surgical intervention. Finally, in patients older than age 40 years, cardiac catheterization can be important to evaluate for the presence of coronary artery disease.

In general, ASDs are closed when patients are between 4 and 5 years of age. Children of this size can usually be operated on without the use of blood transfusion and have excellent outcomes. Patients who are symptomatic may require repair earlier, even in infancy. Some surgeons advocate routine repair in infants and children especially in cases where prematurity-related lung disease may accelerate damage to the pulmonary vascular bed, though this philosophy may not be widespread. In a review by Reddy and colleagues, 116 neonates weighing less than 2500 g who underwent repair of simple and complex cardiac defects with the use of cardiopulmonary bypass were found to have no intracerebral hemorrhages, no long-term neurologic sequelae, and a low operative mortality rate (10%). These results correlated with the length of cardiopulmonary bypass and the complexity of repair. These investigators also found an 80% actuarial survival at 1 year and, more importantly, that growth following complete repair was equivalent to weight-matched neonates free from cardiac defects.

**Treatment.** Simple secundum type ASDs can frequently be repaired via a transcatheter technique, and assessment for transcatheter closure with TTE assessment is generally indicated prior to consideration of a surgical repair. The most common surgical approach requires standard cardiopulmonary bypass (CPB) technique through a midline sternotomy approach. The details of the repair itself are generally straightforward. An oblique atriotomy is made, the position of the coronary sinus and all systemic and pulmonary veins are determined, and the rim of the defect is completely visualized. Closure of an ostium secundum defect is accomplished either by primary repair or by insertion of a patch that is sutured to the rim of the defect. The decision of whether patch closure is necessary can be determined by the size and shape of the defect as well as by the quality of the edges.

The type of repair used for sinus venosus ASDs associated with partial anomalous pulmonary venous connection is dictated by the location of the anomalous pulmonary vein. If the anomalous veins connect to the atria or to the superior vena cava caudal to where the cava is crossed by the right pulmonary artery, the ASD can be repaired by inserting a patch, with redirection of the pulmonary veins behind the patch to the left atrium. Care must be taken with this approach to avoid obstruction of the pulmonary veins or the superior vena cava, although usually the superior vena cava is dilated and provides ample room for patch insertion. If the anomalous vein connects to the superior vena cava cranial to the right pulmonary artery, an alternative technique, the Warden procedure, may be necessary. In this operation, the superior vena cava is transected cranial to the connection of the anomalous vein (usually the right superior pulmonary vein). The caudal end of the transected cava is oversewn. The cranial end of the transected cava is anastomosed to the auricle of the right atrium. Inside the atrium, a patch is used to redirect pulmonary venous blood flow to the left atrium. In contrast to the repair for a defect where the pulmonary veins enter the right atrium or the superior vena cava below the right pulmonary artery, the patch covers the superior vena cava right atrial junction so that blood from the anomalous pulmonary vein that enters the cava is directed to the left atrium. Blood returning from the upper body enters the right atrium via the anastomosis between the superior vena cava and the right atrial appendage.

**Results and Complications of Surgical ASD Closure.** Traditional operative strategies, such as pericardial or synthetic patch closure, have been well established, with a low complication rate and a mortality rate of zero among patients without pulmonary hypertension. The most frequently reported immediate complications include postpericardiotomy syndrome and atrial arrhythmias. Beyond immediate postoperative outcomes, long-term outcomes following surgical closure (up to 20 years) document the low mortality rates and durability of functional status benefit. Importantly, however, atrial arrhythmias, particularly atrial fibrillation, are not completely mitigated by closure and can occur in 10% to 40% of patients, especially in older patients (>40 years) or those with preexisting arrhythmias. Luo and colleagues performed 300 patients from their institution, 152 of whom had surgical closure. Late mortality at 10 years was 3%, and functional health status had declined in only 15 patients during follow-up. Recently, there have been an increasing number of reports regarding the results following surgical closure among elderly patients (>60 years of age), which demonstrate equivalent survival to younger patients, albeit with slightly higher complication rates. Hanninen and colleagues studied 68 patients between 68 and 86 years at their institution undergoing either surgical (n = 13) or device (n = 54) closure. Although the 23% incidence of major complications (including pneumothorax, heart failure, and pneumonia) was higher than that recently reported by Mascio et al using the Society of Thoracic Surgeons’ Congenital Database (20%) or a single-institution review by Hopkins et al (12%), there were no operative deaths among the elderly cohort. Moreover, after ASD closure, echocardiographic indices of right ventricular size and function were significantly improved from preoperative values, and functional capacity as measured by standardized survey instruments was also significantly improved.

**New and Future Approaches to Traditional Surgical ASD Closure.** Because of the uniformly excellent outcomes with traditional surgery, attention has shifted to improving the cosmetic result and minimizing hospital stay and convalescence. Multiple strategies have been described to achieve these aims, including the right submammary incision with anterior thoracotomy, limited bilateral submammary incision with partial sternal split, and limited midline incision with partial sternal split. Some surgeons use either video-assisted thoracic surgery (VATS) in conjunction with the submammary and transxiphoid approaches to facilitate closure within a constricted operative field or totally endoscopic repair in selected patients. Use of robotics has also been reported in a small series of 12 adult patients by Argenziano and colleagues. The morbidity and mortality of all of these approaches are comparable to those of the traditional median sternotomy; however, each has technical drawbacks. Operative precision must be maintained with limited exposure in any minimally invasive technique. Extended CPB and aortic cross-clamp times, coupled with increased cost, may limit the utility of totally endoscopic or robotic-assisted ASD closure except at specific centers. Moreover, certain approaches have a specific patient population in whom they are most applicable. For example, the anterolateral thoracotomy should not be employed in prepubescent girls because it will interfere with breast development. Most totally endoscopic approaches are not feasible in very young patients because of the size of the thoracoscopic ports. Despite these potential drawbacks, however, in carefully selected patients, minimally invasive techniques have demonstrated benefits. Luo and associates performed
a prospective randomized study comparing ministernotomy (division of the upper sternum for aortic and pulmonary lesions and the lower sternum for septal lesions) to full sternotomy in 100 consecutive patients undergoing repair of septal lesions.\textsuperscript{19} The patients in the ministernotomy group had longer procedure times (by 15 to 20 minutes) but had less bleeding and shorter hospital stays. Consistent with these initiatives, conversion of “low-risk” patients undergoing minimally invasive ASD closure to an ambulatory population (discharge from hospital within 24 hours) has recently been described.\textsuperscript{21}

First performed in 1976, transcatheter closure of ASDs with the use of various occlusion devices is gaining widespread acceptance.\textsuperscript{22} Certain types of ASDs, including patent foramen ovale, secundum defects, and some fenestrated secundum defects, are amenable to device closure, as long as particular anatomic criteria (e.g., an adequate superior and inferior rim for device seating and distance from the AV valve) are met. Since the introduction of percutaneous closure (Fig. 20-2A,B), there has been a dramatic rise in device closure prevalence to the point where device closure has supplanted surgical therapy as the dominant treatment modality for secundum ASD.\textsuperscript{23} A study from Karamlou et al\textsuperscript{23} found that ASD and patent foramen ovale closures per capita increased dramatically from 1.08 per 100,000 population in 1988 to 2.59 per 100,000 population in 2005, an increase of 139%. When analyzed by closure type, surgical closure increased by only 24% (from 0.86 per 100,000 population in 1988 to 1.07 per 100,000 in 2005), whereas transcatheter closure increased by 3475% (from 0.04 per 100,000 population in 1988 to 1.43 per 100,000 in 2005). Importantly, this study determined that the paradigm shift favoring transcatheter closure has occurred mainly due to increased prevalence of closure in adults over age 40 years rather than an increase in closure in infants or children.

Despite the simplicity of ASD repair, there are a myriad of options for patients and physicians who care for patients with CHD. The patient population that might benefit from closure (whether device or surgical) is likely to increase, challenging current ideas and treatment algorithms that optimize outcomes.

### Aortic Stenosis

**Anatomy and Classification.** The spectrum of aortic valve abnormality represents the most common form of CHD, with the great majority of patients being asymptomatic until midlife. Obstruction of the left ventricular outflow tract (LVOT) occurs at multiple levels: subvalvular, valvular, and supraavalvular (Fig. 20-3A-D). The critically stenotic aortic valve in the neonate or infant is commonly unicommissural or bicommissural, with thickened, dysmorphic, and myxomatous leaflet tissue and a reduced cross-sectional area at the valve level. Associated left-sided lesions are often present. In a review of 32 cases from the Children’s Hospital in Boston, 59% had unicommissural valves, and 40% had bicommissural valves.\textsuperscript{24} Associated lesions were frequent, occurring in 88% of patients, most commonly patent ductus arteriosus, mitral regurgitation, and hypoplastic LV. Endocardial fibroelastosis (EFE) also is common among infants with critical aortic stenosis (AS). In this condition, the LV is usually prohibitively hypoplastic and noncompliant, rendering these patients poor candidates for recruitment of the LV into the systemic circulation with techniques that can be utilized in those with more normal sized LVs. In some neonates with critical AS, a dilated LV with poor diastolic compliance rather than a hypertrophied LV is encountered.\textsuperscript{24}

Neonates with critical AS are a challenging population because one must make a decision about the suitability of the left-sided structures to support a biventricular circulation. There are recent approaches that include techniques, such as aortic valvotomy coupled with EFE resection and mitral valve intervention, that are directed at LV rehabilitation. The advent of fetal valvotomy for critical AS may also increase the number of infants who are candidates for biventricular repair.

**Pathophysiology.** The unique intracardiac and extracardiac shunts present in fetal life allow even neonates with critical AS to survive. In utero, left ventricular hypertrophy and ischemia cause left atrial hypertension, which reduces the right-to-left flow across the foramen ovale. In severe cases, a reversal of
Figure 20-3. A. Congenital aortic valve stenosis, en fosse echocardiographic view of the stenotic bicuspid aortic valve. Parasternal long axis ecocardiographic view of a patient with discrete subaortic membrane (‘*’ points to the membrane). C. Parasternal long axis ecocardiographic view of a patient with diffuse tunnel like subvalvar aortic stenosis with membrane. Doppler revealed a gradient of 81 mm of Hg (‘*’ represents the area of diffuse narrowing). D. Appearance of supravalvar aortic stenosis on an aortogram performed in the cardiac catheterization lab (‘*’ points to the stenosis). E. Appearance after four patch reconstruction of the same patient shown in Figure 20.3 d. (Re-formatted images obtained from a CT angiogram).
flow may occur, causing right ventricular volume loading. The RV then provides the entire systemic output via the patent ductus arteriosus (ductal-dependent systemic blood flow). Although cardiac output is maintained, the LV suffers continued damage as the intracavitary pressure precludes adequate coronary perfusion, resulting in LV infarction and subendocardial fibroelastosis. The presentation of the neonate with critical AS is then determined by the morphology of the LV and other left-sided heart structures, the degree of left ventricular dysfunction, and the completeness of the transition from a parallel circulation to an in-series circulation (i.e., on closure of the foramen ovale and the ductus arteriosus). Those infants with mild-to-moderate AS in whom LV function is preserved are asymptomatic at birth. The only abnormalities may be a systolic ejection murmur and electrocardiogram (ECG) evidence of left ventricular hypertrophy. However, those neonates with severe AS and compromised LV function are unable to provide adequate cardiac output at birth and will present in circulatory collapse once the ductus closes, with dyspnea, tachypnea, irritability, narrowed pulse pressure, oliguria, and profound metabolic acidosis. If ductal patency is maintained, systemic perfusion will be provided by the RV via ductal flow, and cyanosis may be the only finding.

**Diagnosis.** Neonates and infants with severe valvar AS may have a relatively nonspecific history of irritability and failure to thrive. Angina, if present, is usually manifested by episodic, inconsolable crying that coincides with feeding. As discussed previously, evidence of poor peripheral perfusion, such as extreme pallor, indicates severe LVOT obstruction. Differential cyanosis is an uncommon finding, but it is present when enough antegrade flow occurs only to maintain normal upper body perfusion, while a large patent ductus arteriosus produces blue discoloration of the abdomen and legs.

Physical findings include a systolic ejection murmur, although a quiet murmur may paradoxically indicate a more severe condition with reduced cardiac output. A systolic click correlates with a valvular etiology of obstruction. As LV dysfunction progresses, evidence of congestive heart failure occurs.

The chest radiograph is variable but may show dilatation of the aortic root, and the ECG often demonstrates LV hypertrophy. Echocardiography with Doppler flow is extremely useful in establishing the diagnosis, as well as quantifying the transvalvular gradient. Furthermore, echocardiography can facilitate evaluation for the several associated defects that can be present in critical neonatal AS, including mitral stenosis, LV hypoplasia, LV endocardial fibroelastosis, subaortic stenosis, VSD, or coarctation. The presence of any or several of these defects has important implications related to treatment options for these patients. Although cardiac catheterization is not routinely performed for diagnostic purposes, it can be invaluable as part of the treatment algorithm if the lesion is amenable to balloon valvotomy. Magnetic resonance imaging (MRI) is another very useful technique for assessing the adequacy of the left-sided structures and is increasingly utilized to determine candidacy for biventricular repairs.

**Treatment.** As alluded to previously, the first decision that must be made in the neonate with critical LVOT obstruction is whether the patient is a candidate for biventricular or univentricular repair. Central to this decision is assessment of the degree of hypoplasia of the LV and other left-sided structures. Alsoufi and colleagues have described a rational approach to the neonate with critical LVOT obstruction. The options vary depending on whether the infant follows a single or a biventricular pathway. The options for a single ventricle include the Norwood operation, a hybrid strategy (initial ductal stent and bilateral pulmonary artery bands followed by later completion of the Norwood operation) or heart transplantation. The options for a biventricular heart include balloon valvuloplasty, surgical valvotomy, neonatal Ross operation, or a Yasui operation. Often valvotomy is accompanied by LV rehabilitation techniques, including EFE resection and mitral valve interventions. Fetal aortic valvotomy, which is now offered at specialized centers, is another promising strategy to decompress the LV in fetal life and potentially allow growth of the left-sided structures sufficient to permit a biventricular circulation. Regardless of whether the baby is triaged to a single or biventricular strategy, any infant with severe AS requires urgent intervention. Preoperative stabilization, however, has dramatically altered the clinical algorithm and outcomes for this patient population. The preoperative strategy begins with endotracheal intubation and inotropic support. Prostaglandin infusion is initiated to maintain ductal patency, and confirmatory studies are performed prior to operative intervention. Therapy is generally indicated in the presence of a transvalvular gradient of 50 mmHg with associated symptoms including syncope, CHF, or angina, or if a gradient of 50 to 75 mmHg exists with concomitant ECG evidence of LV strain or ischemia. In the critically ill neonate, a gradient across the aortic valve may not be present because of poor LV function. However, the decision regarding treatment options must be based on a complete understanding of associated defects. For example, in the presence of a hypoplastic LV (left ventricular end-diastolic volume <20 mL/m²) or a markedly abnormal mitral valve, isolated aortic valvotomy should not be performed because studies have demonstrated high mortality in this population following isolated valvotomy.

Patients who have an LV capable of providing systemic output are candidates for intervention to relieve AS, generally through balloon valvotomy. Occasionally, if catheter-based therapy is not an option, relief of valvar AS in infants and children can be accomplished with surgical valvotomy using standard techniques of CPB and direct exposure to the aortic valve. A transverse incision is made in the ascending aorta above the sinus of Valsalva, extending close to, but not into, the noncoronary sinus. Exposure is attained with placement of a retractor into the right coronary sinus. After inspection of the valve, the chosen commissure is incised to within 1 to 2 mm of the aortic wall (Fig. 20-4A,B).

Balloon valvotomy performed in the catheterization lab is generally the procedure of choice for reduction of transvalvular gradients in symptomatic infants and children without significant aortic insufficiency. Balloon valvotomy provides relief of the valvar gradient and allows future surgical intervention (which is generally required in most patients when a larger prosthesis can be implanted) to be performed on an unscarred chest. An important issue when planning aortic valvotomy, whether percutaneously or via open surgical technique, is the risk of inducing hemodynamically significant aortic regurgitation. Induction of more than moderate aortic regurgitation is risky and may result in hemodynamic instability. A gradient of 50 mmHg is generally the upper limit of safety. The decision regarding
The majority of infants who undergo aortic valvotomy will require further intervention on the aortic valve within 10 years following initial intervention.26

Neonates with severely hypoplastic LVs or significant LV endocardial fibroelastosis may not be candidates for biventricular repair and are treated the same as infants with the hypoplastic left heart syndrome (HLHS), which is discussed later (see “Hypoplastic Left Heart Syndrome”).

As mentioned previously, fetal intervention for the aortic valve has been described with the goal being to improve the growth of the left ventricle. The group at Boston Children’s Hospital have reported fairly favorable results in a small cohort.34

Many surgeons previously avoided aortic valve replacement for AS in early childhood because the more commonly used mechanical valves would be outgrown and require replacement later and the obligatory anticoagulation for mechanical valves resulted in a substantial risk for complications. In addition, prosthetic valves have an incidence of bacterial endocarditis or perivalvular leak requiring reintervention.

The use of allografts and the advent of the Ross procedure have largely obviated these issues and made early definitive correction of critical AS a viable option.23,27,28 Donald Ross first described transposition of the pulmonary valve into the aortic position with allograft reconstruction of the pulmonary outflow tract in 1967.27 The result of this operation is a normal trileaflet semilunar valve made of a patient’s native tissue with the potential for growth to adult size in the aortic position in place of the damaged aortic valve (Fig. 20-5). The Ross procedure has become a useful option for aortic valve replacement in children because it has improved durability and can be performed with acceptable morbidity and mortality rates. The placement of a pulmonary conduit, which does not grow and becomes calcified and stenotic over time, does obligate the patient to reintervention (either surgically or using transcatheter techniques) to replace the RV-to-pulmonary artery conduit. Karamlou and colleagues29 have reviewed the outcomes and associated risk factors for aortic valve replacement in 160 children from the Hospital for Sick Children in Toronto. They found that younger age, lower operative weight, concomitant performance of aortic root replacement or reconstruction, and use of prosthesis type other than a pulmonary autograft were significant predictors of death, whereas the use of a bioprosthetic or allograft valve type and earlier year of operation were identified as significant risk factors for repeated aortic valve replacement. Autograft use was associated with a blunted progression of the peak prosthetic valve gradient and a rapid decrease in the left ventricular end-diastolic dimension. In agreement with these findings, Lupinetti and colleagues29 have reviewed the outcomes and associated risk factors for aortic valve replacement with the Ross procedure and found a more significant transvalvular gradient reduction and regression of left ventricular hypertrophy in those patients who underwent the Ross procedure. In some cases, the pulmonary valve may not be usable because of associated defects or congenital absence. These children are not candidates for the Ross procedure and can be treated with cryopreserved allografts (cadaveric human aortic valves) or prosthetic aortic valve replacement. At times, there may be a size discrepancy between the right ventricular outflow tract (RVOT) and the LVOT, especially in cases of severe critical AS in infancy. For these cases, the pulmonary autograft is placed in a manner that also provides enlargement of the aortic annulus (Ross/Konno).

Subvalvular AS occurs beneath the aortic valve and may be classified as discrete or tunnel-like (diffuse). A thin,
fibromuscular diaphragm immediately proximal to the aortic valve characterizes discrete subaortic stenosis. This diaphragm typically extends for 180° or more in a crescentic or circular fashion, often attaching to the mitral valve as well as the interventricular septum. The aortic valve itself is usually normal in this condition, although the turbulence imparted by the subvalvular stenosis may affect leaflet morphology and valve competence.

Diffuse subvalvular AS results in a long, tunnel-like obstruction that may extend to the left ventricular apex. In some individuals, there may be difficulty in distinguishing between hypertrophic cardiomyopathy and diffuse subaortic stenosis. Operation for subvalvular AS is indicated with a gradient exceeding 30 mmHg, in the presence of aortic valve insufficiency, or when symptoms indicating LVOT obstruction are present. Given that repair of isolated discrete subaortic stenosis can be done with low rates of morbidity and mortality, some surgeons advocate repair in all cases of discrete AS to avoid progression of the stenosis and the development of aortic insufficiency, although more recent data demonstrate that subaortic resection should be delayed until the LV gradient exceeds 30 mmHg because most children with an initial LV gradient less than 30 mmHg have quiescent disease. Diffuse AS is a more complex lesion and often requires aortoventriculoplasty. Results are generally excellent, with operative mortality less than 5%.

Supravalvular AS occurs more rarely and also can be classified into a discrete type, which produces an hourglass deformity of the aorta, and a diffuse form that can involve the entire arch and brachiocephalic arteries. The aortic valve leaflets are usually normal, but in some cases, the leaflets may adhere to the supravalvular stenosis, thereby narrowing the sinuses of Valsalva in diastole and restricting coronary artery perfusion. In addition, accelerated intimal hyperplastic changes in the coronary arteries can be demonstrated in these patients because the proximal position of the coronary arteries subjects them to abnormally high perfusion pressures.

The signs and symptoms of supravalvular AS are similar to other forms of LVOT obstruction. An asymptomatic murmur is the presenting manifestation in approximately half of these patients. Syncope, poor exercise tolerance, and angina may all occur with nearly equal frequency. Supravalvar AS is associated with Williams’ syndrome, a constellation of elfin facies, mental retardation, and hypercalcemia. Following routine evaluation, cardiac catheterization should be performed in order to delineate coronary anatomy, as well as to delineate the degree of obstruction. A gradient of 50 mmHg or greater is an indication for operation. However, the clinician must be cognizant of any coexistent lesions, most commonly pulmonic stenosis, which may add complexity to the repair.

The localized form of supravalvular AS can be treated by creating an inverted Y-shaped aortotomy across the area of stenosis, straddling the right coronary artery. The obstructing shelf is then excised, and a pantaloon-shaped patch (Doty technique) or individual sinus patch enlargement (Brom technique) is used (Fig. 20-3E).

The diffuse form of supravalvular stenosis is more variable (Fig. 20-6), and the particular operative approach must be tailored to each specific patient’s anatomy. In general, either an aortic endarterectomy with patch augmentation can be performed or if the narrowing extends past the aorta arch, a prothetic graft can be placed between the ascending and descending aorta. Operative results for discrete supravalvular AS are generally good, with a hospital mortality of less than 1% and an actuarial survival rate exceeding 90% at 20 years. In contrast, however, the diffuse form is more hazardous to repair and carried a mortality of 15% in a recent series.

Patent Ductus Arteriosus

Anatomy. The ductus arteriosus is derived from the sixth aortic arch and normally extends from the main or left pulmonary artery to the upper descending thoracic aorta, distal to the left subclavian artery. In the normal fetal cardiovascular system, ductal flow is considerable (approximately 60% of the combined ventricular output) and is directed exclusively from the pulmonary artery to the aorta. In infancy, the length of the ductus may vary from 2 to 8 mm, with a diameter of 4 to 12 mm.

Locally produced and circulating prostaglandin E2 (PGE2) and prostaglandin I2 (PGI2) induce active relaxation of the ductal musculature, maintaining maximal patency during the fetal period. At birth, increased pulmonary blood flow metabolizes these prostaglandin products, and absence of the placenta removes an important source of them, resulting in a marked decrease in these ductal-relaxing substances. In addition, release of histamines, catecholamines, bradykinin, and acetylcholine all promote ductal contraction. Despite all of these complex...
interactions, the rising oxygen tension in the fetal blood is the main stimulus causing smooth muscle contraction and ductal closure within 10 to 15 hours postnatally. Anatomic closure by fibrosis produces the ligamentum arteriosum connecting the pulmonary artery to the aorta.

Delayed closure of the ductus is termed prolonged patency, whereas failure of closure causes persistent patency, which may occur as an isolated lesion or in association with more complex congenital heart defects. In many of these infants with more complex congenital heart defects, either pulmonary or systemic perfusion may depend on ductal flow, and these infants may decompensate if exogenous PGE is not administered to maintain ductal patency.

Natural History. The incidence of patent ductus arteriosus (PDA) is approximately 1 in every 2000 births; however, it increases dramatically with increasing prematurity. In some series, PDAs have been noted in 75% of infants of 28 to 30 weeks gestation. Persistent patency occurs more commonly in males, with a 2:1 ratio.

PDA is not a benign entity, although prolonged survival has been reported. The estimated death rate for infants with isolated, untreated PDA is approximately 30%. The leading cause of death is congestive heart failure, with respiratory infection as a secondary cause. Endocarditis is more likely to occur with a small ductus and is rarely fatal if aggressive antibiotic therapy is initiated early.

Clinical Manifestations and Diagnosis. After birth, in an otherwise normal cardiovascular system, a PDA results in a left-to-right shunt that depends on both the size of the ductal lumen and its total length. As the pulmonary vascular resistance falls 8 to 10 weeks postnatally, the shunt will increase, and its flow will ultimately be determined by the relative resistances of the pulmonary and systemic circulations.

The hemodynamic consequences of an unrestrictive ductal shunt are left ventricular volume overload with increased left atrial and pulmonary artery pressures and right ventricular strain from the augmented afterload. These changes result in increased sympathetic discharge, tachycardia, tachypnea, and ventricular hypertrophy. The diastolic shunt results in lower aortic diastolic pressure and increases the potential for myocardial ischemia and underperfusion of other systemic organs, while the increased pulmonary flow leads to increased work of breathing and decreased gas exchange. Unrestrictive ductal flow may lead to pulmonary hypertension within the first year of life. These changes will be significantly attenuated if the size of the ductus is only moderate, and they will be completely absent if the ductus is small.

Physical examination of the afflicted infant will reveal evidence of a hyperdynamic circulation with a widened pulse pressure and a hyperactive precordium. Auscultation demonstrates a systolic or continuous murmur, often termed a machinery murmur. Cyanosis is not present in uncomplicated isolated PDA.

The chest radiograph may reveal increased pulmonary vascularity or cardiomegaly, and the ECG may show LV strain, left atrial enlargement, and possibly RV hypertrophy. Echocardiogram with color mapping reliably demonstrates the patency of the ductus as well as estimates the shunt size. Cardiac catheterization is necessary only when pulmonary hypertension is suspected.

Therapy. The presence of a persistent PDA is sufficient indication for closure because of the increased mortality and risk of endocarditis. In older patients with pulmonary hypertension, closure may not improve symptoms and is associated with much higher mortality.

In premature infants, aggressive intervention with indomethacin or ibuprofen to achieve early closure of the PDA is beneficial unless contraindications such as necrotizing enterocolitis or renal insufficiency are present. Term infants, however, are generally unresponsive to pharmacologic therapy with indomethacin, so mechanical closure must be undertaken once the diagnosis is established. This can be accomplished either surgically (Fig. 20-7) or with catheter-based therapy. Currently, transluminal placement of various occlusive devices, such as the Rashkind double-umbrella device or embolization with Gianturco coils, is in widespread use. However, there are a number of complications inherent with the use of percutaneous devices, such as thromboembolism, endocarditis, incomplete occlusion, vascular injury, and hemorrhage secondary to perforation. In addition, these techniques may not be applicable in very young infants because the peripheral vessels do not provide adequate access for the delivery devices. Attempts are being made to develop such devices for premature infants with early successful results in study populations.

Surgical closure can be achieved via either open or video-assisted approaches. The open approach employs a muscle-sparing posterior lateral thoracotomy in the third or fourth intercostal space on the side of the aorta (generally the left). The lung is then retracted anteriorly. In the neonate, the PDA is singly ligated with a surgical clip or permanent suture. Care must be taken to avoid the recurrent laryngeal nerve, which courses around the aortic arch. Occasionally, a short, broad ductus, in which the dimension of

Figure 20-6. Reformatted image obtained after CT angiography of a child with diffuse supravalvar aortic stenosis (‘*’ points to the transverse aortic arch).
its width approaches that of its length, will be encountered. In this case, division between vascular clamps with oversewing of both ends is advisable (Fig. 20-8). In extreme cases, the use of CPB to decompress the large ductus during ligation is an option. Video-assisted thoracoscopic occlusion, using metal clips, also has been described, although it offers few advantages over the standard surgical approach. Preterm newborns and children may do well with a surgical technique, while older patients (older than age 5 years) and those with smaller ducts (<3 mm) do well with coil occlusion. In fact, Moore and colleagues recently concluded from their series that coil occlusion is the procedure of choice for ducts smaller than 4 mm.45 Complete closure rates using catheter-based techniques have steadily improved.

**Outcomes.** In premature infants, the surgical mortality is very low, although the overall hospital death rate is significant as a consequence of other complications of prematurity. In older infants and children, mortality is less than 1%. Bleeding, chylothorax, vocal cord paralysis, and the need for reoperation occur infrequently. With the advent of muscle-sparing thoracotomy, the risk of subsequent arm dysfunction or breast abnormalities is virtually eliminated.46

**Aortic Coarctation**

**Anatomy.** Coarctation of the aorta (COA) is defined as a luminal narrowing in the aorta that causes an obstruction to blood flow. This narrowing is most commonly located distal to the left subclavian artery. The embryologic origin of COA is a subject of some controversy. One theory holds that the obstructing shelf, which is largely composed of tissue found within the ductus, forms as the ductus involutes.47 The other theory holds that a diminished aortic isthmus develops secondary to decreased aortic flow in infants with enhanced ductal circulation.

Extensive collateral circulation develops, predominantly involving the intercostals and mammary arteries as a direct result of aortic flow obstruction. This translates into the well-known finding of “rib-notching” on chest radiograph, as well as a prominent pulsation underneath the ribs.

Other associated anomalies, such as ventricular septal defect, PDA, and ASD, may be seen with COA, but the most common is that of a bicuspid aortic valve, which can be demonstrated in 25% to 42% of cases.48

**Pathophysiology.** Infants with COA develop symptoms consistent with left ventricular outflow obstruction, including pulmonary overcirculation and, later, biventricular failure. In addition, proximal systemic hypertension develops as a result of mechanical obstruction to ventricular ejection, as well as hypoperfusion-induced activation of the renin-angiotensin-aldosterone system.
Interestingly, hypertension is often persistent after surgical correction despite complete amelioration of the mechanical obstruction and pressure gradient.\textsuperscript{49} It has been shown that early surgical correction may prevent the development of long-term hypertension, which undoubtedly contributes to many of the adverse sequelae of COA, including the development of circle of Willis aneurysms, aortic dissection and rupture, and an increased incidence of coronary arteriopathy with resulting myocardial infarction.\textsuperscript{50}

**Diagnosis.** COA is likely to become symptomatic either in the newborn period if other anomalies are present or in the late adolescent period with the onset of left ventricular failure.

Physical examination will demonstrate a hyperdynamic precordium with a harsh murmur localized to the left chest and back. Femoral pulses will be dramatically decreased when compared to upper extremity pulses, and differential cyanosis may be apparent until ductal closure.

Echocardiography will reliably demonstrate the narrowed aortic segment, as well as define the pressure gradient across the stenotic segment. In addition, detailed information regarding other associated anomalies can be gleaned. Aortography (Fig. 20-9) is reserved for those cases in which the echocardiographic findings are equivocal. Cross-sectional imaging with computed tomography (CT) scan or MRI is also increasing to facilitate definition of arch anatomy (i.e., transverse arch hypoplasia), assess intracardiac volumes, and associated defects.

**Therapy.** The routine management of hemodynamically significant COA in all age groups has traditionally been surgical. Transcatheter repairs (Fig. 20-10) are used with increasing frequency in older patients and those with recoarctation following surgical repair. Balloon dilatation of native coarctation in neonates generally is avoided because of the high recoarctation rate. However, in infants who present with severely depressed LV function and a closed ductus arteriosus, initial decompression with balloon dilation of the COA followed by later surgical intervention may be useful. The most common surgical techniques in current use are resection with end-to-end anastomosis or extended end-to-end anastomosis, taking care to remove all residual ductal tissue.\textsuperscript{51,52} Extended end-to-end anastomosis (Fig. 20-11) may also allow the surgeon to treat transverse arch hypoplasia, which is commonly encountered in infants with aortic coarctation.\textsuperscript{53,54} The subclavian flap

\textbf{Figure 20-10.} \textbf{A.} Reformatted images obtained from a CT angio-gram of a child with discrete coarctation of the aorta (\textsuperscript{*} points to the coarctation). \textbf{B.} Aortogram performed in the cardiac catheterization lab after stenting the coarctation (\textsuperscript{*} points to the stent).
Aortoplasty is another repair, although it is used less frequently in the modern era because of the risk of late aneurysm formation and possible underdevelopment of the left upper extremity ischemia. In this method, the left subclavian artery is transected and brought down over the coarcted segment as a vascularized patch. The main benefit of these techniques is that they do not involve the use of prosthetic materials, and evidence suggests that extended end-to-end anastomosis may promote arch growth, especially in infants with the smallest initial aortic arch diameters.

Despite the benefits, however, extended end-to-end anastomosis may not be feasible when there is a long segment of coarctation or in the presence of previous surgery because sufficient mobilization of the aorta above and below the lesion may not be possible. In this instance, prosthetic materials, such as a patch aortoplasty, in which a prosthetic patch is used to enlarge the coarcted segment, or an interposition tube graft must be employed. One of the most important decisions in infants and neonates with COA and some degree of transverse arch hypoplasia is whether the lesion should be approached with a sternotomy or a thoracotomy. Cross-sectional imaging with CT scan can be extremely helpful in assessing the adequacy of the transverse arch and any associated abnormalities with branching that may complicate repair from the side.

The most common complications after COA repair are late restenosis (Fig. 20-12) and aneurysm formation at the repair site. Aneurysm formation is particularly common after patch aortoplasty when using Dacron material. In a large series of 891 patients, aneurysms occurred in 5.4% of the total, with 89% occurring in the group who received Dacron-patch aortoplasty and only 8% occurring in those who received resection with primary end-to-end anastomosis. A further complication, although uncommon, is lower-body paralysis resulting from ischemic spinal cord injury during the repair. This dreaded outcome complicates 0.5% of all surgical repairs, but its incidence can be lessened with the use of some form of distal perfusion, preferably left heart bypass with the use of femoral arterial or distal thoracic aorta for arterial inflow and the femoral vein or left atrium for venous return. These techniques are generally reserved for older patients with complex coarctations that may need prolonged aortic cross clamp times for repair, often in the setting of large collateral vessels and/or previous surgery.

Hypertension is also well recognized following repair of COA. Bouchart and colleagues reported that in a cohort of 35 hypertensive adults (mean age, 28 years) undergoing repair, despite a satisfactory anatomic outcome, only 23 patients were normotensive at a mean follow-up period of 165 months. Likewise, Bhat and associates reported that in a series of 84 patients (mean age at repair, 29 years), 31% remained hypertensive at a mean follow-up of 5 years following surgery.

Although operative repair is still the gold standard, treatment of COA by catheter-based intervention has become more widespread for older children and adults. Both balloon dilatation and primary stent implantation have been used successfully. The most extensive study of the results of balloon angioplasty reported on 970 procedures: 422 native and 548 recurrent COAs. Mean gradient reduction was 74% ± 24% for native and 70% ± 31% for recurrent COA. This demonstrated that catheter-based therapy could produce equally effective results both in recurrent and in primary COA, a finding with far-reaching implications in the new paradigm of multidisciplinary treatment algorithms for CHD. In the Valvuloplasty and Angioplasty of Congenital Anomalies (VACA) report, higher preangioplasty gradient, earlier procedure date, older patient age, and the presence of recurrent COA were independent risk factors for suboptimal procedural outcome.

The gradient after balloon dilatation in most series is generally acceptable. However, there is a significant minority of patients (0%–26%) for whom the procedural outcome is suboptimal, with a postprocedure gradient of 20 mmHg or greater. These patients may be ideal candidates for primary stent placement. Deaths from the procedure also are infrequent (<1% of cases), and the main major complication is aneurysm formation,
which occurs in 7% of patients. With stent implantation, many authors have demonstrated improved resolution of stenosis compared with balloon dilatation alone, yet the long-term complications on vessel wall compliance remain largely unknown because only mid-term data are widely available.

In summary, children younger than age 6 months with native COA should be treated with surgical repair, while those requiring intervention at later ages may be ideal candidates for balloon dilatation or primary stent implantation. Additionally, catheter-based therapy should be employed for those cases of restenosis following either surgical or primary endovascular management.

**Truncus Arteriosus**

**Anatomy.** Truncus arteriosus is a rare anomaly, comprising between 1% and 2% of all live born cases of CHD. It is characterized by a single great artery that arises from the heart, overrides the ventricular septum, and supplies the pulmonary, systemic, and coronary circulations.

The two major classification systems are those of Collett and Edwards, described in 1949, and Van Praagh, described in 1965 (Fig. 20-13). The Collett and Edwards classification focuses mainly on the origin of the pulmonary arteries from the common arterial trunk, whereas the Van Praagh system is based on the presence or absence of a VSD, the degree of formation of the aortopulmonary septum, and the status of the aortic arch.

During embryonic life, the truncus arteriosus normally begins to separate and spiral into a distinguishable anterior pulmonary artery and posterior aorta. Persistent truncus, therefore, represents an arrest in embryologic development at this stage. Other implicated events include twisting of the dividing truncus because of ventricular looping, subinfundibular atresia, and abnormal location of the semilunar valve anlagen.

The neural crest may also play a crucial role in the normal formation of the great vessels, as experimental studies in chick embryos have shown that ablation of the neural crest results in persistent truncus arteriosus. The neural crest also develops into the pharyngeal pouches that give rise to the thymus and parathyroids, which likely explains the prevalent association of truncus arteriosus and DiGeorge’s syndrome.

The annulus of the truncal valve usually straddles the ventricular septum in a “balanced” fashion; however, it is not unusual for it to be positioned predominantly over the RV, which increases the potential for LVOT obstruction following surgical repair. In the great majority of cases, the leaflets are thickened and deformed, which leads to valvular insufficiency. There are usually three leaflets (60%), but occasionally a bicuspid (5%) or even a quadricuspid valve (25%) is present.

In truncus arteriosus, the pulmonary trunk bifurcates, with the left and right pulmonary arteries forming posteriorly and to the left in most cases. The caliber of the pulmonary arterial branches is usually normal, with stenosis or diffuse hypoplasia occurring in rare instances.

The coronary arteries may be normal; however, anomalies are not unusual and occur in 50% of cases. Many of these are relatively minor, although two variations are of particular importance because they have implications in the conduct of operative repair. The first is that the left coronary ostium may arise high in the sinus of Valsalva or even from the truncal tissue at the margin of the pulmonary artery tissue. This coronary artery can be injured during repair when the pulmonary arteries are removed from the trunk or when the resulting truncal defect is closed. The second is that the right coronary artery can give rise to an important accessory anterior descending artery, which often passes across the RV in the exact location where the right ventriculotomy is commonly performed during repair.

**Physiology and Diagnosis.** The main pathophysiologic consequences of truncus arteriosus are (a) the obligatory mixing of systemic and pulmonary venous blood at the level of the ventricular septal defect (VSD) and truncal valve, which leads to arterial saturations near 85% and (b) the presence of a nonrestrictive left-to-right shunt, which occurs during both systole and diastole, the volume of which is determined by the relative resistances of the pulmonary and systemic circulations. Additionally, truncal valve stenosis or regurgitation, the presence of important LVOT obstruction, and stenosis of pulmonary artery branches can further contribute to both pressure and volume-loading of the ventricles. The presence of these lesions often results in severe heart failure and cardiovascular instability early in life. Pulmonary vascular resistance may develop as early as 6 months of age, leading to poor results with late surgical correction.

Patients with truncus arteriosus usually present in the neonatal period, with signs and symptoms of congestive heart failure and mild to moderate cyanosis. A pansystolic murmur may be noted at the left sternal border, and occasionally a diastolic murmur may be heard in the presence of truncal regurgitation.

Chest radiography will be consistent with pulmonary overcirculation, and a right aortic arch can be appreciated 35% of the time. The thymus is prominent by its absence if associated with DiGeorge syndrome (Fig. 20-14). The ECG is usually nonspecific, demonstrating normal sinus rhythm with biventricular hypertrophy.

Echocardiography with Doppler color-flow or pulsed Doppler is diagnostic and usually provides sufficient information to determine the type of truncus arteriosus, the origin of the
coronary arteries and their proximity to the pulmonary trunk, the character of the truncal valves, and the extent of truncal insufficiency (Fig. 20-15). CT scan helps define the pulmonary arteries and the coronary anatomy (Fig. 20-16). Cardiac catheterization can be helpful in cases where pulmonary hypertension is suspected or to further delineate coronary artery anomalies prior to repair.

The presence of truncus is an indication for surgery. Repair should be undertaken in the neonatal period or as soon as the diagnosis is established.

**Repair.** Truncus arteriosus was first managed with pulmonary artery banding as described by Armer and colleagues in 1961. However, this technique led to only marginal improvements in 1-year survival rates because ventricular failure inevitably occurred. In 1967, however, complete repair was accomplished by McGoon and his associates based on the experimental work of Rastelli, who introduced the idea that an extracardiac valved conduit could be used to restore ventricular-to-pulmonary artery continuity. Over the next 20 years, improved survival rates led to uniform adoption of complete repair even in the youngest and smallest infants.

Surgical correction entails the use of CPB. Repair is completed by separation of the pulmonary arteries from the aorta, closure of the aortic defect (occasionally with a patch) to minimize coronary flow complications, placement of a valved cryopreserved allograft or jugular venous valved conduit (Contegra) to reconstruct the RVOT, and VSD closure. Important branch pulmonary arterial stenosis should be repaired at the time of complete repair and can usually be accomplished with longitudinal allograft patch arterioplasty. Severe truncal valve insufficiency occasionally requires truncal valve repair or even replacement, which can be accomplished with a cryopreserved allograft.

**Results.** The results of complete repair of truncus have steadily improved. Ebert reported a 91% survival rate in his series of 77 patients who were younger than 6 months of age; later reports by others confirmed these findings and demonstrated that excellent results could be achieved in even smaller infants with complex-associated defects.

Newer extracardiac conduits also have been developed and used with success, which has widened the repertoire of the modern congenital heart surgeon and improved outcomes. Severe truncal regurgitation, interrupted aortic arch, coexistent coronary anomalies, chromosomal or genetic anomalies, and age younger than 100 days are risk factors associated with perioperative death and poor outcome.

**Total Anomalous Pulmonary Venous Connection**

Total anomalous pulmonary venous connection (TAPVC) occurs in 1% to 2% of all cardiac malformations and is characterized by abnormal drainage of the pulmonary veins into the right heart, whether through connections into the right atrium or into its tributaries. Accordingly, the only mechanism by which oxygenated blood can return to the left heart is through an ASD, which is almost uniformly present with TAPVC.
Unique to this lesion is the absence of a definitive form of palliation. Thus, TAPVC with concomitant obstruction (Fig. 20-17) represents one of the only true surgical emergencies across the entire spectrum of congenital heart surgery.

**Anatomy and Embryology.** The lungs develop from an outpouching of the foregut, and their venous plexus arises as part of the splanchnic venous system. TAPVC arises when the pulmonary vein evagination from the posterior surface of the left atrium fails to fuse with the pulmonary venous plexus surrounding the lung buds. In place of the usual connection to the left atrium, at least one connection of the pulmonary plexus to the splanchnic plexus persists. Accordingly, the pulmonary veins drain to the heart through a systemic vein.

Darling and colleagues classified TAPVC (Fig. 20-18) according to the site or level of connection of the pulmonary veins to the systemic venous system: type I (45%), anomalous connection at the supracardiac level; type II (25%), anomalous connection at the cardiac level; type III (25%), anomalous connection at the infracardiac level; and type IV (5%), anomalous connection at multiple levels. Within each category, further subdivisions can be implemented, depending on whether pulmonary venous obstruction exists. Obstruction to pulmonary venous drainage is a powerful predictor of adverse natural outcome and occurs most frequently with the infracardiac type, especially when the pattern of infracardiac connection prevents the ductus venosus from bypassing the liver.

**Pathophysiology and Diagnosis.** Because both pulmonary and systemic venous blood returns to the right atrium in all forms of TAPVC, a right-to-left intracardiac shunt must be present in order for the afflicted infant to survive. This invariably occurs via a nonrestrictive patent foramen ovale. Because of this obligatory mixing, cyanosis is usually present, and its degree depends on the ratio of pulmonary to systemic blood flow. Decreased pulmonary blood flow is a consequence of pulmonary venous obstruction, the presence of which is unlikely if the right ventricular pressure is less than 85% of systemic pressure.

The child with TAPVC may present with severe cyanosis and respiratory distress, necessitating urgent surgical intervention if a severe degree of pulmonary venous obstruction is present. However, in cases where there is no obstructive component, the clinical picture is usually one of pulmonary overcirculation, hepatomegaly, tachycardia, and tachypnea with feeding. In a child with serious obstruction, arterial blood gas analysis reveals severe hypoxemia (partial pressure of oxygen \([P_{O_2}] < 20 \text{ mmHg}\)), with metabolic acidosis.

Chest radiography (Fig. 20-19) will show normal heart size with generalized pulmonary edema. Two-dimensional echocardiography is very useful in establishing the diagnosis and also can assess ventricular septal position, which may be leftward secondary to small left ventricular volumes, as well as estimate the right ventricular pressure based on the height of the tricuspid regurgitant jet. Echocardiography can usually identify the pulmonary venous connections (types I to IV), and it is rarely necessary to perform other diagnostic tests.

Cardiac catheterization is not recommended in these patients because the osmotic load from the intravenous contrast can exacerbate the degree of pulmonary edema. When cardiac catheterization is performed, equalization of oxygen saturations in all four heart chambers is a hallmark finding in this disease because the mixed blood returned to the right atrium gets distributed throughout the heart.

**Therapy.** Operative correction of TAPVC requires anastomosis of the common pulmonary venous channel to the left atrium, obliteration of the anomalous venous connection, and closure of the ASD.
All types of TAPVC are approached through a median sternotomy, and many surgeons use deep hypothermic circulatory arrest in order to achieve an accurate and widely patent anastomosis. The technique for supracardiac TAPVC includes early division of the vertical vein, retraction of the aorta and the superior vena cava laterally to expose the posterior aspect of the left atrium and the pulmonary venous confluence, and a side-to-side anastomosis between a long, horizontal bialtrial incision and a longitudinal incision within the pulmonary venous confluence. The ASD can then be closed with an autologous pericardial or synthetic patch.

In patients with TAPVC to the coronary sinus without obstruction, a simple unroofing of the coronary sinus can be performed through a single right atriotomy with concomitant closure of the ASD. If pulmonary venous obstruction is present, the repair should include generous resection of roof of the coronary sinus.79

Repair of infracardiac TAPVC entails ligation of the vertical vein at the diaphragm, followed by construction of a proximal, patulous longitudinal venotomy. This repair is usually performed by “rolling” the heart toward the left, thus exposing the left atrium where it usually overlies the descending vertical vein.

As originally described by Lacour-Gayet and colleagues at the Marie-Lannelongue Hospital, Paris, and Coles and colleagues at The Hospital for Sick Children, Toronto, the sutureless technique was developed for patients with anastomotic stenosis occurring after TAPVC repair.80,81 After determining that favorable outcomes were possible using this technique, it is currently used in selected patients upon initial presentation of TAPVC.81 Incisions are made in the venous confluence. Based on the surgeon’s discretion, the incisions are extended into both upper and lower pulmonary veins separately if judged to be important for an unobstructed pathway. An atrioatrial anastomosis is created using the pericardium adjacent to where the pulmonary veins enter the pericardium (Fig. 20-20). This anastomosis avoids direct contact with the incision site in the wall of the pulmonary veins and allows the free egress of blood from the lungs to the left atrium.

Results. Results of TAPVC in infancy have markedly improved in recent years, with an operative mortality of 5% or less in some series.79,82 This improvement is probably multifactorial, mainly as a consequence of early noninvasive diagnosis and aggressive perioperative management. The routine use of echocardiography; improvements in myocardial protection with specific attention to the RV; creation of a large, tension-free anastomosis with maximal use of the venous confluence and atrial tissue; use of a sutureless technique in selected cases; and prevention of pulmonary hypertensive events have likely played a major role in reducing operative mortality. The importance of risk factors for early mortality, such as venous obstruction at presentation, urgency of operative repair, and infradiaphragmatic anatomic type, has been debated.81,83

Bando and colleagues84 made the controversial statement that both preoperative pulmonary venous obstruction and anatomic type had been neutralized as potential risk factors beyond calendar year 1991. Hyde et al82 similarly reported that connection type was not related to outcome. However, a large single-institution report of 377 children with TAPVC by the author from the Hospital for Sick Children in Toronto85 found that, although outcomes had improved over time, patient anatomic factors were still important determinants of both survival and the need for subsequent reoperation. Risk factors for postrepair death were earlier operation year, younger age at repair, cardiac connection type, and postoperative pulmonary venous obstruction. Risk-adjusted estimated 1-year survival for a patient repaired at birth with unfavorable morphology in 2006 was 37% (95% confidence interval [CI], 8%–80%) compared with 96% (95% CI, 91%–99%) for a patient with favorable morphology repaired at age 1 year. Freedom from reoperation was 82% ± 6%.
at 11 years after repair, with increased risk associated with mixed connection and postoperative pulmonary venous obstruction. A study from the Hospital for Sick Children, Toronto, showed a lower incidence of reoperation in the sutureless technique compared to conventional pulmonary venous confluence–left atrial anastomosis. However, there was no statistically significant difference suggesting similar results between the strategies. Although the sutureless technique appears to have favorable outcomes at primary repair for TAPVC, long-term follow-up is necessary to evaluate the occurrence of arrhythmias, such as complete heart block and atrial tachycardia, since an incision on the atrial septum and atrial wall is more invasive compared to the conventional technique.

The most significant postoperative complication of TAPVC repair is pulmonary venous obstruction (Figure 20-21), which occurs 9% to 11% of the time, regardless of the surgical technique employed. Mortality varies between 30% and 45%, and alternative catheter interventions do not offer definitive solutions. Recurrent pulmonary venous obstruction can be localized at the site of the pulmonary venous anastomosis (extrinsic), which usually can be cured with patch enlargement or balloon dilatation, or it may be secondary to endocardial thickening of the pulmonary venous ostia frequently resulting in diffuse pulmonary venous sclerosis (intrinsic), which carries a 66% mortality rate because few good solutions exist. More commonly, postrepair left ventricular dysfunction can occur as the noncompliant LV suddenly is required to handle an increased volume load from redirected pulmonary venous return. This can manifest as an increase in pulmonary artery pressure but is distinguishable from primary pulmonary hypertension (another possible postoperative complication following repair of TAPVC) from the elevated left atrial pressure and LV dysfunction along with echocardiographic evidence of poor LV contractility. In pulmonary hypertension, the left atrial pressure may be low, the LV may appear “underfilled” (by echocardiography), and the RV may appear dilated. In either case, postoperative support for a few days with extracorporeal membrane oxygenation may be lifesaving, and TAPVC should be repaired in centers that have this capacity.

Some investigators have speculated that preoperative pulmonary venous obstruction is associated with increased medial thickness within the pulmonary vasculature, which may predispose these infants to intrinsic pulmonary venous stenosis despite adequate pulmonary venous decompression. The majority of studies demonstrating that preoperative pulmonary venous obstruction is a predictor of subsequent need for reoperation to correct recurrent pulmonary venous obstruction lend credence to this notion.

**Cor Triatriatum**

**Anatomy.** Cor triatriatum is a rare congenital heart defect characterized by the presence of a fibromuscular diaphragm that partitions the left atrium into two chambers: a superior chamber that receives drainage from the pulmonary veins, and an inferior chamber that communicates with the mitral valve and the LV (Fig. 20-22). An ASD frequently exists between the superior chamber and the right atrium, or, more rarely, between the right atrium and the inferior chamber.

**Pathophysiology and Diagnosis.** Cor triatriatum results in obstruction of pulmonary venous return to the left atrium. The degree of obstruction is variable and depends on the size of fenestrations present in the left atrial membrane, the size of the ASD, and the existence of other associated anomalies. If the communication between the superior and inferior chambers is <3 mm, patients usually are symptomatic during the first year of life. The afflicted infant will present with the stigmata of low cardiac output and pulmonary venous hypertension, as well as congestive heart failure and poor feeding.

Physical examination may demonstrate a loud pulmonary S2 sound and a right ventricular heave, as well as jugular venous distention and hepatomegaly. Chest radiography will show cardiomegaly and pulmonary vascular prominence, and the ECG will suggest right ventricular hypertrophy. Two-dimensional echocardiography provides a definitive diagnosis in most cases, with catheterization necessary only when echocardiographic evaluation is equivocal.

**Therapy.** Operative treatment for cor triatriatum is fairly simple. CPB and cardioplegic arrest are used. A right atriotomy usually
allows access to the left atrial membrane through the existing ASD because it is dilated secondary to communication with the pulmonary venous chamber. The membrane is then excised, taking care not to injure the mitral valve or the interatrial septum, and the ASD is closed with a patch. Alternatively, if the right atrium is small, the membrane can be exposed through an incision directly into the superior left atrial chamber, just anterior to the right pulmonary veins. Surgical results are uniformly excellent for this defect, with survival approaching 100%.

The utility of catheter-based intervention for this diagnosis remains controversial, although there have been some reports of successful balloon dilatation.

**Aortopulmonary Window**

**Embryology and Anatomy.** Aortopulmonary window (APW) is a rare congenital lesion, occurring in about 0.2% of patients, characterized by incomplete development of the septum that normally divides the truncus into the aorta and the pulmonary artery.

In the vast majority of cases, APW occurs as a single defect of minimal length, which begins a few millimeters above the semilunar valves on the left lateral wall of the aorta (Fig. 20-23). Coronary artery anomalies, such as aberrant origin of the right or left coronary artery from the main pulmonary artery, are occasionally present.

**Pathophysiology and Diagnosis.** The dominant pathophysiology of APW is that of a large left-to-right shunt with increased pulmonary flow and the early development of congestive heart failure. Like other lesions with left-to-right flow, the magnitude of the shunt is determined by both the size of the defect and the pulmonary vascular resistance.

Infants with APW present with frequent respiratory tract infections, tachypnea with feeding, and failure to thrive. Cyanosis usually is absent because these infants deteriorate prior to the onset of significant pulmonary hypertension. The rapid decline with this defect occurs because shunt flow continues during both phases of the cardiac cycle, which limits systemic perfusion and increases ventricular work.

The diagnosis of APW begins with the physical examination, which may demonstrate a systolic flow murmur, a hyperdynamic precordium, and bounding peripheral pulses. The chest radiograph will show pulmonary overcirculation and cardiomegaly, and the ECG will usually demonstrate either left ventricular hypertrophy or biventricular hypertrophy. Echocardiography (Fig. 20-24) can detect the defect and also provide information about associated anomalies. Retrograde aortography will confirm the diagnosis but is rarely necessary.

**Therapy.** All infants with APW require surgical correction once the diagnosis is made. Repair is undertaken through a median sternotomy and the use of CPB. The pulmonary arteries are occluded once the distal aorta is cannulated, and a transaortic repair using a prosthetic patch for pulmonary artery closure is then carried out. The coronary ostia must be carefully visualized and included on the aortic side of the patch. Alternatively, a two-patch technique can be used, which may eliminate recurrent fistulas from suture line leaks that occasionally occur with the single-patch method.

**Results.** Results are generally excellent, with an operative mortality in most large series of less than 5%.

**Vascular Rings and Pulmonary Artery Slings**

Vascular rings constitute a group of disorders derived from anomalies that result from abnormal development of the aortic arches resulting in compression of the trachea or esophagus. The surgical management of vascular rings dates back to 1945 when Dr. Gross described the surgical management of a kid with double aortic arch. Most children present with symptoms during the first few months of life. Vascular rings can be complete (e.g., double aortic arch, right aortic arch with left ligation) or partial (e.g., innominate artery compression syndrome, pulmonary artery sling).

**Anatomy.** The embryologic basis of vascular rings involves the development of six pairs of aortic arches and the dorsal and ventral aortae. The development of a specific type of vascular ring depends on the deletion or preservation of a specific segment of these structures. The persistence of the right and left fourth arches leads to the development of double aortic arch. Persistence of the fourth right aortic arch and the involution of the left fourth arch leads to the development of a right aortic arch system with various combinations of mirror imaging.

SPECIFIC CONSIDERATIONS

branching, aberrant subclavian arteries or with a left-sided ligamentum arteriosum. When the developing left lung captures its blood supply from the right sixth arch caudad to the tracheobronchial tree, it leads to the development of a pulmonary artery sling. The left pulmonary artery arises from the right pulmonary artery and then wraps around the trachea and esophagus forming a “sling.” The pathophysiology of innominate artery compression syndrome is not very well understood.

Pathophysiology and Diagnosis. The symptoms associated with vascular rings include respiratory distress, barking cough, stridor, apnea, and recurrent respiratory tract infections. The diagnosis often requires a high index of suspicion. Minor respiratory tract infections may precipitate serious respiratory distress. The work up includes chest X-rays, echocardiography, bronchoscopy, CT scan (Fig. 20-25), MRI (Fig. 20-26), and, rarely, cardiac catheterization. Chest X-rays show the relationship of the aortic arch to the trachea. Tracheal compression can be better evaluated using lateral films. Unilateral hyperinflation of the lung is sometimes seen and is often associated with a pulmonary artery sling (Fig. 20-27). PA slings (Fig. 20-28) are often associated with complete tracheal rings necessitating a bronchoscopy when this diagnosis is made (Fig. 20-29).

Patients with dysphagia require a barium esophagogram as a part of their work-up (Fig. 20-30).

Treatment. All symptomatic patients should undergo surgery. On close questioning nearly all patients are asymptomatic. The treatment varies depending on the type of vascular ring. A left posterolateral thoracotomy provides good exposure to most types. A right thoracotomy is often used for innominate artery compression syndrome, and a median sternotomy often with cardiopulmonary bypass is used to treat pulmonary artery slings with or without associated complete tracheal rings. The outcomes and results for vascular rings are excellent (Fig. 20-31). Video-assisted thoracoscopic approaches have been developed for the management of these conditions.94-96 The criticism often stated involves retraction of vascular structures into the mediastinum and losing control of the stumps prior to definitive control leading to exsanguination.96

DEFECTS REQUIRING PALLIATION

Tricuspid Atresia

Tricuspid atresia occurs in 2% to 3% of patients with CHD and is characterized by atresia of the tricuspid valve. This results in discontinuity between the right atrium and RV. The RV is generally hypoplastic, and left-heart filling is dependent on an ASD. Tricuspid atresia is the most common form of the single-ventricle complex, indicating that there is functionally only one ventricular chamber.

Anatomy. As mentioned, tricuspid atresia results in a lack of communication between the right atrium and the RV, and in the
majority of patients there is no identifiable valve tissue or remnant. The right atrium is generally enlarged and muscular, with a fibrofatty floor. An unrestrictive ASD is usually present. The LV is often enlarged as it receives both systemic and pulmonary blood flow, but the left AV valve is usually normal.

The RV, however, is usually severely hypoplastic, and there is sometimes a VSD in its trabeculated or infundibular portion. In many cases, the interventricular communication is a site of obstruction to pulmonary blood flow, but obstruction may also occur at the level of the outlet valve or in the subvalvular infundibulum. In most cases, pulmonary blood flow is dependent on the presence of a PDA, and there may be no flow into the pulmonary circulation except for this PDA.

Tricuspid atresia is classified according to the relationship of the great vessels and by the degree of obstruction to pulmonary blood flow. Because of the rarity of tricuspid atresia with transposed great arteries, we will restrict our discussion to tricuspid atresia with normally related great vessels.

Pathophysiology. The main pathophysiology in tricuspid atresia is that of a univentricular heart of left ventricular morphology. That is, the LV must receive systemic blood via the interatrial communication and then distribute it to both the pulmonary circulation and the systemic circulation. Unless there is a VSD (as is found in some cases), pulmonary flow is dependent on the presence of a PDA. As the ductus begins to close shortly after birth, infants become intensely cyanotic. Reestablishing ductal patency (with PGE$_1$) restores pulmonary blood flow and stabilizes patients for surgical intervention. Pulmonary hypertension is unusual in tricuspid atresia. However, occasional patients have a large VSD between the LV and the infundibular portion of the RV (just below the pulmonary valve). If there is no obstruction at the level of this VSD or at the valve, these infants may actually present with heart failure from excessive pulmonary blood flow. Regardless of whether these infants are “ductal-dependent” for pulmonary blood flow or have pulmonary blood flow provided across a VSD, they will be cyanotic since the obligatory right-to-left shunt at the atrial level will provide complete mixing of systemic and pulmonary venous return so that the LV ejects a hypoxic mixture into the aorta.

Diagnosis. The signs and symptoms of tricuspid atresia are dependent on the underlying anatomic variant, but most infants are cyanotic and hypoxic as a result of decreased pulmonary blood flow and the complete mixing at the atrial level. When pulmonary blood flow is provided through a VSD, there may be a prominent systolic murmur. Tricuspid atresia with pulmonary blood flow from a PDA may present with the soft, continuous murmur of a PDA in conjunction with cyanosis.

In the minority of patients with tricuspid atresia, symptoms of congestive heart failure will predominate. This is often related to excessive flow across a VSD. The natural history of the muscular VSDs in these infants is that they will close and the congestive heart failure will dissipate and transform into cyanosis with reduced pulmonary blood flow. Chest radiography will show decreased pulmonary vascularity. The ECG is strongly suggestive because uncharacteristic left axis deviation will be present, due to underdevelopment of the RV. Two-dimensional echocardiography readily confirms the diagnosis and the anatomic subtype. (Fig 20-32)

Treatment. The treatment for tricuspid atresia in the earlier era of palliation was aimed at correcting the defect in the pulmonary circulation. That is, patients with too much pulmonary flow received a pulmonary band, and those with insufficient flow received a systemic-to-pulmonary artery shunt. Systemic-to-pulmonary artery shunts, or Blalock-Taussig (BT) shunts, were first applied to patients with tricuspid atresia in the 1940s and 1950s. Likewise pulmonary artery banding was applied.
to patients with tricuspid atresia and congestive failure in 1957. However, despite the initial relief of either cyanosis or congestive heart failure, long-term mortality was high, as the single ventricle was left unprotected from either volume or pressure overload.

Recognizing the inadequacies of the initial repairs, Glenn described the first successful cavopulmonary anastomosis, an end-to-side right pulmonary artery-to-superior vena cava shunt in 1958, and later modified this to allow flow to both pulmonary arteries. This end-to-side right pulmonary artery-to-superior vena cava anastomosis was known as the bidirectional Glenn, and it is the first stage to final Fontan repair in widespread use today (Fig. 20-33). The Fontan repair was a major advancement in the treatment of CHD, as it essentially bypassed the right heart and allowed separation of the pulmonary and systemic circulations. It was first performed by Fontan in 1971 and consisted of a classic Glenn anastomosis, ASD closure, and direct connection of the right atrium to the proximal end of the left pulmonary artery using an aortic homograft. The main pulmonary artery was ligated, and a homograft valve was inserted into the orifice of the inferior vena cava.

Multiple modifications of this initial repair were performed over the next 20 years. One of the most important was the description by deLeval and colleagues of the creation of an interatrial lateral tunnel that allowed the inferior vena caval blood to be channeled exclusively to the superior vena cava. A total cavopulmonary connection could then be accomplished by dividing the superior vena cava and suturing the superior portion to the upper side of the right pulmonary artery and the inferior end to the augmented undersurface of the right pulmonary artery. Pulmonary flow then occurs passively, in a laminar fashion, driven by the central venous pressure. This repair became known as the modified Fontan operation.

Another important modification, the fenestrated Fontan repair, was introduced in 1988. In this procedure, a residual 20% to 30% right-to-left shunt is either created or left unrepaired at the time of cavopulmonary connection to help sustain systemic output in the face of transient elevations in the pulmonary vascular resistance postoperatively.

Figure 20-32. Echo showing tricuspid atresia. The ‘*’ demonstrates the membranous tissue instead of the presence of a tricuspid valve.

Figure 20-33. Angiogram showing a widely patent Glenn. The SVC (‘*’) is seen draining into the central pulmonary artery.
The last notable variation on the original Fontan repair uses an extracardiac prosthetic tube graft (Fig. 20-34), usually 18 to 20 mm in diameter, as the conduit directing inferior vena cava blood to the pulmonary arteries. This technique has the advantages of decreasing atrial geometric alterations by avoiding intra-atrial suture lines and improving flow dynamics in the systemic venous pathway by maximizing laminar flow. Several investigators have shown a decrease in supraventricular arrhythmias, as well as an improvement in ventricular function, which may be secondary to decreased atrial tension and alleviation of chronic elevations in coronary sinus pressure.

One potential disadvantage of the extracardiac Fontan is that it delays performance of the Fontan in order to allow placement of a conduit of sufficient size. Despite these innovative approaches, the current strategy for operative management still relies on the idea of palliation. Patients are approached in a staged manner, to maximize their physiologic state so that they will survive to undergo a Fontan operation. The therapeutic strategy must begin in the neonatal period and should be directed toward reducing the patient’s subsequent risk factors for a Fontan procedure. Accordingly, small systemic pulmonary shunts, which are usually performed through a median sternotomy, should be constructed for palliation of ductus-dependent univentricular physiology. This can easily be replaced with a bidirectional Glenn shunt or hemi-Fontan operation at 6 months of life. In non–ductus-dependent univentricular physiology, the infant can be managed medically until primary construction of a bidirectional cavopulmonary anastomosis becomes feasible. This is possible in the majority of cases because the physiologically elevated pulmonary vascular resistance prevents pulmonary overcirculation during the neonatal period.

The Fontan is usually performed when the child is between 2 and 4 years of age, and it is generally successful if the infant was staged properly, with a protected single ventricle, and there is adequate pulmonary artery growth. The pulmonary vascular resistance should be below 4 Wood units, and the ejection fraction should be more than 45% to ensure success. In patients with high pulmonary artery pressure, fenestration of the atrial baffle may be helpful because their pulmonary vascular resistance may preclude adequate cardiac output postoperatively.

**Results.** Recent reports of the Fontan procedure for tricuspid atresia have been encouraging, with an overall survival of 86% and an operative mortality of 2%. The main complications following repair are atrial arrhythmias, particularly atrial flutter; conduit obstruction requiring reoperation; protein-losing enteropathy; and decreased exercise tolerance.

A prospective multi-institutional study from the Congenital Heart Surgeons Society reported the outcomes of 150 neonates with tricuspid atresia and normally related great vessels. Five-year survival was 86%, and by the age of 2 years, 89% had undergone cavopulmonary anastomosis, and 75% of those surviving cavopulmonary anastomosis underwent Fontan operation within 3 years. Competing risks methodology was used in this study to determine the rates of transition to end-states and their associated determinants (Fig. 20-35). Risk factors for death without cavopulmonary anastomosis in this study included the presence of mitral regurgitation and palliation with systemic-to-pulmonary artery shunts not originating from the innominate artery. Factors associated with decreased transition rate to cavopulmonary anastomosis included patient variables (younger age at admission to a participating institution and noncardiac anomalies) and procedural variables (larger systemic-to-pulmonary arterial shunt diameter and previous palliation).

**Hypoplastic Left Heart Syndrome**

HLHS comprises a wide spectrum of cardiac malformations, including hypoplasia or atresia of the aortic and mitral valves and hypoplasia of the LV and ascending aorta. HLHS has a reported prevalence of 0.2 per 1000 live births and occurs twice as often in boys as in girls. Left untreated, HLHS is invariably fatal and is responsible for 25% of early cardiac deaths in neonates. However, the recent evolution of palliative surgical procedures has dramatically improved the outlook for patients with HLHS, and an improved understanding of anatomic and physiologic alterations has spurred advances in parallel arenas such as intrauterine diagnosis and fetal intervention, echocardiographic imaging, and neonatal critical care.

**Anatomy.** As implied by its name, HLHS involves varying degrees of underdevelopment of left-sided structures (Fig. 20-36), including the LV and the aortic and mitral valves. Thus, HLHS can be classified into four anatomic subtypes based on the valvular morphology: (a) aortic and mitral stenosis; (b) aortic and mitral atresia; (c) aortic atresia and mitral stenosis; and (d) AS and mitral atresia. Aortic atresia tends to be associated with more severe degrees of hypoplasia of the ascending aorta than does AS.

Even in cases without frank aortic atresia, however, the aortic arch is generally hypoplastic and, in severe cases, may even be interrupted. There is an associated coarctation shelf in 80% of patients with HLHS, and the ductus itself is usually quite large, as is the main pulmonary artery.

The segmental pulmonary arteries, however, are small, secondary to reduced intravascular pulmonary blood flow, which is itself a consequence of the left-sided outflow obstruction (Fig. 20-36). The left atrial cavity is generally smaller than normal and is accentuated because of the leftward displacement of the septum primum. There is almost always an interatrial communication via the foramen ovale, which can be large, but more
commonly restricts right-to-left flow. In rare cases, there is no atrial-level communication, which can be lethal for these infants because there is no way for pulmonary venous return to cross over to the RV.

Associated defects can occur with HLHS, and many of them have importance with respect to operative repair. For example, if a VSD is present, the LV can retain its normal size during development even in the presence of mitral atresia. This is because a right-to-left shunt through the defect impels growth of the LV. This introduces the feasibility of biventricular repair for this subset of patients.

Although HLHS undoubtedly results from a complex interplay of developmental errors in the early stages of cardiogenesis, many investigators have hypothesized that the altered blood flow is responsible for the structural underdevelopment that characterizes HLHS. In other words, if the stimulus for normal development of the ascending aorta from the primordial aortic sac is high-pressure systemic blood flow from the LV through the aortic valve, then an atretic or stenotic aortic valve, which impedes flow and leads to only low-pressure diastolic retrograde flow via the ductus, will change the developmental signals and result in hypoplasia of the downstream structures (Fig. 20-37). Normal growth and development of the LV and mitral valve can be secondarily affected, resulting in hypoplasia or atresia of these structures.

**Pathophysiology and Diagnosis.** In HLHS, pulmonary venous blood enters the left atrium, but atrial systole cannot propel blood across the stenotic or atretic mitral valve into the LV. Thus, the blood is shunted across the foramen ovale into the right atrium, where it contributes to volume loading of the RV. The end result is pulmonary venous hypertension from outflow obstruction at the level of the left atrium, as well as pulmonary overcirculation and right ventricular failure. As the pulmonary vascular resistance falls postnatally, the condition is exacerbated because right ventricular output is preferentially directed away from the systemic circulation, resulting in profound underperfusion of the coronary arteries and the vital organs. Closure of the ductus is incompatible with life in these neonates.

Neonates with severe HLHS receive all pulmonary, systemic, and coronary blood flow from the RV. Generally, a child with HLHS will present with respiratory distress within the first day of life, and mild cyanosis may be noted. These infants must be rapidly triaged to a tertiary center, and echocardiography should be performed to confirm the diagnosis. Prostaglandin E$_1$ must be administered to maintain ductal patency, and the

---

**Figure 20-35.** Competing risks depiction of events after diagnosis in 150 patients with tricuspid atresia. All patients began alive and thereafter migrated to one of four mutually exclusive end states (death, bidirectional cavopulmonary anastomosis [BDCPA], single-stage Fontan completion, or remaining alive without BDCPA) at time-dependent rates defined by the underlying hazard functions. At any point in time, the sum of proportions of children in each state is 100%. For example, estimated prevalences after 2 years from diagnosis are as follows: 89% BDCPA, 6% dead without BDCPA, 4% alive without BDCPA, and 1% single-stage Fontan completion. Solid lines represent parametric point estimates; dashed lines enclose 70% confidence intervals; circles with error bars represent nonparametric estimates; numbers in parentheses indicate the estimated proportion of patients in each state at 2 years from diagnosis. *(Reproduced with permission from Karamlou T, Ashburn DA, Caldarone CA, et al: Matching procedure to morphology improves outcomes in neonates with tricuspid atresia, J Thorac Cardiovasc Surg. 2005 Dec;130(6):1503-1510.)*

**Figure 20-36.** Echo In a patient with HLHS. Note the extremely hypoplastic left ventricle (*`).
ventilatory settings must be adjusted to avoid excessive oxygenation and increase carbon dioxide tension. These maneuvers will maintain pulmonary vascular resistance and promote improved systemic perfusion.

Cardiac catheterization should generally be avoided because it is not usually helpful and might result in injury to the ductus and compromised renal function secondary to the osmotic dye load.

**Treatment.** In 1983, Norwood and colleagues described a two-stage palliative surgical procedure for relief of HLHS that was later modified to the currently used three-stage method of palliation. Stage 1 palliation, also known as the modified Norwood procedure (Fig. 20-38), bypasses the LV by creating a single outflow vessel, the neoaorta, which arises from the RV.

The current technique of arch reconstruction involves completion of a connection between the pulmonary root, the native ascending aorta, and a piece of pulmonary homograft used to augment the diminutive native aorta. There are several modifications of this anastomosis, most notably the Damus-Kaye-Stansel (DKS) anastomosis, which involves dividing both the aorta and the pulmonary artery at the sinotubular junction. The proximal aorta is anastomosed to the proximal pulmonary artery, creating a “double-barreled” outlet from the heart. This outlet is anastomosed to the distal aorta, which can be augmented with homograft material if there is an associated coarctation. At the completion of arch reconstruction, a 3.5- or 4-mm shunt is placed from the innominate artery to the right pulmonary artery. The interatrial septum is then widely excised, thereby creating a large interatrial communication and preventing pulmonary venous hypertension.

The DKS connection, as described earlier, might avoid postoperative distortion of the tripartite connection in the neoaorta, and thus decrease the risk of coronary insufficiency. It can be used when the aorta is 4 mm or larger. Unfortunately, in many infants with HLHS, especially if there is aortic atresia, the aorta is diminutive and often less than 2 mm in diameter. The alternate technique available to provide pulmonary blood flow instead of a shunt is a RV-PA conduit often referred to as a “Sano.” It is usually a 5 or 6 mm ribbed Gore-tex graft.

The postoperative management of infants following stage 1 palliation is complex because favorable outcomes depend on establishing a delicate balance between pulmonary and systemic perfusion. Recent literature suggests that these infants require adequate postoperative cardiac output in order to supply both the pulmonary and the systemic circulations and that the use of oxi-metric catheters to monitor mixed venous oxygen saturation (Svo₂) aids clinicians in both the selection of inotropic agents and in ventilatory management. Introduction of a shunt between the RV and the pulmonary artery (Sano shunt) diminishes the diastolic flow created by the modified BT shunt and may augment coronary perfusion, resulting in improved postoperative cardiac function. A recent prospective, randomized, multi-institutional trial sponsored by the National Institutes of Health, the Systemic Ventricle Reconstruction (SVR) trial, compared the outcomes of neonates having either a modified Blalock–Taussig shunt (MBTS) or a Sano shunt. The SVR trial demonstrated that transplantation-free survival 12 months after randomization was higher with the Sano shunt than with the MBTS (74% vs. 64%, P = .01). However, the Sano shunt group had more unintended interventions (P = .003) and complications (P = .002). Right ventricular size and function at the age of 14 months and the rate of nonfatal serious adverse events at the age of 12 months were similar in the two groups. Data collected over a mean (± standard deviation) follow-up period of 32 ± 11 months showed a nonsignificant difference in transplantation-free survival between the two groups (P = .06).

Since the initial SVR publications in 2010, the 3-year and 6-year results have been analyzed. At 3 years, the combined death and cardiac transplantation rates for the RVPAS vs. MBTS groups were 33% vs. 39% (P = .14). When all available data were examined by Kaplan-Meier analysis (mean follow-up 4.4 ± 1.0 years), there was also no difference between groups (log rank P = .11). Overall, there were 100 deaths and 10 transplantations in the MBTS cohort and 86 deaths and 11 transplantations in the RVPAS group. At 6 years, although the point averages continued to reflect a difference favoring the RVPAS (combined death/transplantation rate, 36%) in comparison with the MBTS (41%), the number of subjects was not sufficient to
demonstrate a statistically significant difference between the two groups (log rank *P* = 0.13). Similar to the 3-year results, RVPAS subjects had a higher incidence of any catheter intervention (0.38 vs. 0.23 interventions/patient-year, *P* <0.001), including balloon angioplasty (*P* = 0.014), stent (*P* = 0.009), and coiling (*P* <0.001).113,114 Currently, there remains an ongoing controversy regarding MBTS vs. RV-PA conduit as the source of pulmonary blood flow after the Norwood operation.119,120

Although surgical palliation with the Norwood procedure is still the mainstay of therapy for infants with HLHS, a combined surgical and percutaneous option (hybrid procedure), which consists of bilateral pulmonary artery banding and placement of a ductal stent, has emerged as a promising alternative that obviates the need for CPB in the fragile neonatal period.121,122 The hybrid procedure is performed in a “hybrid suite,” incorporating both advanced fluoroscopic imaging facilities combined with complete operating room capabilities. A 3- or 3.5-mm PTFE tube graft is cut to a width of 3 to 4 mm and used as the bands on the branch pulmonary arteries, placed just distal to the main pulmonary artery. The ductal stent is then positioned in order to cover all ductal tissue and is deployed through a purse-string suture in the main pulmonary artery. A reverse systemic-to-pulmonary shunt is considered in patients with aortic atresia and preductal coarctation to improve coronary perfusion; however, a recent study demonstrated no difference in survival between those with and without the shunt.123 The hybrid procedure can also be used as a bridge to heart transplantation in those infants with severe AV valve regurgitation or otherwise unsuitable single-ventricle anatomy.124

Following stage 1 palliation, the second surgical procedure is the creation of a bidirectional cavopulmonary shunt (Fig. 20-39) or hemi-Fontan, generally at 3 to 6 months of life when the pulmonary vascular resistance has decreased to normal levels. This is the first step in separating the pulmonary and systemic circulations, and it decreases the volume load on the single ventricle. The existing innominate artery-to-pulmonary shunt (or RV-to-pulmonary shunt) or MBTS is eliminated during the same operation.

The third stage of surgical palliation, known as the modified Fontan procedure, completes the separation of the systemic and pulmonary circulations and is performed between 18 months and 3 years of age, or when the patient experiences increased cyanosis (i.e., has outgrown the capacity to perfuse the systemic circulation with adequately oxygenated blood). This has traditionally required a lateral tunnel within the right atrium to direct blood from the inferior vena cava to the pulmonary artery, allowing further relief of the volume load on the RV and providing increased pulmonary blood flow to alleviate cyanosis. More recently, many favor using an extracardiac conduit (e.g., 18- to 20-mm tube graft) to connect the inferior vena cava to the pulmonary artery (Fig. 20-40).

Not all patients with HLHS require this three-stage palliative repair. Some infants afflicted with a milder form of HLHS, recently described as hypoplastic left heart complex (HLHC), have aortic or mitral hypoplasia without intrinsic valve stenosis and antegrade flow in the ascending aorta. In this group, a two-ventricle repair can be achieved with reasonable outcome. Tcherewenkov has published the results with 12 patients with HLHC who underwent biventricular repair at a mean age of 7 days.114 The operative technique consisted of a pulmonary homograft patch aortoplasty of the aortic arch and ascending aorta and closure of the interatrial and interventricular communications. The left heart was capable of sustaining systemic perfusion in 92% of patients, and early mortality was 15.4%. Four patients required reoperations to relieve LVOT obstruction, most commonly between 12 and 39 months following repair. The group from Boston Children’s Hospital has been very aggressive in left ventricular recruitment. These operations still carry a high burden of late death and several reoperations.

Although the Norwood procedure is the most widely performed initial operation for HLHS, transplantation can be used as a first-line therapy and may be preferred when anatomic or physiologic considerations exist that preclude a favorable outcome with palliative repair. Significant tricuspid regurgitation, intractable pulmonary artery hypertension, or progressive right ventricular failure are cases where cardiac replacement may be advantageous. Widespread adaptation of transplantation as

Figure 20-40. Extra cardiac fenestrated Fontan. ‘*’ shows the fenestration. (Used with permission from Kelly Rosso MD.)
first-line treatment for HLHS has been limited by improved Norwood survival rates as the operation and pre- and postoperative management of the patient have evolved and by limited organ availability. Organ availability should be considered prior to electing transplantation, as 24% of infants died awaiting transplantation in the largest series to date.\textsuperscript{126,127}

**Results.** Outcomes for HLHS are still significantly worse than those for other complex cardiac defects. However, with improvements in perioperative care and modifications in surgical technique, the survival following the Norwood procedure now exceeds 90% in experienced centers.\textsuperscript{115-120} The outcome for low-birth-weight infants has improved, but low weight still remains a major predictor of adverse survival, especially when accompanied by significant tricuspid valve insufficiency, a restrictive interatrial communication, poor RV function, or extracardiac or chromosomal anomalies.

**DEFECTS THAT MAY BE PALLIATED OR REPAIRED**

**Ebstein’s Anomaly**

**Anatomy.** This is a rare defect, occurring in less than 1% of CHD patients. The predominant maldevelopment in this lesion is the inferior displacement of the tricuspid valve into the RV, although Bove\textsuperscript{128} and others have emphasized the fact that Ebstein’s anomaly is primarily a defect in right ventricular morphology rather than an isolated defect in the tricuspid valve. The anterior leaflet is usually attached in its normal position to the annulus, but the septal and posterior leaflets are displaced toward the ventricle. This effectively divides the RV into two parts: the inlet portion (atrialized RV) and the outlet portion (true or trabeculated RV) (Fig. 20-41). The atrialized RV is usually thin and dilated. Similarly, the tricuspid annulus and the right atrium are extremely dilated, and the tricuspid valve is usually regurgitant with a “sail-like” leaflet (Fig. 20-42). There is commonly an ASD present, which results in a right-to-left shunt at the atrial level. Occasionally, there is true anatomic pulmonary atresia or milder forms of RVOT obstruction.

A Wolff-Parkinson-White (WPW) syndrome (Fig. 20-43) type of accessory pathway with associated preexcitation is present in 15% of patients.\textsuperscript{128}

**Pathophysiology.** Right ventricular dysfunction occurs in patients with Ebstein’s anomaly because of two basic mechanisms: the inflow obstruction at the level of the atrialized ventricle, which produces ineffective RV filling and contractile dysfunction. Inflow obstruction and tricuspid regurgitation, which is exacerbated by progressive annular dilatation, both produce ineffective RV filling. Contractile dysfunction of the RV is a result of a decrease in the number of myocardial fibers, as well as the discordant contraction of the large atrialized portion.

The lack of forward flow at the right ventricular level may lead to physiologic or functional pulmonary atresia, and the infant is dependent on ductal patency for survival. All systemic venous return must be directed through an ASD to the left atrium, where it can be shunted through the ductus for gas exchange. However, the left ventricular function is usually compromised in infants with severe Ebstein’s anomaly as well because the enormous RV and the to-and-fro flow within the atrialized RV prevent adequate intracardiac mixing. Left ventricular function may also be severely compromised in Ebstein’s anomaly because the large RV causes left ventricular compression (Fig. 20-44A,B).

**Diagnosis.** There is a spectrum of clinical presentation in infants with Ebstein’s anomaly that mirrors the anatomic spectrum of this anomaly. Some infants with less severe forms may present with a mild degree of cyanosis, whereas the onset of clinical symptoms in patients surviving childhood is gradual, with the average age of diagnosis in the mid-teens.

However, the infant with severe atrialization and pulmonary stenosis will be both cyanotic and acidotic at birth. The chest radiograph may demonstrate the classic appearance, which

consists of a globular “wall-to-wall” heart (Fig. 20-45), similar to that seen with pericardial effusion. The ECG may show right bundle-branch block and right axis deviation. WPW syndrome, as mentioned earlier, is a common finding in these patients. Echocardiography will confirm the diagnosis and provide critical information including tricuspid valvular function, size of the atrialized portion of the RV, degree of pulmonary stenosis, and the atrial size.\textsuperscript{128}

The Great Ormond Street Score (GOSE) (Table 20-1),\textsuperscript{129} which consists of the area of the right atrium plus the area of the atrialized portion of the RV divided by the diastolic area of the remaining cardiac chambers, has been proposed as a useful prognostic tool to stratify neonates with Ebstein’s anomaly. A score of greater than 2 translates into uniformly fatal outcome. Electrophysiology study with radiofrequency ablation is indicated in patients with evidence of WPW syndrome or in children.

with a history of supraventricular tachycardia, undefined wide-complex tachycardia, or syncope.

**Treatment.** Surgery is indicated for symptomatic infants and for older children and adults with arrhythmias, progressive cyanosis, or New York Heart Association class III or IV. However, the operative repair may be different, depending on the patient’s age, because older children usually are candidates for a biventricular or one-and-a-half ventricle repair, whereas moderate survival has been reported for neonates, using a procedure that converts the anatomy to a single-ventricle physiology, as described by Starnes and coworkers.130

The surgical approach in widespread use today for patients surviving infancy was described by Danielson and colleagues in 1992.128,131 This procedure entails excision of redundant right atrial tissue and patch closure of any associated ASD, plication of the atrialized portion of the ventricle with obliteration of the aneurysmal cavity, posterior tricuspid annuloplasty to narrow the tricuspid annulus, reconstruction of the tricuspid valve if the anterior leaflet is satisfactory, or replacement of the tricuspid valve if necessary.131 If the tricuspid valve is not amenable to reconstruction, valve replacement should be considered. Care must be taken when performing the posterior annuloplasty, or during the conduct of tricuspid valve replacement, to avoid the conduction system, because complete heart block can complicate this procedure. In addition, patients who demonstrated preoperative evidence of preexcitation should undergo electrophysiologic mapping and ablation.

Neonatal Ebstein’s anomaly is a separate entity. Results with surgical correction have been poor, and many neonates are not candidates for operative repair as previously described. Surgical options for the symptomatic neonate include palliative procedures, the one-and-a-half ventricle repair, or conversion to single-ventricle physiology.132 Arguably, the most favorable outcomes in symptomatic neonatal Ebstein’s anomaly or repair in slightly older infants have been achieved using the right ventricular exclusion premise. This technique, known as the “Starnes” procedure (Fig. 20-46),130 uses a fenestrated patch to close the tricuspid valve orifice coupled with systemic-to-pulmonary artery shunt. The patch must be fenestrated to allow decompression of the RV in instances of anatomic pulmonary atresia. Although Knott-Craig and colleagues132 have described tricuspid valve repair for the full spectrum of neonates and infants with excellent short- and mid-term results, these results have not been reproduced in other institutions.133 The one-and-a-half ventricle repair was first described by Billingsly and coworkers as an attempt to achieve a more physiologic “pulsatile” pulmonary circulation in patients with a hypoplastic or dysplastic RV.134 This is accomplished by diverting the superior vena caval blood directly into the pulmonary arterial system by a bidirectional cavopulmonary shunt while recruiting the RV to propel the inferior vena caval blood directly to the pulmonary arteries via the RVOT. Thus, the hemodynamics of the one-and-a-half ventricle repair are characterized by separate systemic and pulmonary circulations in series. The systemic circulation is fully supported by a systemic ventricle, and the pulmonary circulation is supported by both the bidirectional Glenn shunt and the hypoplastic (pulmonary) ventricle. Proponents of this approach report a decreased right atrial pressure and a decrease in inferior vena cava hypertension, which is theorized to be responsible for many of the dreaded complications of the Fontan circulation, including protein-losing encephalopathy, hepatic congestion, atrial arrhythmias, and systemic ventricular failure. In addition, the maintenance of pulsatile pulmonary blood flow, as opposed to continuous laminar flow as in the Fontan circulation, may be advantageous to the pulmonary microcirculation, although it has not been proven in any studies thus far.134,135 Certain criteria, most notably an adequate tricuspid valve Z score, as well as

the absence of severe pulmonary hypertension or concomitant defects requiring intricate intracardiac repair, should be satisfied prior to electing the one-and-a-half ventricle approach. Patients who do not fulfill these criteria may be approached with a two-ventricle repair and atrial fenestration or a Fontan repair.

In the infant with severe Ebstein’s anomaly, initial stabilization with prostaglandin to maintain ductal patency, mechanical ventilation, and correction of cyanosis is mandatory. Metabolic acidosis, if present from compromised systemic perfusion, must be aggressively treated with afterload reduction. Many of these infants will improve over 1 to 2 weeks as pulmonary vascular resistance falls and they are able to improve antegrade flow into the pulmonary circulation through their abnormal RV and tricuspid valve. When stabilization and medical palliation fail, surgical management remains an option, although its success depends on numerous anatomic factors (e.g., adequacy of the tricuspid valve, RV, and pulmonary outflow tract), and surgery for symptomatic neonates with Ebstein’s anomaly carries a high risk. Knott-Craig and associates reported three cases where two-ventricle repair was undertaken by subtotal closure of the ASD, extensive resection of the right atrium, and vertical plication of the atrialized chamber. Five-year follow-up revealed all patients to be asymptomatic and in sinus rhythm without medications. Recently, they have reported on their 20-year experience with treating 32 such neonates with an overall mortality of 40%. Surgical management of neonates with Ebstein’s anomaly remains challenging. For neonates with Ebstein’s anomaly and anatomical pulmonary atresia, single-ventricle palliation is associated with lower early mortality compared with two-ventricle repair.

Results. In the neonatal period, the most common postoperative problem, whether after a simple palliative procedure such as a BT shunt or following a more extensive procedure such as attempted exclusion of the RV, has been low cardiac output. Supraventricular tachycardia also has been problematic postoperatively. Complete heart block necessitating pacemaker implantation should be uncommon if the techniques described to avoid suturing between the coronary sinus and the tricuspid annulus are used.

There are few published reports of outcomes, due to the rarity of this defect. However, based on the natural history of this condition, which is remarkably benign for the majority of older patients, the outlook should be excellent for patients who have survived the neonatal period.

Transposition of the Great Arteries

Anatomy. Complete transposition is characterized by connection of the atria to their appropriate ventricles with inappropriate ventriculoarterial connections. Thus, the aorta arises anteriorly from the RV, while the pulmonary artery arises posteriorly from the LV. Van Praagh and coworkers introduced the term dextro-transposition of the great arteries (D-TGA) to describe this defect, whereas levo-transposition of the great arteries (L-TGA) describes a form of corrected transposition where there is concomitant AV discordance.

D-TGA requires an obligatory intracardiac mixing of blood, which usually occurs at both the atrial and the ventricular levels or via a patent ductus. Significant coronary anomalies occur frequently in patients with D-TGA. The most common pattern, occurring in 68% of cases, is characterized by the left main coronary artery arising from the leftward coronary sinus, giving rise to the left anterior descending and circumflex arteries. The most common variant is for the circumflex coronary artery to arise as a branch from the right coronary artery instead of from the left coronary artery.

Pathophysiology. D-TGA results in parallel pulmonary and systemic circulations, with patient survival dependent on intracardiac mixing of blood. After birth, both ventricles are relatively noncompliant, and thus, infants initially have higher pulmonary flow due to the decreased downstream resistance. This causes left atrial enlargement and a left-to-right shunt via the patent foramen ovale.

Postnatally, the LV does not hypertrophy because it is not subjected to systemic afterload. The lack of normal extraterine left ventricular maturation has important implications for the timing of surgical repair because the LV must be converted to the systemic ventricle and be able to function against systemic vascular resistance. If complete repair is done within the first few weeks of life, the LV usually adapts easily to systemic resistance since it is conditioned to high intrathoracic pulmonary vascular resistance. After a few weeks of life, the LV that is conditioned to the decrease in pulmonary resistance that occurs when the lungs inflate after birth may have difficulty adapting to systemic vascular resistance without preoperative preparation or postoperative support. Novel techniques of LV “preparation” using a pulmonary arterial band have been used in cases where complete repair has been delayed (Fig. 20-47A,B).

Clinical Manifestations and Diagnosis. Infants with D-TGA and an intact ventricular septum are usually cyanotic at birth, with an arterial Po2 between 25 and 40 mmHg. If ductal patency is not maintained, deterioration will be rapid with ensuing metabolic acidosis and death. Conversely, those infants with a coexisting VSD may be only mildly hypoxemic and may come to medical attention after 2 to 3 weeks, when the falling pulmonary vascular resistance leads to symptoms of congestive heart failure.

The ECG will reveal right ventricular hypertrophy, and the chest radiograph will reveal the classic egg-shaped configuration. Definitive diagnosis is made by echocardiography, which reliably demonstrates ventriculoarterial discordance and any associated lesions. Cardiac catheterization is rarely necessary, except in infants requiring surgery after the neonatal period, to assess the suitability of the LV to support the systemic circulation. Limited catheterization, however, is useful for performance of atrial septostomy in neonates with inadequate intracardiac mixing.

Surgical Repair. Blalock and Hanlon introduced the first operative intervention for D-TGA with the creation of an atrial septectomy to enhance intracardiac mixing. This initial procedure was feasible in the pre-CPB era, but carried a high mortality rate. Later, Rashkind and Causo developed a catheter-based balloon septostomy, which largely obviated the need for open septectomy.

These early palliative maneuvers, however, met with limited success, and it was not until the late 1950s, when Senning and Mustard developed the first “atrial repair,” that outcomes improved. The Senning operation consisted of rerouting venous flow at the atrial level by incising and realigning the atrial septum over the pulmonary veins and using the right atrial free wall to create a pulmonary venous baffle (Fig. 20-48).

Although the Mustard repair (Fig. 20-49) was similar, it made use of either autologous pericardium or synthetic material to create the interatrial baffle. These atrial switch procedures
resulted in a physiologic correction, but not an anatomic one, as the systemic circulation is still based on the RV. Still, survival rose to 95% in most centers by using an early balloon septostomy followed by an atrial switch procedure at 3 to 8 months of age.\(^{141,142}\)

Despite the improved early survival rates, long-term problems, such as superior vena cava or pulmonary venous obstruction, baffle leak, arrhythmias, tricuspid valve regurgitation, and right ventricular failure, prompted the development of the arterial switch procedure by Jatene in 1975.\(^{143}\) The arterial switch procedure involves the division of the aorta and the pulmonary artery, posterior translocation of the aorta (LeCompte maneuver), mobilization of the coronary arteries, placement of a pantaloon-shaped pericardial patch, and proper alignment of the coronary arteries on the neoaorta (Fig. 20-50).

The most important consideration is the timing of surgical repair because arterial switch should be performed within 2 weeks after birth, before the LV loses its ability to pump against systemic afterload. In patients presenting later than 2 weeks, the LV can be retrained with preliminary pulmonary artery banding.
and aortopulmonary shunt followed by definitive repair. Alternatively, the unprepared LV can be supported following arterial switch with a mechanical assist device for a few days while it recovers ability to manage systemic pressures. Echocardiography can be used to assess left ventricular performance and guide operative planning in these circumstances.

The subset of patients who present with D-TGA complicated by LVOT obstruction and VSD may not be suitable for an arterial switch operation. The Rastelli operation, first performed in 1968, uses placement of an intracardiac baffle to direct left ventricular blood to the aorta and an extracardiac valved conduit to establish continuity between the RV and the pulmonary artery, which has led to successful outcomes in these complex patients.144

Results. For patients with D-TGA, intact ventricular septum, and VSD, the arterial switch operation provides excellent long-term results with a mortality rate of less than 5%. Operative risk is increased when unfavorable coronary anatomic configurations are present or when augmentation of the aortic arch is required. The most common complication is supravalvular pulmonary stenosis, occurring 10% of the time, which may require ballooning or reoperation (Fig. 20-51).145

Results of the Rastelli operation have improved substantially, with an early mortality rate of 5%.146 Late mortality rate results were less favorable because conduit failure requiring reoperation, pacemaker insertion, or relief of LVOT obstruction was frequent.

Figure 20-50. The Arterial Switch Operation. A. The maneuver of Lecompte (positioning the pulmonary artery anterior to the aorta) is shown with aortic cross-clamp repositioning to retract the pulmonary artery during the neoaortic reconstruction. A and B. After the coronary patches are rotated for an optimal lie, they are sutured to the linearly incised sinuses of Valsalva at the old pulmonary artery (neoaorta) (C). Figure 20-51. Angiographic appearance of the pulmonary arteries before and after balloon dilation. The RV pressures dropped from “systemic” to “1/2 systemic” after dilation.
Double-Outlet Right Ventricle

Anatomy. Double-outlet RV (DORV) accounts for 5% of CHD and exists when both the aorta and pulmonary artery arise wholly, or in large part, from the RV (Fig. 20-52). DORV encompasses a spectrum of malformations because the incomplete shift of the aorta toward the LV is often associated with other abnormalities of cardiac development, such as ventricular looping and infundibular-truncal spiraling. The vast majority of hearts exhibiting DORV have a concomitant VSD, which varies in its size and spatial association with the great vessels. The VSD is usually nonrestrictive and represents the only outflow for the LV; its location relative to the great vessels dictates the dominant physiology of DORV, which can be analogous to that of a large isolated VSD, tetralogy of Fallot, or D-TGA. In 1972, Lev et al suggested considering DORV as a spectrum of hearts that “pass imperceptibly from tetralogy with VSD with overriding aorta into double-outlet right ventricle with subaortic VSD.” Thus, Lev and colleagues described a classification scheme for DORV based on the “commitment” of the VSD to either or both great arteries. The VSD can be subaortic, doubly committed, noncommitted, or subpulmonic.

The subaortic type is the most common (47%) and occurs when the VSD is located directly beneath the aortic annulus. Doubly committed VSD (4%) is present when the VSD lies beneath both the aorta and the pulmonary artery, which are usually side-by-side in this lesion. The noncommitted VSD (26%) exists when the VSD is remote from the great vessels. The subset of DORV hearts with the VSD located beneath the pulmonary valve also are classified as the Taussig–Bing syndrome (Fig. 20-53). This occurs in 23% of cases of DORV with VSD, and it occurs when the aorta rotates more anteriorly, with the pulmonary artery rotated more posteriorly.

Clinical Manifestations and Diagnosis. Patients with DORV typically present with one of the following three scenarios: (a) those with doubly committed or subaortic VSD present with congestive heart failure and a high propensity for pulmonary hypertension, much like infants with a large single VSD; (b) those with a subaortic VSD and pulmonary stenosis present with cyanosis and hypoxia, much like infants with tetralogy of Fallot; and (c) those with subpulmonic VSD present with cyanosis, much like those with D-TGA, because streaming directs desaturated systemic venous blood to the aorta and oxygenated blood to the pulmonary artery. Thus, the three critical factors influencing the clinical presentation and subsequent management of infants with DORV are the size and location of the VSD, the presence or absence of important RVOT obstruction, and the presence of other anomalies (especially associated hypoplasia of left-sided structures sometimes seen with subpulmonary VSD).

Echocardiography is the mainstay of diagnosis and can also provide valuable information regarding the feasibility of biventricular repair. Specific anatomic questions that should be resolved to assist in surgical planning in addition to those mentioned earlier include the coronary anatomy (presence of a conal branch or left anterior descending from the right coronary coursing across the conus), the presence of additional muscular VSDs remote from either great vessel, and the distance between the tricuspid and pulmonary valve. Cardiac catheterization is rarely necessary in neonates or infants, except to determine the degree of pulmonary hypertension and to determine the effects of previous palliative procedures on the pulmonary arterial anatomy.

Therapy. The goals of corrective surgery are to relieve pulmonary stenosis, to provide separate and unobstructed outflow pathways from each ventricle to the correct great vessel, and to achieve separation of the systemic and pulmonary circulations.

Double-Outlet Right Ventricle With Noncommitted Ventricular Septal Defect

The repair of hearts with DORV and noncommitted VSD can be accomplished by constructing an intraventricular tunnel connecting the VSD to the aorta, closing the pulmonary artery, and placing a valved extracardiac conduit from the RV to the pulmonary artery. In patients without pulmonary stenosis who have intractable congestive failure, a pulmonary artery band can be placed in the first 6 months to control pulmonary artery...
overcirculation and prevent the development of pulmonary hypertension.

Infants with pulmonary stenosis can be managed with a systemic-to-pulmonary shunt followed by biventricular repair as described by Belli and colleagues in 1999, or with a modified Fontan. There is no consensus on the timing of repair, but recent literature suggests that repair within the first 6 months is associated with better outcome. However, in cases where an extracardiac-valved conduit is necessary, it is better to delay definitive repair until the child is 2 to 3 years of age because this allows placement of a larger conduit and possibly reduces the number of future obligatory conduit replacements.

Double-Outlet Right Ventricle With Subaortic or Doubly Committed Ventricular Septal Defect Without Pulmonary Stenosis

This group of patients can be treated by creating an intracardiac baffle that directs blood from the LV into the aorta. Enlargement of the VSD may be necessary to allow ample room for the baffle; this should be done anterosuperiorly to avoid injury to the conduction system that normally lies inferoposteriorly along the border of the VSD. In addition, other important considerations in constructing the LV outflow tunnel include the prominence of the conal septum, the attachments of the tricuspid valve to the conal septum, and the distance between the tricuspid and pulmonary valves. In some instances, unfavorable anatomy may preclude placement of an adequate intracardiac baffle, necessitating single ventricle repair.

Double-Outlet Right Ventricle With Subaortic or Doubly Committed Ventricular Septal Defect With Pulmonary Stenosis

Repair of this defect is similar to the above except that concomitant RVOT reconstruction must be performed in addition to the intracardiac tunnel. The RVOT augmentation can be accomplished with the placement of a transannular patch or with placement of an extracardiac-valved conduit when an anomalous left anterior descending artery precludes use of a patch.

Taussig–Bing Syndrome Without Pulmonary Stenosis

These infants are best treated with a balloon septostomy during the neonatal period to improve mixing, followed by VSD closure baffling LV egress to the pulmonary artery and an arterial switch operation. The Kawashima procedure, in which an intraventricular tunnel is used to baffle LV egress directly to the aorta, may alternatively be used when the aorta is more posterior or when there is associated pulmonary stenosis.

Taussig–Bing Syndrome With Pulmonary Stenosis

This defect may be treated with a variety of techniques, depending on the specific anatomic details and the expertise of the treatment team. A Rastelli-type repair, which involves construction of an intraventricular tunnel through the existing VSD that connects the LV to both great vessels, followed by division of the pulmonary artery at its origin and insertion of a valved conduit from the RV to the distal pulmonary artery, can be performed. Alternatively, a Yasui procedure, which involves baffling the VSD to the pulmonary artery and creation of a DKS anastomosis between the pulmonary artery and the aorta with patch augmentation, can be accomplished concomitant with placement of an RV pulmonary artery conduit.

Results. The results of DORV repairs are generally favorable, especially for the tetralogy-type DORV with subaortic VSD. However, more complex types of DORV, including noncommitted VSD and Taussig–Bing type, still carry important morbidity and mortality. Furthermore, repeated interventions for RVOT reconstruction or staged operations for patients triaged to single-ventricle pathways pose late hazards for patients surviving initial repair. A single-institution series evaluated 393 patients with DORV. The authors found that the need for reintervention approached 37% at 15 years following repair. Arterial switch operation, as opposed to Rastelli-type repair, was associated with an increased risk of early postrepair mortality, but mitigated against the risk of late death. Patients with hypoplastic left-sided structures and a nonsubaortic VSD may fare better with a single-ventricle repair.

Tetralogy of Fallot

Anatomy. The original description of tetralogy of Fallot (TOF) by Etienne Louis Fallot, as the name implies, included four abnormalities: a large perimembranous VSD adjacent to the tricuspid valve; an overriding aorta; a variable degree of RVOT obstruction, which might include hypoplasia and dysplasia of the pulmonary valve as well as obstruction at the subvalvar and pulmonary artery level; and right ventricular hypertrophy. More recently, the Van Praagh et al pointed out that TOF could be more correctly termed monology of Fallot, since the four components are explained by the malposition of the infundibular septum. When the infundibular septum is displaced anteriorly and leftward, the RVOT is narrowed and its anterior displacement results in failure of fusion of the ventricular septum between the arms of the trabeculo-septo-marginalis (Fig. 20-54).

The morphology of TOF is markedly heterogeneous and includes an absent pulmonary valve, concomitant AV septal defects, and pulmonary atresia with major aortopulmonary collaterals. The present discussion will focus only on the so-called classic presentation of TOF without coexisting intracardiac defects.

Anomalous coronary artery patterns, related to either origin or distribution, have been described in TOF. However, the most surgically important coronary anomaly occurs when

![Figure 20-54. Tetrology of Fallot. (Used with permission from Kelly Rosso MD.)](image-url)
the left anterior descending artery arises as a branch of the right coronary artery. This occurs in approximately 3% of cases of TOF and may preclude placement of a transannular patch, as the left anterior descending coronary artery crosses the RVOT at varying distances from the pulmonary valve annulus.\textsuperscript{158}

**Pathophysiology and Clinical Presentation.** The initial presentation of a child afflicted with TOF depends on the degree of RVOT obstruction. Children with cyanosis at birth usually have severe pulmonary annular hypoplasia with concomitant hypoplasia of the peripheral pulmonary arteries. Most children, however, present with mild cyanosis at birth, which then progresses as the right ventricular hypertrophy further compromises the RVOT. Cyanosis usually becomes significant within the first 6 to 12 months of life, and the child may develop characteristic “tet” spells, which are periods of extreme hypoxemia. These spells are characterized by decreased pulmonary blood flow and an increase in systemic blood flow. They can be triggered by any stimulus that decreases systemic vascular resistance, such as fever, agitation, or vigorous physical activity. Cyanotic spells increase in severity and frequency as the child grows, and older patients with uncorrected TOF may often squat, which increases peripheral vascular resistance and relieves the cyanosis.

Evaluation in the older patient with TOF may demonstrate clubbing, polycythemia, hemoptysis, or brain abscesses. Chest radiography will demonstrate a boot-shaped heart (Fig. 20-55), and EKG will show the normal pattern of right ventricular hypertrophy. Echocardiography confirms the diagnosis because it demonstrates the position and nature of the VSD, defines the character of the RVOT obstruction, and often visualizes the branch pulmonary arteries and the proximal coronary arteries. Cardiac catheterization is rarely necessary and is actually risky in TOF since it can create spasm of the RVOT muscle and result in a hypercyanotic episode (tet spell). Occasionally, aortography (Fig. 20-56) is necessary to delineate the coronary artery anatomy.

**Treatment.** John Deanfield\textsuperscript{160} stated “…long follow-up inevitably means surgery in an earlier era: More recent surgery, at a younger age, with better preoperative, operative, and postoperative care, will improve long-term results. Data from the former (earlier) era will be overly pessimistic.” This statement is particularly pertinent as surgical correction of TOF has evolved from a staged approach of antecedent palliation in infancy followed by intracardiac repair to primary repair during the first few months of life without prior palliative surgery.

However, systemic-to-pulmonary shunts, generally an MBTS, may still be preferred with an unstable neonate younger than 3 months of age, when an extracardiac conduit is required because of an anomalous left anterior descending coronary artery, or when pulmonary atresia, significant branch pulmonary artery hypoplasia, or severe noncardiac anomalies coexist with TOF.

Traditionally, TOF was repaired through a right ventriculotomy, providing excellent exposure for closure of the VSD and relief of the RVOT obstruction, but concerns that the resultant scar would significantly impair right ventricular function or lead to lethal arrhythmias led to the development of a transatrial approach. Transatrial repair, except in cases when the presence of diffuse RVOT hypoplasia requires insertion of a transannular patch, is now being increasingly advocated by many, although its superiority has not been conclusively demonstrated.\textsuperscript{161}

The operative technique involves the use of CPB. All existing systemic-to-pulmonary arterial shunts, as well as the ductus arteriosus, are ligated. A right atriotomy is then made, and the anatomy of the VSD and the RVOT are assessed by retracting the tricuspid valve. The outflow tract obstruction is relieved by resecting the offending portion of the infundibular septum as well as any muscle trabeculations. If necessary, a pulmonary valvotomy or, alternatively, a longitudinal incision in the main pulmonary artery can be performed to improve exposure. The diameter of the pulmonary valve annulus is assessed by inserting Hegar dilators across the outflow tract; if the pulmonary artery/aorta diameter is less than 0.5, or the estimated RV/LV pressure is greater than 0.7, or the size of the pulmonary valve is less than a Z score of −2.5, a transannular patch is inserted. Patch closure of the VSD is then accomplished, taking...
care when placing sutures along the posteroinferior portion to avoid the conduction system.

**Results.** Operative mortality for primary repair of TOF in infancy is less than 5% in most series. Previously reported risk factors such as transannular patch insertion or younger age at time of repair have been eliminated secondary to improved intraoperative and postoperative care. According to the Society of Thoracic Surgeons Congenital Heart Surgery Database, discharge mortality from 3059 operations from 2002 to 2007 was 7.5% for initial palliation, 1.3% for primary repair, and 0.9% for staged repair, indicating similar outcomes for patients getting primary repair compared to staged repair. Nevertheless, for neonatal repair, discharge mortality increased to 6.2% with palliation and 7.8% with primary repair. This may be partly explained by a higher chance of postoperative complications in neonates.

A major complication of repaired TOF is the development of pulmonary insufficiency, which subjects the RV to the adverse effects of acute and chronic volume overload. This is especially problematic if residual lesions such as a VSD or peripheral pulmonary stenosis exist. Pulmonary valve regurgitation after repair of TOF is relatively well tolerated in the short term, partly because the hypertrophied RV usually adapts to the altered hemodynamic load. The detrimental effects of chronic pulmonary valve regurgitation are, however, numerous, and include progressive right ventricular dilatation and failure, tricuspid valve regurgitation, exercise intolerance, arrhythmia, and sudden death. Mechanoelectrical interaction, by which a dilated RV provides the substrate for electrical instability, might underlie the propensity toward ventricular arrhythmia. In support of this contention, Gatzoulis and colleagues found that the risk of symptomatic arrhythmia was high in patients with marked right ventricular enlargement and QRS prolongation on resting ECG of more than 180 ms. Karamlou et al have shown that similar structural and hemodynamic abnormalities, including a larger right atrial volume and right ventricular chamber size, are also related to atrial arrhythmias in patients following TOF repair. We found that prolongation of the QRS duration beyond a threshold of 160 ms increased the risk of atrial arrhythmias. Together, these data show that a similar mechanism could be responsible for both atrial and ventricular arrhythmias after repair in TOF patients.

When significant deterioration of ventricular function occurs, insertion of a pulmonary valve may be required, although this is rarely necessary in infants. Unfortunately, there are no universal criteria establishing the timing of pulmonary valve replacement. The current criteria for pulmonary valve replacement are the presence of two of the following criteria: RVEDD index >160 ml/m2, RVEDI >70 ml/m2, LVEDV index >65 ml/m2, RVEF <45%, RVOT aneurysm, and clinical symptoms or signs, including syncope or VT. PVR can be achieved with minimal morbidity and mortality.

The alternative to surgical PVR is percutaneous pulmonary valve implantation. The Melody valve system (Fig. 20-57) is the most popular of such systems. Following risk adjustment, no significant differences were observed between surgical or transcatheter PVR. However, transcatheter PVR was associated with a shorter hospitalization. Hospitalization costs are similar for both procedures.

Arrhythmias are potentially the most serious late complication following TOF repair. In a multicenter cohort of 793 patients studied by Gatzoulis et al, a steady increase was documented in the prevalence of ventricular and atrial tachyarrhythmia and sudden cardiac death in the first 5 to 10 years after intracardiac repair. Clinical events were reported in 12% of patients at 35 years after repair. Prevalence of atrial arrhythmias from other studies, however, ranges from 1% to 11%, which is a reflection of the strong time dependence of arrhythmia onset.

Underlying causes of arrhythmia following repair are complex and multifactorial, resulting in poorly defined optimum screening and treatment algorithms. Older repair age has been associated with an increased frequency of both atrial and ventricular arrhythmias. Impaired ventricular function secondary to a protracted period of cyanosis before repair might contribute to the propensity for arrhythmia in older patients.

**Ventricular Septal Defect**

**Anatomy.** VSD refers to a hole between the LV and RV. These defects are common, comprising 20% to 30% of all cases of CHD, and may occur as an isolated lesion or as part of a more
complex malformation. VSDs vary in size from 3 to 4 mm to more than 3 cm and are classified into four types based on their location in the ventricular septum: perimembranous (or paramembranous, conoventricular), AV canal (inlet), outlet or supracristal, and muscular (Fig. 20-58).

Perimembranous VSDs are the most common type requiring surgical intervention, comprising approximately 80% of cases. These defects involve the membranous septum and include the malalignment defects seen in tetralogy of Fallot. In rare instances, the anterior and septal leaflets of the tricuspid valve adhere to the edges of the perimembranous defect, forming a channel between the LV and the right atrium. These defects result in a large left-to-right shunt due to the large pressure differential between the two chambers.

AV canal defects, also known as inlet defects, occur when part or all of the septum of the AV canal is absent. The VSD lies beneath the tricuspid valve and is limited upstream by the tricuspid annulus, without intervening muscle.

The supracristal or outlet VSD results from a defect within the conal septum. Characteristically, these defects are limited upstream by the pulmonary valve and are otherwise surrounded by the muscle of the infundibular septum.

Muscular VSDs are the most common type and may lie in four locations: anterior, midventricular, posterior, or apical. These are surrounded by muscle and can occur anywhere along the trabecular portion of the septum. The rare “Swiss-cheese” type of muscular VSD consists of multiple communications between the RV and LV, complicating operative repair.

Pathophysiology and Clinical Presentation. The size of the VSD determines the initial pathophysiology of the disease. Large VSDs are classified as nonrestrictive and are at least equal in diameter to the aortic annulus. These defects allow free flow of blood from the LV to the RV, elevating right ventricular pressures to the same level as systemic pressure.

Consequently, the pulmonary-to-systemic flow ratio (Qp to Qs) is inversely dependent on the ratio of pulmonary vascular resistance to systemic vascular resistance. Nonrestrictive VSDs produce a large increase in pulmonary blood flow, and the afflicted infant will present with symptoms of congestive heart failure. However, if untreated, these defects will cause pulmonary hypertension with a corresponding increase in pulmonary vascular resistance. This will lead to a reversal of flow (a right-to-left shunt), which is known as Eisenmenger’s syndrome.

Small restrictive VSDs offer significant resistance to the passage of blood across the defect, and therefore right ventricular pressure is either normal or only minimally elevated and the ratio of Qp to Qs rarely exceeds 1.5. These defects are generally asymptomatic because there are few physiologic consequences. However, there is a long-term risk of endocarditis because endocardial damage from the jet of blood through the defect may serve as a possible nidus for colonization (Fig. 20-59A,B).

Diagnosis. The child with a large VSD will present with severe congestive heart failure and frequent respiratory tract infections. Children with Eisenmenger’s syndrome may be deceptively asymptomatic until frank cyanosis develops.

The chest radiograph will show cardiomegaly and pulmonary overcirculation, and the ECG will show signs of left ventricular or biventricular hypertrophy. Echocardiography provides definitive diagnosis and can estimate the degree of shunting as well as pulmonary arterial pressures. Cardiac catheterization has
SPECIFIC CONSIDERATIONS

PART II

largely been supplanted by echocardiography, except in older children where measurement of pulmonary resistance is necessary prior to recommending closure of the defect.

Treatment. VSDs may close or narrow spontaneously, and the probability of closure is inversely related to the age at which the defect is observed. Thus, infants at 1 month of age have an 80% incidence of spontaneous closure, whereas a child at 12 months of age has only a 25% chance of closure.170 This has an important impact on operative decision-making because a small or moderate-size VSD may be observed for a period of time in the absence of symptoms. Large defects and those in severely symptomatic neonates should be repaired during infancy to relieve symptoms and because irreversible changes in pulmonary vascular resistance may develop during the first year of life.

Repair of isolated VSDs requires the use of CPB with moderate hypothermia and cardioplegic arrest. The right atrial approach (Fig. 20-60) is preferable for most defects, except apical muscular defects, which often require a right ventriculotomy for adequate exposure. Supracristal defects may alternatively be exposed via a pulmonary arteriotomy or through an incision in the RV immediately beneath the pulmonary valve (Fig. 20-61). Regardless of the type of defect present, a right atrial approach can be used initially to inspect the anatomy, as this may be abandoned should it offer inadequate exposure for repair. After careful inspection of the heart for any associated malformations, a patch repair is employed, taking care to avoid the conduction system. Routine use of intraoperative transesophageal echocardiography should be used to assess for any residual defect.

Successful percutaneous device closure of VSDs using the Amplatzer device has been described.152 The device has demonstrated a 100% closure rate in a small series of patients with isolated or residual VSDs, or as a collaborative treatment strategy for the VSD component in more complex congenital lesions. Proponents of device closure argue that its use can decrease the complexity of surgical repair, avoid reoperation for a small residual lesion, or avoid the need for a ventriculotomy. The use of devices to close paramembranous defects can cause heart block because the defect is in close association to the conduction system (Fig. 20-62).171 The procedure can be performed percutaneously or through the percutaneous approach. Embolization of the device is an added risk.

Multiple or “Swiss-cheese” VSDs represent a special case, and many cannot be repaired during infancy. In patients in whom definitive VSD closure cannot be accomplished, temporary placement of a pulmonary artery band can be employed to control pulmonary flow. This allows time for spontaneous closure of many of the smaller defects, thus simplifying surgical repair.172

Some centers, however, have advocated early definitive repair of the Swiss-cheese septum, by using oversize patches, fibrin glue, and combined intraoperative device closure, as well as techniques to complete the repair transatrially.173

Results. Even in very small infants, closure of VSDs can be safely performed with hospital mortality near 0%. The main risk factor remains the presence of other associated lesions, especially when present in symptomatic neonates with large VSDs.

Figure 20-61. Echocardiographic appearance of a supracristal VSD (arrow). Note its location just beneath the pulmonary valve (‘*’).
Atrioventricular Canal Defects

Anatomy. AV canal defects result from failure of fusion of the endocardial cushions in the central portion of the heart, causing a lesion that involves the atrial and the ventricular septum, as well as the anterior mitral and septal tricuspid valve leaflets. Defects involving primarily the atrial septum are known as partial AV canal defects and frequently occur in conjunction with a cleft anterior mitral leaflet. Complete AV canal defects have a combined deficiency of the atrial and ventricular septum associated with a common AV orifice rather than separate tricuspid and mitral valves. The common AV valve generally has five leaflets, three lateral (free wall) and two bridging (septal) leaflets. The defect in the ventricular septum can lie either between the two bridging leaflets or beneath them. The relationship between the septal defect and the anterior bridging leaflet forms the basis of the Rastelli classification for complete AV canal defects (Fig. 20-63).174,175

Pathophysiology and Diagnosis. Partial AV canal defects, in the absence of AV valvular regurgitation, frequently resemble isolated ASDs. Left-to-right shunting predominates as long as pulmonary vascular resistance remains low. However, 40% of patients with partial AV canal defects have moderate-to-severe valve incompetence, and progressive heart failure occurs early in this patient population.175 Complete AV canal defects produce more severe pathophysiologic changes because the large intracardiac communication and significant AV valve regurgitation contribute to ventricular volume loading and pulmonary hypertension. Children with complete AV canal defects develop signs of congestive heart failure within the first few months of life.

Treatment. The management of patients with AV canal defects can be especially challenging. Timing of operation is individualized. Patients with partial defects can be electively repaired between 2 and 5 years of age, whereas complete AV canal defects should be repaired within the first year of life to prevent irreversible changes in the pulmonary circulation. Complete repair in infancy should be accomplished, with palliative procedures such as pulmonary artery banding reserved for only those infants with other complex lesions or who are too ill to tolerate CPB.

The operative technique requires the use of either continuous hypothermic CPB or, for small infants, deep hypothermic circulatory arrest. The heart is initially approached through an oblique right atriotomy, and the anatomy is carefully observed. In the case of a partial AV canal, the cleft in the mitral valve is repaired with interrupted sutures and the ASD is closed with a pericardial patch. Complete AV canal defects are repaired by patch closure of the VSD, separating the common AV valve into tricuspid and mitral components and suspending the neovalves from the top of the VSD patch and closing the ASD.

Results. Partial AV canal defects have an excellent outcome, with a mortality rate of 0% to 2% in most series.175 Complete AV canal defects are associated with an operative mortality of 3% to 4%.176

The most frequently encountered postoperative problems are complete heart block (1%–2%), right bundle-branch block (22%), arrhythmias (11%), RVOT obstruction (11%), and severe mitral regurgitation (13%–24%).175 The increasing use of intraoperative transesophageal echocardiography may positively

influence outcomes, as the adequacy of repair can be assessed and treated without need for subsequent reoperation.\textsuperscript{174-175}

**Interrupted Aortic Arch**

**Anatomy.** Interrupted aortic arch (IAA) is a rare defect, comprising approximately 1\% of all cases of CHD.\textsuperscript{177} It is defined as an absence of luminal continuity between the ascending and descending aorta and does not occur as an isolated defect in most cases because a VSD or PDA is usually present. IAA is classified based on the location of the interruption (Fig. 20-65 to Fig. 20-67).

**Clinical Manifestations and Diagnosis.** Infants with IAA have ductal-dependent systemic blood flow and will develop profound metabolic acidosis and hemodynamic collapse upon ductal closure. In the rare instance of failed ductal closure, the diagnosis may be missed during infancy, and the child will present with symptoms of congestive heart failure from a persistent left-to-right shunt.

Once definitive diagnosis is made in infants, usually with echocardiography, preparations are made for operative intervention, and prostaglandin E\textsubscript{1} is infused to maintain ductal patency and correct acidosis. The infant’s hemodynamic status should be optimized with mechanical ventilation and inotropic support. An effort should be made to increase pulmonary vascular resistance by decreasing the fractional inspired oxygen and avoiding hyperventilation because this will preferentially direct blood into the systemic circulation.

**Treatment.** Initial strategies for the management of IAA involved palliation through a left thoracotomy by using one of the arch vessels as a conduit to restore aortic continuity. Pulmonary artery banding can be simultaneously performed to limit left-to-right shunting because it is not feasible to repair the VSD or other intracardiac communications with this approach.

However, complete one stage surgical repair in infants with IAA is now preferable. The operative technique involves use of a median sternotomy and CPB with short periods of circulatory arrest. Aortic arch reconstruction can be accomplished with either direct anastomosis or patch aortoplasty followed by closure of the VSD.\textsuperscript{178}

In certain cases, the defect will involve hypoplasia of the left heart, precluding attempts at definitive repair. These infants should be managed with a Norwood procedure followed by a Fontan repair.

**Results.** Outcomes in infants with IAA have improved substantially over the last decades as a result of improved perioperative care. Operative mortality is now less than 10\% in most series.\textsuperscript{177,179} Some authors advocate the use of patch augmentation of the aorta to ensure adequate relief of LVOT obstruction and to diminish anastomotic tension, thus reducing the subsequent risk of restenosis and tracheobronchial compression.\textsuperscript{178}

**Pediatric Mechanical Circulatory Support**

Mechanical circulatory support has become standard therapy for adults with end stage heart failure. There has been a significant lag with development of similar devices for the pediatric population. This is probably related to the smaller market for these devices and the technical challenges associated with the anatomical constraints secondary to anatomy and size of the patients. Extracorporeal membrane oxygenation (ECMO)
has been the mainstay of mechanical support in many centers for the pediatric population. The adaptation of other adult devices to the pediatric population has led to the slow but steady development of pediatric durable mechanical devices. The Berlin Heart EXCOR (Berlin Heart AG, Berlin, Germany) device was approved by the FDA in 2011 in the United States as a paracorporeal device that can be used as a bridge to transplantation. This device has a 73% overall survival post implant at 12 months.\(^9\)

Infection, stroke and bleeding remain significant morbidities associated with it. Young age and small body surface area still remain poor prognostic factors. In 2010, the National Heart, Lung, and Blood Institute launched the Pumps for Kids, Infants, and Neonates (PumpKIN) program to promote development of new devices with the goal of clinical use.

ECMO remains the most commonly used form of mechanical support in the pediatric population in the United States. Per the ECLS Registry report released by the Extracorporeal Life Support Organization, as of January 2017, there were a total of 16,531 ECMO runs performed for cardiac causes, internationally.\(^1\)

The survival to discharge is about 40% in the neonatal population as opposed to 50% in the pediatric population. ECMO remains the only means of salvage for newborns and infants in many institutions. The biggest limitation remains the short duration it can be used. It is often used as a bridge to recovery and sometimes as a bridge to transplantation. The ability to place small infants on ECMO with peripheral cannulation continues to make it a very attractive first line option.

Ventricular assist devices can be either of the pulsatile or continuous types. The Berlin Heart EXCOR (Berlin Heart AG, Berlin, Germany) remains a classic example of a pulsatile device. The Impella 2.5 (Abiomed) (Fig. 20-68) has been used in the pediatric population as a temporary support device for recovering myocarditis, during treatment of acute rejection after heart transplantation and high-risk interventions in fragile patients with marginal function.\(^1\) Other continuous flow devices available for the pediatric patient include the Heartmate II and Heartmate III devices (Thoratec, Pleasanton, CA), DeBakey VAD Child (MicroMed Technology, Houston, TX), PediMag (Thoratec, Pleasanton, CA), Jarvik2015 and HeartWare HVAD (Fig 20-69) (HeartWare international Inc, Framingham, MA).\(^2\)

The total artificial heart (Syncardia Systems Inc, Tuscon, Az, USA) is an implantable biventricular device that replaces both ventricles. With the new introduction of the 50 ml pump, its popularity in the pediatric population has risen.

Posttransplant survival of patients bridged with and without mechanical circulatory support (ventricular assist device or total artificial heart) at 5 years post transplant remains the same. However, patients bridged to transplant with ECMO have a significantly worse survival.\(^3\) All in all, the field of pediatric heart surgery is very exciting and rapidly expanding.

Pediatric Heart Transplantation

Heart transplantation is currently an accepted mode of therapy in infants and children. Annually, about 600 pediatric heart transplants are performed worldwide,\(^4\) about 400 of which are performed in the United States.\(^5\) The common indications for heart transplant in the pediatric population are congenital heart disease, dilated cardiomyopathy, retransplantation, and other rare indications (e.g., arrhythmogenic right ventricular dysplasia, cancer, muscular dystrophy, and restrictive cardiomyopathy). The most common congenital heart defect requiring transplantation remains hypoplastic left heart syndrome. Although in the past some centers have advocated primary heart transplantation for this lesion, the improved outcomes with surgical palliation have eliminated this as an option. The first year post transplant remains the greatest risk for mortality. The overall median survival is 20.7 years for infants, 18.2 years for children age 1 to 5 years, 14 years for age 6 to 10 years, and 12.7 years for those age 11 to 17 years.\(^6\) Males seem to have a modestly superior overall survival compared with females. The causes of mortality include cardiac allograft vasculopathy, acute
rejection, infections, and graft failures. In the current era, the expected 1-year survival rate is 80% to 90%, the 2-year survival rate is 80% to 85%, and the 5-year survival rate is approximately 70% to 80% in experienced centers.interestingly, infants who undergo transplantation in the first month of life appear to have a survival advantage over infants who undergo transplantation during the remainder of the first year of life.

The two main techniques for performing the implant of the heart are the right atrial technique developed by lower and Shumway and the bicaval-left atrial technique described by Sievers and associates. In the latter technique, implantation consists of five anastomoses performed using a running prolene suture. These include the left atrial cuff, aorta, pulmonary artery, and the superior and inferior vena cava. One of the cornerstones of postoperative management remains immunosuppression. The triple drug regimen remains popular, corticosteroids, calcineurin inhibitor (cyclosporine or tacrolimus), and an antiproliferative agent (azathioprine or mycophenolate mofetil). Endomyocardial biopsy and coronary angiography are performed at regular intervals to monitor rejection. The field of pediatric heart transplantation has made huge strides since the days of “Baby Fae.”

Public Reporting and the STS Database in Congenital Heart Surgery

There has been a recent impetus in the field of congenital and pediatric cardiac surgery toward public reporting of outcomes. The advantages of this include promoting patient autonomy, shows a commitment to quality improvement, and also serves as a free marketing tool. The Society of Thoracic Surgeons Congenital Heart Surgery Database (STS-CHSD), is the largest clinical database in the world for congenital and pediatric cardiac surgery. It was founded in 1994. It contains data of about 394,980 operations as of September 9, 2016. These data are the foundation for assessment of performance by benchmark and comparison of individual programmatic outcomes to national aggregate data, development and subsequent application of sophisticated risk adjustment models, quality improvement initiatives, research, voluntary public reporting, development of reimbursement strategies, and governmental and regulatory collaborations.190 The database is currently in its 25th overall data harvest and records and represents data from 120 participants and 392 surgeons. Thus, this database has greater than 95% penetrance. STS CHSD public reporting started in January 2015, and participation is voluntary. Reporting is restricted to the hospital level and involves a rolling 4-year analytic window of data. Public reporting is based on the STS CHSD Operative Mortality Risk Model. Developed in 2014, this risk model calculates the operative mortality rate of hospitals performing such surgery, adjusting for procedural and patient level factors. The overall mortality rate over a 4-year period and the operative mortality rate for each of the five STAT (Society of Thoracic Surgeons—European Association for Cardio-Thoracic Surgery) categories is reported. The STAT categories are a multi-institutional, validated complexity stratification tool. They range from a score of 1 to 5, and the risk of mortality increases with each category. In addition, the STS star rating system was introduced, and every institution is rated as one, two, or three stars. This system is based on the confidence limits of the O/E (observed to expected) overall mortality for the institution (Fig. 20-70). One star equals higher than expected operative

**Figure 20-70.** Program performance as currently reported by the STS-CHSD.
mortality (the 95% confidence interval for their risk-adjusted O/E mortality ratio was entirely above the number 1), two stars equals the same as expected operative mortality (the 95% confidence interval for their risk-adjusted O/E mortality ratio overlapped with the number 1), and three stars equals lower than expected operative mortality (the 95% confidence interval for their risk-adjusted O/E mortality ratio was entirely below the number 1). The Spring 2016 STS CHSD Feedback Report includes data from 117 participants in the STS-CHSD, including 14 one-star programs, 83 two-star programs, and 8 three-star programs. Twelve participants did not receive a star rating due to incomplete data. Public reporting increased from 23% to 57.6% (all three-star programs, 50 two-star and three one-star programs). The online public reporting portal can be accessed at www.sts.org/congenital-public-reporting-module-search.

There are several criticisms to the current methodology used for reporting. Important limitations of current publicly reported data (including the STS star rating system) will need to be addressed in future initiatives in order to completely engage parents of children with CHD and reassure providers that risk-adjustment models are optimized. There are four specific areas that should be considered when making decisions how to improve this methodology: (a) While the mortality risk-adjustment model on which the star rating system is based is mature now, there are not comparable models that provide risk-adjusted morbidity (complication) rates. The assessment of the quality of congenital heart disease care at different centers should include complication metrics and incorporate failure-to-rescue as an important discriminator; (b) the star rating system does not provide risk-adjusted outcomes for specific procedures or, more importantly, for specific diagnoses. This is mainly because of the exceptionally wide spectrum of diagnoses and procedures in pediatric cardiac surgery that preclude sufficiently large numbers in most procedure-specific categories; (c) the star rating system, although the “best” we have at present, may not be understood equally by all families. It will be critical to provide equivalent information to the large numbers of underresourced and non–English-speaking families; (d) finally, the current adjusted mortality rate reported by the STS is calculated from a statistical formula and refers to what the hospital’s mortality rate would be if the measured performance (in this case the mortality rate) were extrapolated to the overall case-mix or make-up of patients within the entire STS database. This is a critical point because a hospital’s case-mix is highly variable, and discrimination based on mortality is mostly related to outcomes of more complex procedures. In other words, if hospital A has excellent survival for less complex procedures and therefore performs very few highly complex procedures (i.e., choosing a case-mix consistent with its expertise), the application of an extrapolated mortality rate may not reflect the actual quality of care for that particular hospital. This issue is evident because the majority of experienced centers with arguably the highest complexity received a “middle star” rating of 2. This rating may reflect calibration issues with the current rating system, whereby centers are potentially penalized for high-complexity predominance.

Fortunately, there are efforts to correct these deficiencies. In 2016, the STS CHSD Task Force and STS Quality Measurement Task Force began to collaborate on an initiative to refine risk adjustment for chromosomal abnormalities, syndromes, and noncardiac congenital anatomic abnormalities and to then enhance the STS CHSD Mortality Risk Model with this additional information. Upon completion of this project, STS CHSD Task Force plans to collaborate with the STS Quality Measurement Task Force to study the relationship between volume (programmatic volume and surgeon volume) and outcome using this enhanced STS CHSD Mortality Risk Model. Also, currently under development is a multidomain quality metric that incorporates mortality, morbidity, postoperative length of stay, and the occurrence of complications. As the largest congenital and pediatric cardiac surgical clinical data registry in the world, containing data about nearly all pediatric cardiac operations performed in the United States, STS CHSD contains a truly representative sample of national aggregate data that is useful for multiple purposes.

**Future Directions**

The future of congenital heart surgery remains very bright and exciting. The development of novel technologies such as four-dimensional MRI flow studies (Fig. 20-71) and three-dimensional printing have offered this field several new tools to help understand complex anatomy and pathophysiology. Three-dimensional printing of complex congenital heart defects has helped surgeons in preoperative planning by allowing translation of two-dimensional cross-sectional imaging studies into a tangible and easily visualized model. The hollow nature of the human heart and the direct correlation of structure to disease in the congenital population allows this technology to be used in abundance in this field. Its utilization to train young surgeons is very appealing (Figs. 20-72 and 20-73). Current research in the field of genetics, device bioengineering and miniaturization, stem cell therapy, and fusion imaging technology is expected to further improve patient outcome. The improved outcomes and survival of these young and fragile patients with congenital heart disease has led to the development of a complex new field termed *adult congenital heart disease*. The field of congenital heart surgery is young and offers brilliant, motivated, and upcoming surgeons a very daunting challenge to better the future of these babies.

Clinical Evaluation
As with any other field in medicine, the history and physical examination form the foundation for the evaluation of a patient with acquired heart disease requiring surgical intervention. Obtaining a complete history identifies comorbid conditions and assists in delineating the operative risks and prognosis after surgery. Physical examination reveals factors that may increase the complexity of surgery, such as previous surgery or the presence of peripheral arterial or cerebrovascular disease. These may influence the operative approach, but they also help guide the choice and sequence of diagnostic studies. A complete assessment of the patient allows the surgeon to make educated decisions regarding the optimal treatment strategy for the patient.

History
Symptoms suggestive of heart disease include: chest discomfort, fatigue, edema, dyspnea, palpitations, and syncope. Adequate definition of these symptoms calls for detailed history-taking, paying particular attention to onset, intensity, radiation, duration, and exacerbating or alleviating factors. The demands on the heart are determined by its loading conditions and the metabolic state of the patient. Cardiac symptoms are commonly accentuated with physical exertion or postural changes.

Angina pectoris is the hallmark of coronary artery disease (CAD), but may occur with other cardiac pathologies that result in ischemia from a mismatch between the supply of oxygen by the coronary circulation and the metabolic demand of the myocardium. Typically, angina is described as tightness, heaviness, or dull pain, frequently substernal, that lasts for a few minutes. This discomfort may radiate to the left arm, neck, mandible, or epigastrium. Angina is most often provoked by activities that increase metabolic demand on the heart such as exercise, eating, and states of intense emotion, and it is typically alleviated by rest or use of nitroglycerin. It is important to note that a significant number of patients with myocardial ischemia, particularly diabetics, females, and the elderly, may have “silent” angina or angina equivalents (dyspnea, diaphoresis, nausea, or fatigue). The overlap of these features with those of noncardiac etiologies...
such as costochondritis, biliary colic, gastroesophageal reflux disease, diffuse esophageal spasm, and peptic ulcer disease, to name a few, can sometimes lead to misdiagnosis.

Heart failure can occur from either left and/or right heart dysfunction, and respective symptoms arise from congestion of blood flow owing to an inadequate cardiac output. Left heart failure manifests as dyspnea, usually with exertion. Orthopnea, defined as dyspnea while lying flat, suggests worsened pulmonary congestion with increased venous return. Ascites, peripheral edema, and hepatomegaly reflect congestion in the systemic venous circulation and are prominent features of right heart failure. Peripheral edema can occur in right heart failure secondary to systemic venous congestion or in left heart failure due to salt and fluid retention as a result of impaired renal perfusion. Patients with chronic suboptimal perfusion and oxygenation can also have digital clubbing and cyanosis.

It is difficult to implicate cardiac disease based solely on the presence of fatigue, which is a very nonspecific symptom. However, most cardiac pathologies do result in fatigue or exercise intolerance to some degree. It is important to differentiate fatigue from exertional dyspnea which some patients may experience.

Dyspnea is another common symptom. Although generally a late symptom in patients with valvular heart disease or cardiomyopathy, it may be a relatively early complaint in some patients, particularly those with mitral stenosis. As stated previously, dyspnea is also an anginal equivalent and may signal a myocardial ischemic episode. Many primary pulmonary disorders feature dyspnea as their cardinal symptom and should be evaluated simultaneously as the physiology of the heart and lungs are intimately related and can have dramatic influences on one another.

Patients typically describe palpitations as a “skipped beat” or “racing heart.” Depending on the clinical context, such as occasional premature atrial or ventricular beats in otherwise healthy individuals, these may be benign. Clinically significant arrhythmias, however, require thorough investigation. Atrial fibrillation is the most common arrhythmia and can occur alone or with other cardiac pathologies. It results in an irregular, and at times, rapid heartbeat. Concurrent symptoms such as angina, lightheadedness, or syncope are particularly worrisome for life-threatening arrhythmias such as ventricular tachycardia or ventricular fibrillation, particularly in patients with preexisting heart failure.

Syncope associated with heart disease results from an abrupt reduction in cerebral perfusion. Many of the potential cardiac etiologies are serious, including sinus node dysfunction, atrioventricular conduction abnormalities, malignant arrhythmias, aortic stenosis, and hypertrophic obstructive cardiomyopathy. Noncardiac causes of syncope include, but are not limited to, neurologic causes (e.g., transient ischemic attacks [TIAs]), orthostatic hypotension, vasovagal events, and carotid sinus hypersensitivity. Any episode of syncope warrants a thorough evaluation and search for the root cause. In addition to a thorough inquiry regarding the aforementioned symptoms, it is important to obtain details about the patient’s medical and...
surgical history, family history, social habits (including alcohol and tobacco use), current medications, focused review of systems, as well as an assessment of the patient’s functional status and frailty. Frailty is often defined as a state of increased vulnerability to adverse health outcomes. Clinicians can use frailty index calculators to assess a patient’s risk for adverse outcomes following cardiac intervention. Specific attention should also be directed to the patient’s comorbidities which not only sheds light on their general health but also helps delineate expected risks from surgery. A strong family history of coronary artery disease, myocardial infarction, hypertension, or diabetes is of particular importance as they increase the individual’s risk for having an adverse cardiac event.

**Functional Disability and Angina.** With regard to heart failure, functional capacity is strongly correlated with mortality. The New York Heart Association (NYHA) functional class is a widely used classification system in categorizing patients based on their functional status (Table 21-1). The NYHA classification has become one basis by which to compare patient populations in many studies. Although less commonly used, the Canadian Cardiovascular Society (CCS) angina classification is also used to incorporate anginal symptoms into the functional assessment for prognostic value (Table 21-2).

### Physical Examination

The physical examination is an invaluable tool in directing further diagnostic studies in the management of a patient with suspected heart disease. The astute clinician may be able to detect subtle signs that may further characterize the underlying pathology.

The general appearance of a patient is important in the clinical assessment. A pale, diaphoretic, and obviously uncomfortable patient is more likely to be in a clinically critical condition than one who is conversing comfortably with an unremarkable demeanor. In addition to basic vital signs, particular attention should be directed to the patient’s mental status as well as the color and temperature of the skin, as these may be reflective of the general adequacy of perfusion. Overall frailty and dementia have also been shown to be predictors of operative and late mortality.

Palpation of the precordium may demonstrate deviation in the point of maximal impulse, indicative of ventricular hypertrophy, or parasternal heaves, seen in right ventricular overload. Auscultation should be performed in a quiet environment as critical murmurs, rubs, or gallops may be subtle. Murmurs are characterized by their location, timing, quality, and radiation. They are typically secondary to valvular or other structural pathology, and new findings require further investigation. A rub due to pericardial friction is indicative of endocarditis. A third heart sound (S₃) is generated by the rapid filling of a stiff ventricle and can be normal in young patients, but when present in older adults, is indicative of diastolic dysfunction and is pathologic. Increased contribution of the atrial pump function to ventricular filling may manifest as a fourth heart sound (S₄) and is also suggestive of ventricular dysfunction.

Palpation of peripheral pulses is important not only to assess the adequacy of perfusion, but also the burden of coronary artery disease often correlates with the degree of peripheral arterial disease. The presence of a carotid bruit may indicate clinically significant stenosis and may alter the course and timing of treatment, especially if symptomatic. Heart failure will frequently have extracardiac manifestations and examination of the other organ systems should not be neglected. For example, auscultation of the lung fields may reveal rales in patients with pulmonary edema. The use of accessory muscles of breathing may be present in patients with significant pleural effusions and volume overload. The presence of jugular venous distention and hepatosplenomegaly may signal right heart failure.

Additionally, clinicians should know the manifestation of other cardiac pathologies including endocarditis and rheumatic heart disease, although less commonly seen. Endocarditis is an inflammation of the endocardium, usually on the heart valves. A cardiac murmur is a common physical exam finding. Relatively uncommon but more specific clinical manifestations for infectious endocarditis are: Janeway lesions, which are nontender erythematous macules on the palms and soles; Osler nodes, which are described as tender subcutaneous nodules mostly on the pads of the fingers and toes; and Roth spots, which are exudative hemorrhagic lesions of the retina with pale centers.

Cardiac Risk Assessment in Noncardiac Surgery Patients

Cardiovascular complications occur in approximately 3% of patients undergoing inpatient noncardiac surgery. The American College of Cardiology (ACC) and American Heart Association (AHA) have formed a joint task force to publish a consensus statement, with periodic focused updates, on guidelines and recommendations that were revised in 2017. The aim of these guidelines is to incorporate surgery-specific risks and patient characteristics to guide perioperative decision-making in the management of patient with valvular heart disease.

Surgical procedures have been categorized based on cardiovascular risk into low risk, moderate risk, and vascular procedures. Vascular procedures, likely due to both the nature of the procedures themselves as well as the associated cardiovascular pathology in many of these patients, carry the highest reported risk of cardiac events at more than 7%. Low risk procedures, including endoscopic procedures, superficial operations, cataract surgery, breast surgery, and ambulatory surgeries, have a risk generally less than 1%. Intermediate risk procedures include intraperitoneal and intrathoracic surgery, head and neck surgery, orthopedic procedures, and prostate surgery.

Patient characteristics can be classified by the status of the patient’s cardiac disease, comorbid conditions, and functional capacity. Patients are considered to be at major perioperative clinical risk if they have one or more of the following active cardiac conditions: acute coronary syndrome, decompensated heart failure, significant arrhythmias, or severe valvular heart disease. In these patients, intensive evaluation and treatment prior to surgery (unless emergent) is warranted, prior to proceeding with noncardiac surgery.

If the patient does not have any of the previously mentioned active cardiac conditions, the perioperative risk of major adverse cardiac events (MACE) should be estimated. Both the operation performed and the patient’s risk factors are predictive of MACE, and the ACC/AHA guidelines recommend the use of either the American College of Surgeons’ NSQIP risk calculator or the Revised Cardiac Risk Index for the estimation of patient-specific risk. Patients at low (<1%) risk or patients at elevated risk with functional capacity greater than or equal to 4 metabolic equivalents (METs), should proceed to surgery without further testing. It is reasonable to perform pharmacologic stress testing in patients with poor or unknown functional capacity if this testing will impact decision making or perioperative care. Patients with abnormal stress test results should undergo confirmatory test such as coronary angiography, if indicated, before an elective noncardiac surgery. The previous guidelines included intermediate and low cardiovascular risk profiles, but this has been replaced by cardiovascular risk factors in the update. These risk factors are: history of ischemic heart disease, history of prior or compensated heart failure, history of cerebrovascular disease, diabetes mellitus, and renal insufficiency. Based on the number of present risk factors and the surgery-specific risk, the guidelines recommend pathways for further evaluation and risk management. The most recent guidelines from ACC/AHA were published in 2014 (Fig. 21-1). One important subgroup of patients at elevated risk are those who have recently undergone percutaneous coronary intervention. In these patients, elective noncardiac surgery should be delayed until the risk of stent thrombosis decreases (30 days for bare metal stents and 180 to 365 days for drug-eluting stents), and dual antiplatelet therapy should be continued unless the risk of bleeding exceeds the risk of stent thrombosis.

Diagnostic Studies

Electrocardiogram and Chest X-ray. Electrocardiograms (ECGs) and chest X-rays are noninvasive diagnostic studies that provide invaluable information in the preoperative assessment of patients with cardiac pathology. ECGs can be useful in detecting old myocardial infarction, dilation or hypertrophy of the cardiac chambers, arrhythmias, and conduction abnormalities. A stress ECG requires a patient to exercise to a target heart rate and is used to help diagnose ischemic pathologies that may not be evident at rest.

A plain film of the chest can detect pulmonary pathology, sequelae of heart failure (e.g., pulmonary edema, cardiac enlargement, pleural effusions), as well as presence of hardware (e.g., prosthetic heart valves, sternal wires, pacemakers, and defibrillators).

Echocardiography. Echocardiography utilizes reflected sound waves to image the heart. Transthoracic echocardiography (TTE) is used widely due to its noninvasive nature. It is the primary diagnostic tool used to evaluate structural diseases of the heart, including valvular pathology, septal defects, cardiomyopathies, and cardiac masses. Although more invasive, transesophageal echocardiography (TEE) can provide more information and better definition of some valvular and structural abnormalities. It is particularly useful in identifying left atrial thrombi in patients with atrial fibrillation. Echocardiography is indispensable in assessing surgical prostheses such as valves, leads, or mechanical circulatory support devices. These examinations can be performed with M-mode imaging (motion along a single line) as well as two-dimensional (2D) and three-dimensional (3D) imaging depending on the information required.

Doppler technology has become a standard addition to assess changes in flow patterns across dysfunctional valves. Velocity measurements can be obtained to estimate pressure gradients across structures using the continuity equation. A common example would be the estimation of pulmonary arterial systolic pressure calculated from the regurgitant tricuspid jet profile during right ventricular systole.

Transesophageal echocardiography requires no sedation and is generally performed with the patient in a slight left lateral decubitus position. Standardized views are obtained with the ultrasound probe placed in the apical, parasternal, subcostal, and suprasternal positions. The apical four-chamber view is a useful window for visualizing all four cardiac chambers simultaneously as well as the tricuspid and mitral valves. Other windows can be obtained to assess specific structures such as the individual valve anatomy or myocardial wall segments. Dobutamine-stress echocardiography is a study similar in idea to the stress ECG that utilizes a pharmacologic agent to assess the patient for ischemia or stress-induced valvular abnormalities.

Transesophageal echocardiography, on the other hand, is performed using a special endoscope with an ultrasound probe mounted on its end that is introduced orally into the esophagus under sedation. Posterior structures such as the mitral valve and left atrium are particularly well visualized. TEEs are frequently used intraoperatively during cardiothoracic surgery to assess global cardiac function, integrity of valve repairs and replacements, intracavitary thrombus and/or air, and aortic atherosclerosis or dissections that can have significant influences on operative strategy.

Echocardiography utilizes reflected sound waves to image the heart. Transthoracic echocardiography (TTE) is used widely due to its noninvasive nature. It is the primary diagnostic tool used to evaluate structural diseases of the heart, including valvular pathology, septal defects, cardiomyopathies, and cardiac masses. Although more invasive, transesophageal echocardiography (TEE) can provide more information and better definition of some valvular and structural abnormalities. It is particularly useful in identifying left atrial thrombi in patients with atrial fibrillation. Echocardiography is indispensable in assessing surgical prostheses such as valves, leads, or mechanical circulatory support devices. These examinations can be performed with M-mode imaging (motion along a single line) as well as two-dimensional (2D) and three-dimensional (3D) imaging depending on the information required.

Doppler technology has become a standard addition to assess changes in flow patterns across dysfunctional valves. Velocity measurements can be obtained to estimate pressure gradients across structures using the continuity equation. A common example would be the estimation of pulmonary arterial systolic pressure calculated from the regurgitant tricuspid jet profile during right ventricular systole.

Transesophageal echocardiography requires no sedation and is generally performed with the patient in a slight left lateral decubitus position. Standardized views are obtained with the ultrasound probe placed in the apical, parasternal, subcostal, and suprasternal positions. The apical four-chamber view is a useful window for visualizing all four cardiac chambers simultaneously as well as the tricuspid and mitral valves. Other windows can be obtained to assess specific structures such as the individual valve anatomy or myocardial wall segments. Dobutamine-stress echocardiography is a study similar in idea to the stress ECG that utilizes a pharmacologic agent to assess the patient for ischemia or stress-induced valvular abnormalities.

Transesophageal echocardiography, on the other hand, is performed using a special endoscope with an ultrasound probe mounted on its end that is introduced orally into the esophagus under sedation. Posterior structures such as the mitral valve and left atrium are particularly well visualized. TEEs are frequently used intraoperatively during cardiothoracic surgery to assess global cardiac function, integrity of valve repairs and replacements, intracavitary thrombus and/or air, and aortic atherosclerosis or dissections that can have significant influences on operative strategy.
There are some more recent additions to the echocardiographic armamentarium that capitalize on the strengths of ultrasound imaging. Three-dimensional TEE is playing an increasing role in the preoperative and intraoperative evaluation of patients with valvular heart disease and is especially helpful in percutaneous mitral intervention. Tissue Doppler imaging is based on principles akin to conventional Doppler echocardiography, but attention is directed to the myocardium itself as opposed to the motion of blood to quantify abnormalities in wall motion. Strain imaging with speckle-tracking echocardiography measures the actual deformation of the myocardium by following inhomogeneities inherent to the myocardium and is a useful measure of myocardial function.

**Radionuclide Studies.** Although ECGs are useful, inexpensive, and safe, baseline abnormalities in the ECG may limit its diagnostic capacity. In particular, ventricular rhythms, bundle-branch blocks, left ventricular hypertrophy, drug effects, and baseline ST-segment depressions can make stress ECGs difficult to interpret for the presence of myocardial ischemia. In this setting, myocardial perfusion imaging (MPI) using radionuclides can be utilized. Thallium 201 ($^{201}$Tl) was the initial radionuclide used for MPI, but due to its long half-life and relatively low photoprobe, it has largely been replaced by technetium-99m (sestamibi and tetrofosmin) because of its more favorable characteristics. In the past, planar imaging with three separate 2D views of the heart were obtained. Currently, it is more common to have the images acquired by single-photon emission computed tomography (SPECT) technology, which detects emitted photons from 180° to 360° around the patient. The signals are then processed to reconstruct multiple slices that together provide a 3D image. The distribution of radionuclides depends on perfusion, and therefore areas that show uptake at rest, but not during stress, are concerning for ischemia. The amount of uptake at both rest and stressed states is compared to assess ischemia and viability of the myocardium. Territories that do not show uptake at rest or during stress are likely to be nonviable scar. The sensitivity and specificity of exercise SPECT are 87% and 73%, respectively.8,9

The image acquisition may also be gated to a simultaneously obtained ECG to assess global ventricular function. The endocardial and epicardial borders (as delineated by radionuclide uptake) are detected throughout the cardiac cycle and the ejection fraction, along with end-systolic and end-diastolic volumes, can be calculated. This study is also useful in revealing hypokinetic segments of the myocardium.

One significant drawback of SPECT imaging is that it shows regional ischemia well, but it does not adequately detect global or “balanced” ischemia that can occur with diffuse CAD. Positron emission tomography (PET) has been used due to its ability to obtain absolute quantitative data on both myocardial perfusion and metabolism. Tracers used in PET scans can be divided into those that assess perfusion (oxygen-15, nitrogen-13, and rubidium-82) and those that assess metabolism (carbon-11 and fluorine-18). The specificity of PET in detecting CAD is better than SPECT at 86% due to its superior spatial resolution.10

**Magnetic Resonance Imaging.** Magnetic resonance imaging (MRI) has a wide variety of uses in cardiac imaging depending on the pulse sequence and signal weighting. Cine-loop imaging of the heart throughout the cardiac cycle can yield information on global chamber function, geometry, and valvular pathologies.

The differential response of normal and ischemic myocardium to certain pulse sequences allows imaging of myocardial perfusion using MRI. Use of contrast agents such as gadolinium can enhance scar tissue and are very useful in viability assessment. Myocardial strain imaging can also be performed taking advantage of radio-frequency tagging of the myocardium, which deforms with the tissue and can be followed throughout the cardiac cycle.

**Cardiac Catheterization.** Cardiac catheterization involves access to the cardiac chambers, coronary arteries, and great vessels with a peripherally inserted catheter under fluoroscopic guidance. It is a versatile tool used to investigate cardiac chamber pressures, valvular abnormalities, wall motion, and coronary artery anatomy. While some of these roles are being replaced by less invasive techniques mentioned previously, cardiac catheterization continues to be widely performed and is the gold standard for the assessment of coronary artery disease.11

Left heart catheterization is performed by percutaneous access of the femoral, or radial, artery. Under fluoroscopic guidance, the catheter is threaded into the ascending aorta where a contrast aortogram may be performed. Coronary angiography requires manipulation of this catheter into the coronary ostia where contrast is directly injected. With advancement of the catheter retrograde through the aortic valve, left ventricular pressures can be obtained. This measurement is used to calculate direct pressure gradients across the aortic valve, in contrast to echocardiography that indirectly measures pressure, and can be used to confirm severe aortic stenosis. Again, contrast injection into the left ventricle can be used to estimate ejection fraction and visualize hypokinetic segments of the myocardium. Inappropriate retrograde leakage of contrast may indicate insufficiency of the aortic and/or mitral valves.

Coronary angiography provides information on hemodynamically significant stenoses in the coronary circulation as well as an anatomical roadmap for surgeons to plan revascularization (Fig. 21-2A,B). A stenosis is considered to be significant if it narrows the lumen of the artery by 70% (or 50% in the case of left main coronary artery). Borderline lesions or complex lesions may be assessed by fractional flow reserve (FFR) or instantaneous wave-free radio (iFR), which obviates the need of adenosine.12 This has been shown to very helpful in guiding revascularization strategies in recent clinical trials.13 Additional assessment can also be done using intravascular ultrasound (IVUS) inside the coronary circulation. There is some variability in the coronary arterial anatomy with the posterior descending artery being supplied by the right coronary artery in approximately 80% of patients (right dominant) or the left coronary artery in approximately 15% of patients (left dominant). The remaining patients have a codominant circulation where the posterior descending artery is supplied by both the right and left coronaries.

Right heart catheterization is performed by the introduction of catheter through a peripheral vein that is advanced into the right side of the heart.14 Right-sided pressures and structures are assessed in a similar fashion as in the left heart. Extension of the catheter into the pulmonary artery allows measurement of pulmonary artery pressures as well as pulmonary capillary wedge pressure (reflecting left ventricular end diastolic pressure) with an occlusive balloon. In addition to these measurements, cardiac output can be measured using thermodilution or by the Fick method using oxygen saturations of blood sampled from the various locations during the procedure.
ACQUIRED HEART DISEASE

CHAPTER 21

Figure 21-2. Cardiac catheterization angiography. A. Stenosis of right coronary artery indicated by the arrow. B. Still image of a normal left ventriculogram.

An advantage of cardiac catheterization is that it offers an opportunity for interventional therapy of coronary artery disease, arrhythmias, valvular abnormalities, and other structural defects of the heart. Cardiac catheterization is generally safe, but being an invasive procedure, it is associated with rare complications. The overall mortality is 0.11%, and total rate of major complications, including MI, stroke, arrhythmia, vascular injury, contrast reaction including allergic reaction and contrast-induced nephropathy, hemodynamic instability, and cardiac perforation is usually <2%.15

Cardiac Computed Tomography. Multislice computed tomography (CT) imaging can be used to assess the coronary vasculature. The coronary calcium score is an index developed to quantify the degree of coronary atherosclerotic burden by measuring Hounsfield units in a noncontrast cardiac CT. Although this technique is quite sensitive for angiographic stenoses (>50%) it remains fairly nonspecific as calcification often precedes significant luminal narrowing.16 CT coronary angiography using intravenous contrast is also utilized to assess coronary pathology and is particularly useful in the emergency room to perform a “triple rule-out” for acute coronary events, pulmonary embolism, and aortic dissection in patients who present with undifferentiated chest pain. LV ejection fraction may be measured by this technique, and, together with the degree of coronary stenosis, it has been shown to have incremental prognostic value for the presence of coronary artery disease and in the prediction of adverse coronary events.17

EXTRACORPOREAL PERFUSION

History

Prior to the development of extracorporeal perfusion, heart surgery was rarely performed and was limited to brief periods of asystole and/or hypothermia. The need for obtaining a bloodless operating field, while maintaining perfusion of heart and other organs, was evident.

John Gibbon’s motivation to develop a means for extracorporeal perfusion came from a desire to safely open the pulmonary artery in a patient who suffered from a pulmonary embolus following a cholecystectomy. After numerous experimental iterations, Gibbon’s cardiopulmonary bypass machine was first used clinically in 1953 to repair an atrial septal defect in an 18-year-old woman.18 Although Gibbon is credited for its invention, the development of modern cardiopulmonary bypass (CPB) is a culmination of the work of many investigators throughout the world. The early bubble oxygenators have evolved into the currently used membrane oxygenators. The search for an ideal biocompatible material that minimizes the inflammatory cascade initiated by the contact of blood with the circuit components continues to this day.

Technique

The basic CPB circuit consists of the venous cannulae, a venous reservoir, pump, oxygenator, filter, and the arterial cannula. Anticoagulation is required during CPB, and 300 to 400 units/kg of heparin are given to increase the activated clotting time (ACT) to greater than 450 seconds. Once an adequate level of anticoagulation is achieved, arterial cannulation is performed through a purse-string suture or through a side graft sewn onto the native artery. The distal ascending thoracic aorta is the most common site of cannulation. Other routinely utilized sites of cannulation include the femoral artery, the axillary artery, the innominate artery, or the distal aortic arch, and they are altered based on the indicated surgical repair and the presence of native arterial disease. Venous cannulation is performed through purse-string sutures placed on the right atrium either for a single cannula or for two separate cannulae placed into the superior and inferior vena cava, respectively. Alternatively, the venous cannula may be inserted from the femoral vein and advanced into the right atrium and superior vena cava using TEE guidance. This technique is frequently used in minimally invasive cardiac surgery. Effective communication between the surgeon, the anesthesiologist, and the perfusionist is mandatory for effective
Cardiopulmonary bypass. Once the appropriate cannulations and connections are complete, CPB is commenced. Venous return is initiated followed by arterial flow while monitoring systemic blood pressure. At normothermia, the flow required is approximately 2.4 L/min/m², but with hypothermia, oxygen consumption is reduced by 50% for every 10°C drop in temperature, and a flow of only 1 L/min/m² is required at 18°C. Once the heart is decompensated and hemodynamics are acceptable, ventilation is stopped. The oxygenator is adjusted to maintain a Pao₂ of 150 mmHg and normocarbia. Blood can also be filtered and returned through vents that are placed in chambers of the heart (such as the left ventricle or pulmonary artery) or through the cardiotomy suction used to aspirate blood from the surgical field.

When the cardiac procedure is complete, the patient is rewarmed, the lungs ventilated, and the heart defibrillated, if needed. The venous return to the CPB machine is gradually reduced allowing the heart to fill. The pump is also slowed while hemodynamics and global cardiac function are assessed with a TEE probe. Inotropic and vasopressor support may be used to augmen cardiac function and treat hypotension. Once CPB has been weaned and stable hemodynamics achieved, the cannulae are removed. The heparin anticoagulation is reversed with 1 mg protamine per 100 units of heparin and hemostasis is achieved.19

Adverse Effects

Cardiopulmonary bypass has a number of deleterious effects as various intertwining processes result in derangements in hemostasis, an enhanced systemic inflammatory response, and end-organ function.

Anticoagulation prior to the commencement of CPB is required as contact of blood with the artificial surfaces of the circuit can initiate a thrombogenic cascade. Generation of thrombin plays a major role in both thrombotic and bleeding phenomena during CPB. The endothelium that normally regulates the fine balance between procoagulant and anticoagulant pathways is perturbed. Fibrinogen is consumed rapidly as thrombin converts fibrinogen to fibrin while fibrinolytic mechanisms (initiated by the activated endothelium) degrade the fibrin macromolecules. Platelets are activated by the converging hemostatic pathways and are consumed.

The response of the humoral and cellular immune systems partly overlap with the hemostatic pathways. The classic and alternative complement pathways are activated by CPB generating powerful chemotactic molecules and anaphylatoxins.20 Monocytes, platelets, and neutrophils are activated releasing acute inflammatory mediators and cytokines that persist even after conclusion of CPB.21 These inflammatory cells also produce reactive oxidants that may have cytotoxic and cardiovascular effects such as vasoconstriction and hypotension.

The large quantity of unfractionated heparin used during cardiac surgery predisposes patients to developing heparin-induced thrombocytopenia (HIT) with an incidence of 1% to 5%.22 Platelet factor-4 (PF-4) is produced by platelets and avidly binds to heparin to form a heparin-PF-4 complex that can be antigenic in some patients binding IgG. The IgG-heparin-PF-4 complex can bind to platelets, which causes release of more PF-4, perpetuating the process. The earliest sign is a sudden drop of more than 50% in the platelet count, usually seen from several hours to days after surgery. HIT can be confirmed with an enzyme-linked immunosorbent assay (ELISA) or serotonin release assay (SRA). Of the patients with HIT, 20% to 50% of patients develop thromboses in arterial or venous beds, designated as heparin-induced thrombocytopenia and thrombosis (HITT), which can be life-threatening.23 Treatment is anticoagulation with nonheparin anticoagulant (e.g., argatroban, bivalirudin).

The etiology of end-organ dysfunction resulting from extracorporeal circulation can mostly be categorized into one of three mechanisms: hypoperfusion, embolization, and whole-body inflammatory response. Although cardiac output and blood pressure are monitored carefully during CPB, they are surrogates for regional perfusion and cannot detect end-organ hypoperfusion directly. This can be a problem particularly with the cerebral, renal, and mesenteric circulations. With manipulation of diseased vessels and dysregulation of the native coagulation system, macroscopic and microscopic emboli are a concern. Activated cells and circulating cytotoxic products of the immune response may cause microvascular injury and edema of other organs manifesting as neurocognitive deficits, respiratory failure, and renal injury.24

Myocardial Protection

During CPB, pharmacologic agents in cardioplegic solutions may be delivered into the coronary circulation to arrest the heart, allowing for a still operating target and improved myocardial protection. The most common cardioplegia consists of potassium-rich solutions that can be mixed with autologous blood and are delivered into the coronary circulation.25 Antegrade cardioplegia is delivered into the root of a cross-clamped aorta or directly into the individual coronary ostia using specialized catheters. A retrograde cardioplegia catheter is a balloon-cuffed catheter that is placed through the right atrium into the coronary sinus and is used to perfuse the coronary circulation in the opposite direction through the venous circulation. This has the advantage of more uniform distribution in patients with diffuse coronary artery disease and is not dependent on a competent aortic valve for delivery.

There is continued debate regarding the best method (antegrade vs. retrograde vs. both), type (crystalloid vs. blood), temperature (cold vs. warm vs. tepid), and interval (continuous vs. intermittent) of cardioplegia delivery. The optimal combination is beyond the scope of this text. However, most cardiac surgeons in the United States favor cold blood potassium cardioplegia.

CORONARY ARTERY DISEASE

History

Aortocoronary bypass for myocardial ischemia was first proposed and performed in laboratory animals by Carrel in 1910.26 The Vineberg operation, one of the initial attempts at surgical revascularization of the myocardium, was introduced in 1951.27 This procedure involved implantation of the internal thoracic artery directly into the myocardium itself. While some patients were relieved of their anginal symptoms, this resulted in virtually no increase in coronary flow and was soon supplanted by methods to restore flow directly. Coronary endarterectomy was introduced by Longmire during this time period but had high rates of restenosis and occlusion.28 The use of vein patches to repair the arteriotomy sites was described by Senning in 1961.29 The first saphenous vein coronary artery bypass grafting (CABG) was performed by Sabiston in 1962,30 but was popularized by Favalaro and Sones in 1967.31 In 1968, the internal thoracic artery was introduced as a bypass conduit by Green, who used it to bypass the left anterior descending coronary artery.32
Etiology and Pathogenesis
Atherosclerotic stenoses are the primary mechanism of CAD. The pathophysiologic process is initiated with vascular endothelial injury and is potentiated by inflammatory mechanisms, circulating lipids, toxins, and other vasoactive agents in the blood. Macrophages and platelets are attracted to this area of endothelial dysfunction inciting a local inflammatory response. During this process, macrophages infiltrate into the intimal layers and accumulate cholesterol-containing low-density lipoproteins. The growth factors secreted promote proliferation of smooth muscle cells within the intima and media of the arteries. Together with the accumulation of the lipid-laden macrophages, the smooth muscle hyperplasia results in an atheroma and subsequent stenosis of the vessel. These atheromas have a fibrous cap that may rupture, exposing the underlying cells and extracellular matrix, which are very prothrombotic. Acute plaque rupture and thrombus formation is thought to be the main pathophysiologic mechanism responsible for acute coronary syndromes.33-35

Risk Factors and Prevention
Prior to the establishment of modern management strategies, the annual mortality rate from ischemic heart disease was 482 out of 100,000 persons.36 Since the peak of coronary heart disease mortality in 1968, modern primary and secondary prevention strategies such as risk factor modification, percutaneous and surgical revascularization, use of medications (e.g., aspirin, HMG-CoA reductase inhibitors [statins], and β-blockers), has decreased mortality from coronary artery disease by 74%.36

The major risk factors for atherosclerosis include advanced age, cigarette smoking, hypertension, dyslipidemias, sedentary lifestyle, obesity, and diabetes. Likely due to increased public awareness and aggressive medical management, these risk factors (with the exception of glucose intolerance and obesity) have recently been on the decline.

Current guidelines outlined in the AHA/ACC consensus statement summarize the secondary prevention recommendations.37 Class I recommendations include smoking cessation and avoidance of environmental tobacco exposure, blood pressure control to under 140/90 mmHg (under 130/80 mmHg in those with diabetes or chronic kidney disease), LDL cholesterol levels less than 100 mg/dL, aspirin therapy in all patients without contraindications, a BMI target of less than 25 kg/m², diabetes management with target HbA1c <7%, and encouragement of daily moderate-intensity aerobic exercise. β-Blockers should be used in all patients with LV dysfunction and following MI, ACS, or revascularization, unless a specific contraindication is present. Renin-angiotensin-aldosterone system blockade in patients with hypertension, LV dysfunction, diabetes, or chronic kidney disease should also be considered.

Clinical Manifestations
Patients with CAD may have a spectrum of presentations, including angina pectoris, myocardial infarction, ischemic heart failure, arrhythmias, and sudden death.

Angina pectoris is the pain or discomfort caused by myocardial ischemia and is typically substernal and may radiate to the left upper extremity, neck, or epigastrium. The variety of presentations can make myocardial ischemia challenging to diagnose. Characteristics of chest pain that make myocardial ischemia less likely include pleuritic chest pain, pain reproducible by movement or palpation, or brief episodes lasting only seconds. Typical angina is relieved by rest and/or use of sublingual nitroglycerin. Differential diagnoses to be considered include, but are not limited to, musculoskeletal pain, pulmonary disorders, esophageal spasm, pericarditis, aortic dissection, gastroesophageal reflux, neuropathic pain, and anxiety.

Myocardial infarction is a serious consequence of CAD occurring when ischemia results in myocardial necrosis. This may be silent and need not be preceded by angina. Necrosis may result in disruption of the myocardial integrity leading to devastating conditions such as intracardiac shunts from ventricular septal defects, acute valvular regurgitation from rupture of necrotic papillary muscles, and cardiac aneurysms, which have the potential for fatal rupture.

Ischemic insults from CAD may lead to congestive heart failure. The initial myocardial damage sets off a cascade of both local and systemic responses. Over time, these changes can cause deleterious myocardial loading and abnormal neurohumoral responses that result in pathologic remodeling of the heart. Heart failure should be suspected in patients who present with dyspnea, orthopnea, fatigue, and edema.

Arrhythmias may also be sequelae of CAD. Ischemic etiologies should be investigated in patients who present with new arrhythmias. CAD may result in arrhythmias following an acute MI or as the result of ultrastructural and electrophysiologic remodeling secondary to chronic ischemic heart disease. Ischemia of the electrical conduction system may be present in the form of new onset complete or partial atrioventricular conduction blocks.

Preoperative Evaluation
A focused history and physical examination is essential with particular attention directed to the signs, symptoms, and clinical manifestations mentioned previously. The patient’s functional status is of importance not only because it is a component of preoperative risk assessment, but also because quality of life improvement and symptomatic relief are both goals of surgical therapy.

Coronary angiography is the primary diagnostic tool. The coronary anatomy and degrees of stenoses are delineated allowing for planning of surgical revascularization.

Noninvasive diagnostic studies, in combination with provocative maneuvers (exercise or pharmacologic agents) offer information regarding the functional significance of ischemic disease. A stress ECG is frequently used as a screening tool with 50% sensitivity and 90% specificity for coronary artery with a threshold of 1 mm of ST-segment depression.39 This test, however, requires patients to achieve a certain elevation in their heart rate and is therefore not suitable for those that cannot achieve this goal. Furthermore, baseline ECG abnormalities may render it impossible to detect typical ischemic changes with stress.

Echocardiography and nuclear imaging may be performed under pharmacologic stress (with dobutamine or dipyridamole) to assess reversible ischemia and myocardial viability. Technetium-99m or thallium-201 perfusion scans and stress echocardiography are more sensitive than stress ECG.39 These studies also have the ability to assess global ventricular function in terms of left ventricle ejection fraction, which can be used to determine operative risk. Please refer to the diagnostic studies section for more details.

CORONARY ARTERY BYPASS GRAFTING
Indications
A joint committee established by the ACC/AHA have published guidelines for surgical revascularization (CABG) in
Table 21-3
Algorithm set forth by ACC/AHA guidelines for preoperative cardiovascular evaluation before noncardiac surgery for patients who are scheduled for nonemergent, non-low risk surgery, no active cardiac disease, and less than 3 METs

DM = Diabetes mellitus; LITA = Left internal thoracic/mammary artery; LM = Left main coronary artery; LV = left ventricle; VT = ventricular tachycardia. Class of recommendation: I – Benefit far outweighs risks and procedure should be performed; Ia – Benefit outweighs risks and procedure is considered to be reasonable; Iib – Potential benefits may exceed risks and procedure may be considered; II – Procedure not helpful and may cause harm. Level of evidence: A – Strong; multiple supporting randomized controlled trials or meta-analyses. B – Limited; data based on a single randomized trial or nonrandomized trials. C – Very limited; based on expert consensus, case studies or standards of care.
modest with an incremental cost-effectiveness ratio of $30,454 per quality-adjusted life year gained.47

**Everolimus-Eluting Stents or Bypass Surgery for Left Main Coronary Artery Disease (EXCEL Trial, 2016).** This study randomized 1905 patients with left main coronary artery disease of low or intermediate complexity to PCI or CABG. At 3 years, no difference was observed in the primary endpoint of death, stroke, myocardial infarction or ischemia-driven revascularization. However, it should be noted that the PCI group exhibited a greater increase in these events between 30 days and three years than the CABG group (11.5% vs. 7.9%).48

**Summary**

PCI technology has improved over time, and rates of periprocedural adverse events have decreased significantly. Management strategies must be tailored to the individual patient’s clinical status and context, but CABG maintains improved long-term outcome and remains the standard of care for patients with left-main, multivessel coronary artery disease and patients with diabetes. Recent and upcoming trials will continue to clarify which patient populations benefit most from either revascularization strategy.

**Operative Techniques and Results**

**Bypass Conduit Selection.** The most important criterion in conduit selection is graft patency. The conduit with the highest patency rate (98% at 5 years and 85%–90% at 10 years) is the internal thoracic artery, which is most commonly left attached proximally to the subclavian artery (although occasionally used as a free graft) and anastomosed distally to the target coronary artery.49,50 The use of both internal thoracic arteries has been shown to increase event-free survival in a number of studies.51-52

The greater saphenous vein can be harvested using an open or endoscopic technique. In the open technique, the initial incision is made along the course of the vein on the medial aspect of the lower extremity. The vein is harvested with meticulous attention directed toward minimizing manipulation of the vein itself. The incision may be continuous or bridged in an attempt to decrease the size of the incision, but multiple bridged incisions may have the potential risk of increased conduit manipulation during harvest. Endoscopic harvest is performed by making a small incision just above and medial to the knee where the endoscope is inserted. Side branches are cauterized under endoscopic visualization using bipolar electrocautery until dissection is carried proximally until the required length of vein is mobilized. A proximal counterincision is then made to extract the venous conduit, which is prepared in the standard fashion.

The radial artery is another frequently used conduit. After confirmation of ulnar collateral flow to the hand by the clinical Allen’s test or a duplex ultrasound study, an incision is made from a point just proximal to the radial styloid process and ending just medial and distal to the biceps tendon on the nondominant hand. With lateral retraction of the brachioradialis muscle, the radial artery is dissected sharply with care to avoid injury to the cutaneous nerves in this area and minimize manipulation of the artery itself. This artery can also be harvested using an endoscopic technique.

Many studies have looked at the patency rates of the radial artery graft in comparison to the saphenous vein graft. Although some studies have resulted in equivocal data, general consensus favors the use of radial arterial grafts over vein grafts with 5-year patency rates of 98% and 86%, respectively.53-54

From a historical perspective, the anterior circulation (left anterior descending artery) is generally bypassed using the internal thoracic artery, and the lateral (circumflex artery) or inferior (right coronary artery) territories are bypassed using a saphenous vein or radial artery graft. These conduits may be combined to form a composite T- or Y-graft, or sewn to multiple targets as sequential grafts. Since patency is best with arterial grafts, recent data have suggested that the best long-term results are achieved using a multiple or all-arterial revascularization strategy, particularly in patients >70 years of age and patients with diabetes.55-57 Other conduits such as the gastroepiploic arteries, lesser saphenous veins, and cephalic veins have been described, but these are not widely used and will not be discussed here.

**Conventional Coronary Artery Bypass Grafting.** Traditionally, CABGs are performed with the patient lying supine through a median sternotomy. Left internal thoracic artery and other conduit harvests are performed. After the patient is heparinized, cardiopulmonary bypass is initiated. The aorta is cross-clamped, and cardioplegia is delivered. Once adequate myocardial protection has been achieved, coronary arteriotomies are made, and distal anastomoses are performed using polypropylene suture (Fig. 21-3A,B). The proximal anastomoses are then performed directly onto the ascending aorta or onto preexisting grafts. It is important to note that significant coronary stenoses can cause differential distribution of cardioplegia and myocardial protection. It is therefore recommended to use retrograde cardioplegia or to revascularize the area with the most concern for ischemia first and give cardioplegia down the completed graft. The left internal thoracic artery to left anterior descending (LAD) graft is frequently performed last to avoid kinking or disruption of this important conduit. Once all grafts

Conventional CABG Results. Several early randomized trials showed improved survival in patients who received a CABG as opposed to medical therapy. A propensity-matched study identified that CABG greatly benefited patients with LV dysfunction and left main stenosis >50% compared to medical management. The Bypass Angioplasty Revascularization Investigation (BARI) trial demonstrated impressively superior results with CABG compared to PCI in terms of 5-year cardiac mortality (5.8% vs. 20.6%) in patients with diabetes in addition to CAD. In a study examining the benefits of CABG over medical management for specific CAD distributions, survival was better in patients with proximal LAD stenoses, regardless of the number of diseased vessels. In general, these studies show survival rates of over 90% at 5 years and approximately 75% at 10 years following CABG.

The mortality and morbidity of the procedure itself has changed over time. Data from the Society of Thoracic Surgeons (STS) database accounts for 1,497,254 patients who underwent solitary CABG from 2000 to 2009. The mortality rate of CABGs has improved significantly from 2.4% in 2000 to 1.9% in 2009, despite the relatively constant predicted mortality rate of around 2.3%. In parallel with this, postoperative complication rates have also decreased: stroke (1.6%–1.2%), bleeding requiring reoperation (2.4%–2.2%), and deep sternal wound infection (0.59%–0.37%).

Off-pump Coronary Artery Bypass. To avoid the adverse consequences of cardiopulmonary bypass, off-pump coronary artery bypass (OPCAB) was developed and has been adopted in some centers over the past two decades.

With OPCAB, the heart is left beating. Performing anastomoses on the beating heart requires the use of myocardial stabilization devices, which help portions of the epicardial surface to remain relatively immobile while the anastomoses are being performed (Fig. 21–4).

Apical suction devices are used to aid in exposure, particularly of the lateral and inferior vessels. Many creative maneuvers have been developed, including patient repositioning, opening the right pleural space to allow for cardiac displacement, and creation of a pericardial cradle to minimize compromise of cardiac function while exposing the various surfaces of the heart. Temporary proximal occlusion of the target coronary artery, or the use of an intracoronary shunt, are necessary to...
provide adequate exposure of the anastomosis. Occlusion causes temporary ischemia, and if not tolerated during a test occlusion, coronary shunts can be employed.

**OPCAB Results.** The superiority of OPCAB over on-pump CABG remains a controversy despite the large body of literature on this topic. A pooled analysis of two randomized trials, the Beating Heart Against Cardioplegic Arrest Studies (BHACAS 1 & 2), is one of several studies that have touted lower short-term mortality rates with the off-pump compared to the on-pump technique.\(^\text{65-67}\) Other studies, however, have demonstrated equivocal or contrary results.\(^\text{68-70}\) Furthermore, the prospective and much larger ROOBY (Randomized On/Off Bypass) trial showed increased rates of adverse cardiac events with OPCAB compared to conventional CABG.\(^\text{71}\) Despite the initial enthusiasm for the theoretical advantages of avoiding cardiopulmonary bypass, consistent benefits in clinical outcome have not been observed. There does seem to be a more or less uniform trend towards decreased perioperative blood product transfusions with OPCAB compared to on-pump CABG. In terms of other measures of early outcome, postoperative renal failure, stroke, and acute MI, the superiority of OPCAB has been unclear.\(^\text{69,72,73}\) A more recent Cochrane review by Moller et al did not demonstrate any significant benefit of off-pump compared with on-pump CABG regarding mortality, stroke, or myocardial infarction. In contrast, better long-term survival in the group of patients undergoing on-pump CABG with the use of cardiopulmonary bypass and cardiopulmonary arrest was observed.\(^\text{74}\)

The higher cardiac morbidity in the ROOBY trial was associated with decreased 1-year angiographic patency rates.\(^\text{71}\) However, studies with contrasting findings exist, quoting equivalent rates of graft patency for OPCAB usage.\(^\text{75,76}\) The broad variety in results may be suggestive that other factors (e.g., surgeon skill, technical difficulty, patient factors) may be dominating the outcome rather than the use or avoidance of cardiopulmonary bypass.\(^\text{77}\) After almost two decades, OPCAB has not been widely adopted and remains less than 20% of all CABG procedures in the United States.

**Minimally Invasive Direct Coronary Artery Bypass.** As an extension of the off-pump coronary revascularization technique, minimally invasive direct coronary artery bypass (MIDCAB) has been described. MIDCAB is performed using a left anterior mini-thoracotomy through which mobilization of the left internal thoracic and direct in situ anastomosis to the left anterior descending artery (or its diagonal branches) is performed. This technique is primarily applicable to single-vessel disease, although reports of multivessel revascularizations do exist.

**MIDCAB Results.** A review of 411 patients undergoing MIDCAB quotes an operative mortality >1%. In this study, all patients received revascularization of the LAD only, regardless of the number of diseased vessels. The 3-year mortality in patients with single-vessel disease following a MIDCAB was 3.1%, which was not surprisingly, lower than those with multivessel disease (8.7%).\(^\text{78}\)

There is an inherent selection bias in retrospective reviews comparing MIDCAB to OPCAB or conventional CABG as MIDCAB patients tend to have less extensive disease. Because of this, there have been multiple randomized controlled trials looking at the efficacy of MIDCAB compared to PCI. A meta-analysis of 12 randomized prospective trials comparing PCI to MIDCAB revascularization of isolated proximal left anterior descending artery demonstrated comparable results in terms of mortality and MI but a lower revascularization requirement in the MIDCAB group.\(^\text{79}\)

A recent meta-analysis by Lee et al revealed CABG, as compared with PCI with DES, reduced long-term rates of the composite of all-cause death, myocardial infarction, or stroke in patients with left main or multivessel CAD. Compared to PCI with DES, CABG was found to be superior in patients with multivessel CAD (\(P = 0.001\)), but no between-group differences in those with left main CAD (\(P = 0.427\)).\(^\text{80}\) Similar conclusions have been made by multiple other studies.

**Total Endoscopic Coronary Artery Bypass.** With the advent of robotic surgical technology allowing stereoscopic visualization and increased instrument dexterity, total endoscopic coronary artery bypass (TECAB) has become possible. In July 2004, the da Vinci robotic surgical system received FDA approval for use in coronary anastomoses. Extracorporeal circulation with peripheral cannulation has been used in earlier reports, but the development of mechanical stabilizers has provided the ability to perform the internal thoracic artery harvest and coronary anastomosis off-pump with use of the robotic arms only. Several studies have looked at the feasibility of TECAB and have shown acceptable results, but this procedure has not been adopted by most surgeons because of its steep learning curve, longer operative times, and lack of demonstrable clinical benefit.\(^\text{81-83}\) Although the volume of robotic-assisted CABG is increasing, such procedures constituted <1% of all CABG procedures performed in the United States in 2012.\(^\text{84}\)

**Hybrid Coronary Revascularization.** With the increasing collaboration between cardiothoracic surgeons and interventional cardiologists, hybrid coronary revascularization (HCR) combining a minimally invasive surgical technique (MIDCAB or TECAB) with PCI has become a reality. This capitalizes on a major advantage of both treatments, utilizing the durable left internal thoracic artery to left anterior descending coronary artery bypass graft while treating other stenoses with PCI, obviating the need for a large surgical incision or cardiopulmonary bypass. HCR is not without its downsides as there are some concerns with this approach because aggressive anti-platelet therapy is required with PCI and may increase the hemorrhagic complications of surgical revascularization. A small study comparing HCR to OPCAB showed comparable graft patency and decreased hospital stay with HCR without an increase in complication rates.\(^\text{85}\) There are, however, some studies that have reported increased rates of requirement for reintervention in patients undergoing HCR, and this requires further study.\(^\text{86,87}\) A recent multicenter prospective observational study showed equivalent outcomes between HCR and multivessel PCI.\(^\text{88}\) HCR has not gained widespread acceptance, and its clinical value remains a matter of debate.

**Transmyocardial Laser Revascularization.** Despite the advancement of technology and revascularization strategies, patients with end-stage coronary artery disease may not be amenable to complete revascularization. Transmyocardial laser revascularization (TMR) relies on a CO\(_2\) or holmium:yttrium-aluminum-garnet (Ho:YAG) laser to create multiple transmural channels (1 mm in diameter) through the myocardium. The initial concept was that these channels would serve as conduits for direct perfusion from the ventricle, but evidence suggests that the resultant angiogenesis is primarily responsible for the improved perfusion. A meta-analysis of seven randomized controlled trials comparing TMR to medical therapy for chronic...
angina has shown higher rates of angina improvement in the TMR but was not able to show a difference in mortality between the two groups.90

TMR is also being used as an adjunct to CABG in the treatment of extensive CAD that is not amenable to surgical revascularization alone. In a study looking at the benefits of TMR in addition to CABG, Allen et al concluded that TMR decreases angina burden when added to CABG in patients who cannot be revascularized by CABG alone.90 The current STS guidelines support the consideration of TMR in patients with ischemic myocardial territories that cannot be revascularized by PCI or CABG.91 Because of equivocal late results at most centers, this therapeutic strategy has not gained widespread acceptance, and ACC/AHA guidelines give TMR a class IIb recommendation for treatment of refractory angina.90

New Developments

Regenerative Medicine and Tissue Engineering. Provocative investigations are being performed on the level of signaling molecules, gene therapy, stem cells, and tissue engineering to regenerate or replace damaged tissue in patients with ischemic heart disease. Growth factors, such as fibroblast growth factor (FGF) and vascular endothelial growth factor (VEGF), are receiving attention due to their ability to induce growth of new vessels. Although concerns regarding systemic administration of these pleiotropic signaling molecules exist, early placebo-controlled clinical trials have shown some promising results with administration of these agents.92,93 Adenoviral transfection of diseased tissue with transgenes for growth factors and transcription factors has been attempted with variable results.

Research in tissue engineering has been directed at creation of vascular conduits that are resistant to atherosclerosis. Stem cells have also been infused directly into the site of injury or in the generation of new tissue around a biodegradable scaffold.94 Despite their potential, these technologies are still in their infancy, and significant progress will be needed before more widespread clinical adoption.

VALVULAR HEART DISEASE

General Principles

The number of patients undergoing surgical management of valvular heart disease has increased over the last decade, from a total of 26,547 isolated aortic or mitral valve procedures reported to the STS Adult Cardiac Surgery Database in 2006 to 45,253 such procedures in 2015.95 In 2016, valve procedures represented over 50% of the cases performed at our institution. Although congenital and inherited etiologies represent important clinical entities, age-associated and acquired conditions still represent the primary causes of valvular heart disease and are the focus of this section.

The most common screening method for valvular heart disease is cardiac auscultation, with murmurs classified based primarily on their timing in the cardiac cycle, but also on their configuration, location and radiation, pitch, intensity, and duration (Table 21-6).96 Although some systolic murmurs are related to normal physiologic increases in blood flow, some may indicate cardiac disease, such as valvular aortic stenosis (AS), that are important to diagnose, even when asymptomatic. Diastolic and continuous murmurs, on the other hand, are frequently

AI = aortic insufficiency; ASD = atrial septal defect; MR = mitral regurgitation; MS = mitral stenosis; MVP = mitral valve prolapse; PDA = patent ductus arteriosus; PR = pulmonic regurgitation; TI = tricuspid insufficiency; TS = tricuspid stenosis; VSD = ventricular septal defect.
pathologic in nature. Dynamic cardiac auscultation provides further evidence as to the significance and origin of many murmurs (Table 21-7).96

Although auscultation may provide initial evidence to the existence of valvular disease, associated signs and symptoms may help narrow the diagnosis. Abnormalities in the splitting of the heart sounds and additional heart sounds should be noted, as should the presence of pulmonary rales. Peripheral pulses should be checked for abnormal intensity or timing, and the presence of a jugular venous wave should be documented. Additionally, symptoms of syncope, angina pectoris, heart failure, and peripheral thromboembolism are important and may help guide diagnosis and management.

Several imaging examinations are also available to aid in the diagnosis and classification of various valvular disorders. Electrocardiograms may provide information regarding ventricular hypertrophy, atrial enlargement, arrhythmias, conduction abnormalities, prior myocardial infarction, and evidence of active ischemia that would prompt further workup. Posteroanterior and lateral chest X-rays are also easy to obtain and may yield information regarding cardiac chamber size, pulmonary blood flow, pulmonary and systemic venous pressure, and cardiac calcifications. The gold standard for the evaluation of valvular heart disease is transthoracic echocardiography (TTE), which is helpful in the noninvasive evaluation of valve morphology and function, chamber size, wall thickness, ventricular function, pulmonary and hepatic vein flow, and pulmonary artery pressures. Specialized examinations based on the specific findings of TTE examinations are discussed in the following sections.

Regardless of the etiology, valvular heart disease can produce a myriad of hemodynamic derangements. Left untreated, valvular stenosis and insufficiency can produce significant pressure and volume overload on the affected cardiac chamber, respectively, with mixed disease consequently causing mixed pathology. Although the heart can initially compensate for alterations in cardiac physiology, cardiac function eventually deteriorates, leading to heart failure, decreased patient functional status, ventricular dysfunction, and eventually death. In order to optimize long-term survival, surgery or transcatheter therapeutics are recommended in various forms of valvular heart disease and in an increasing number of elderly and high-risk patients.

### Surgical Options

Although valve repair is increasingly indicated, especially in patients with aortic, mitral or tricuspid insufficiency, valve replacement is appropriate in certain patient populations. Valve replacement can be accomplished with either mechanical or biological prostheses, and the choice of valve depends on many patient-specific factors such as age, health status, and desire for future pregnancy. Preexisting indications or contraindications to anticoagulation therapy also influence the choice of mechanical versus tissue valve prosthesis.

Current options for mechanical valve replacement include either tilting disc valves or bileaflet valves. Although mechanical valves are highly durable, they require permanent anticoagulation to mitigate the risk of valve thrombosis and thromboembolic sequelae.97 Due to the concordant risk of hemorrhagic complications, patient characteristics such as debility, lifestyle, and contraindications to systemic anticoagulation therapy may preclude mechanical valve replacement. Moreover, young women who are planning future pregnancies cannot take warfarin due to its teratogenic potential. Conversely, patients with other indications for systemic anticoagulation, such as other risk factors for thromboembolism (i.e., atrial fibrillation), or the presence of a mechanical prosthetic valve in place in another position, may benefit from mechanical valve replacement. Current ACC/AHA guidelines recommend a shared-decision-making process between patient and physician when determining the choice of valve prosthesis, with the use of

bioprosthetic valves in all patients who have a contraindication to lifelong anticoagulation or who are unwilling to receive it.98

The potential to avoid the hazards of serious bleeding complications spurred the development of valve prostheses using biological materials, which obviates the need for systemic anticoagulation therapy. As tissue valves are naturally less thrombogenic, the attendant yearly risks of both thromboembolic and anticoagulation-related complications are considerably less than with mechanical valves.99 Consequently, tissue valve replacement is generally recommended for patients averse to systemic anticoagulation therapy, with potential concerns regarding compliance or follow-up while taking anticoagulant medications, and in the case of reoperation for a thrombosed mechanical valve. However, biological valves are more prone to degeneration, especially when implanted in the mitral position, and in younger patients, and those in renal failure, on hemodialysis, or with hypercalcemia.99 Improved manufacturing methods have made currently available tissue valves more durable than previous versions, and valve replacement with a biological prosthesis is generally preferred in patients without other indications for anticoagulation therapy who are >60 years of age for the aortic position and >70 years of age for the mitral position. The availability of transcatheter aortic valves for re-replacement, has resulted in patients and surgeons preferring bioprosthetic aortic valves in patients even <60 years of age in many centers.

**Mechanical Valves.** The first bileaflet mechanical valve was introduced in 1977. Bileaflet valves are comprised of two semi-circular leaflets that open and close, creating one central and two peripheral orifices (Fig. 21-5). Bileaflet mechanical valves have demonstrated excellent flow characteristics, low risk of late valve-related complications, including valve failure, and are currently the most commonly implanted type of mechanical valve prosthesis in the world.100

Although mechanical valves necessitate systemic anticoagulation, careful monitoring of the International Normalized Ratio (INR) reduces the risk of thromboembolic events and hemorrhagic complications and improves overall survival.101 Patients undergoing mechanical aortic valve replacement generally have a target INR of 2 to 3 times normal; however, after a randomized study, one of the mechanical aortic valves has been improved for an INR range of 1.5 to 2.0.102 Patients undergoing mechanical mitral valve replacement frequently have increased left atrial size, concomitant atrial fibrillation, and are at higher risk for thromboembolism that those undergoing aortic valve replacement and are thus recommended to have a target INR 2.5 to 3.5 times normal. When managed appropriately, the yearly risk of major bleeding is <1.4%. Patients with mechanical mitral valve prostheses have nearly twice the thromboembolic risk of those with mechanical aortic valve prostheses (1.3% vs. 0.8% per year).103

**Tissue Valves.** A xenograft valve is one implanted from another species, such as porcine xenograft valves, or manufactured from tissue such as bovine pericardium. A variety of xenograft tissue valves exist and are primarily differentiated by the presence or absence of a mounting stent. Stented valves are the most commonly implanted, and the most popular valve in the United States is a stented bovine pericardial valve.104

The more traditional stented valves are attached to a sewing ring, which decreases the technical complexity of valve replacement compared with stentless valves (Fig. 21-6). The chief disadvantage of stented tissue valves is a smaller effective orifice area, which increases the transvalvular gradient. This phenomenon is referred to as patient prosthetic mismatch. This effect is most pronounced in patients with small prosthetic valve areas, specifically <0.85 cm² valve area per square meter body surface area and may affect survival, symptomatic improvement, and the hemodynamic response to exercise following surgery.105

Stentless porcine xenograft valves were developed in order to minimize the limitations in flow characteristics seen in patients with small prosthetic valve areas and have demonstrated an increase in effective valve area of approximately 10% over stented xenografts of equivalent size.106 They can result in improved hemodynamics, both at rest and with exercise.106 The absence of a stent and sewing ring both increases the technical complexity of valve replacement and takes advantage of the biologic mobility of the aortic valve apparatus. Though results with stentless valves seem promising, some stentless valves have been shown to have poor durability,107 and stentless valves have not been widely adopted due to the technical complexity of implantation.

Recently, rapid deployment valves have been introduced to further decrease the complexity and time required for aortic valve replacement. Two of these valves are on the market in the United States. The Perceval valve by LivaNova is the only sutureless, stentless valve available.108 These rapid deployment valves have shown improved hemodynamics, particularly in patients with small annuli, and shorter implantation times. In some series, these benefits have been shown to reduce early morbidity.108

**Homografts.** Homograft valves from human cadavers, also known as allografts, have been used for aortic valve replacement since the technique was originally described over 50 years ago.109 Since that time, homografts have typically been used for aortic and pulmonary valve replacements and have been successfully harvested from brain dead organ donors and the
explanted hearts of heart transplant recipients. Following harvest, these valves are sterilized using an antibiotic solution and subsequently stored in fixative or cryopreservation solution.

Like other types of tissue valves, the risk of thromboembolic complications with homograft valves is low, and systemic anticoagulation therapy is not required. Additionally, the structure of homograft valves is naturally low-profile, allowing for larger effective valve orifices and lower postoperative transvalvular gradients compared with stented xenograft valves. Additionally, they have been shown to have some advantages in patients with endocarditis.  

The major shortcoming of homograft valves is their limited long-term durability due to tissue degeneration. Within one year of implantation, these valves undergo substantial loss of cellular components and subsequent structural compromise, which may ultimately lead to valve failure. Although enhanced preservation techniques has improved cellular viability, which approaches the 15-year viability of xenograft valves, the limited availability of these valves and techniques has limited the use of homograft tissue valves.

**Autografts.** In 1967, Donald Ross described a procedure in which the diseased aortic valve was replaced using the patient’s native pulmonary valve as an autograft, which was in turn replaced with a homograft in the pulmonic position. The procedure resulted in minimal transvalvular gradients and favorable left ventricular mechanics, both at rest and during exercise. Known as the Ross procedure, this operation has been shown to be particularly beneficial in children, as the pulmonary trunk grows with the child and long-term anticoagulation is not required.

The late results of the Ross procedure are discussed later in this chapter. In addition to potential concerns with durability, performance of the Ross procedure has also been limited by its technical complexity and the increased surgical risk associated with double valve replacement.

**Valve Repair.** Valve repair offers a number of advantages over valve replacement, due in large part to the preservation of the patient’s native valvular and subvalvular apparatus. In mitral valve (MV) surgery, preservation of the mitral apparatus has been shown to lead to better postoperative left ventricular function and survival. Additionally, as there is no implanted prosthesis, the patient avoids the risks of chronic anticoagulation, infection, thromboembolic complications, and prosthetic valve failure after surgery.

In the case of MV repair, freedom from reoperation and valve-related complications has been excellent in certain patient populations, even at 20-year follow-up. It has also been demonstrated that patients undergoing MV surgery with moderate functional tricuspid regurgitation (TR) do not experience increased perioperative complication rates when a concomitant tricuspid valve (TV) repair is performed. Midterm results in this group are encouraging, with greater than 98% freedom from reoperation reported by some groups at 5 years, suggesting further indications for valve repair.

Despite its advantages for the patient, valve repair is generally more technically demanding than valve replacement and may occasionally fail. Both the suitability of the patient for valve repair and the skill and expertise of the surgeon performing the operation are important when considering valve repair in the individual patient.

**MITRAL VALVE DISEASE**

**Mitral Stenosis**

**Etiology.** Acquired mitral stenosis (MS) is most often caused by rheumatic fever, with approximately 60% of patients with pure MS presenting with a clinical history of rheumatic heart disease. Rarely, other conditions can cause obstruction to filling of the left ventricle (LV), mimicking MS. Acquired causes of MV stenosis include left atrial myxoma, prosthetic valve thrombosis, mucopolysaccharidosis, previous chest radiation, and severe annular calcification.

**Pathology.** Although rheumatic heart disease is associated with a transmural pancarditis, pathological fibrosis of the valves.
SPECIFIC CONSIDERATIONS

Figure 21-7. Mitral stenosis. The thickened, fused leaflets of the diseased mitral valve are viewed through a left atriotomy. (Reproduced with permission from Centers for Disease Control and Prevention, Edwin P. Ewing, Jr.)

Results primarily from the endocarditic process. The damage caused by endocardial inflammation and fibrosis is progressive, causing commissural fusion, subvalvular shortening of the chordae tendineae, and calcification of the valvular and subvalvular apparatus. The resulting stenotic MV has a funnel shape, with doming of the leaflets, and a significantly narrowed orifice caused by interchordal and commissural fusion (Fig. 21-7). The degree of mitral stenosis should be determined preoperatively, as these pathological features may help determine the timing and type of intervention to perform.

**Pathophysiology.** As the normal MV area of 4.0 to 5.0 cm\(^2\) is reduced by the rheumatic process, blood can flow from the left atrium to the left ventricle only if it is propelled by an ever-increasing pressure gradient. This increased left atrial pressure causes left atrial enlargement and eventually pulmonary hypertension and decreased exercise tolerance. Patients with diastolic valve doming, usually accompanied by a history of rheumatic fever, are defined as having stage A MS, even with normal transmitral flow velocities. Stage B MS is defined by an increased transmural flow velocity with mitral valve area greater than 1.5 cm\(^2\). This condition is associated with mild to moderate left atrial enlargement but normal pulmonary arterial pressure. Stage C MS consists of a severely stenotic valve (mitral valve area ≤1.5 cm\(^2\)) without symptoms. This is frequently associated with commissural fusion and diastolic doming of the leaflets as well as a pulmonary arterial pressure of >30 mmHg. Stage D MS is defined as the aforementioned criteria with the onset of decreased exercise tolerance and/or dyspnea on exertion (Table 21-8).

The onset of symptoms is due to the evolution of pathophysiological processes, beginning with an elevation in left atrial pressure. The increased left atrial pressure is subsequently transmitted to the pulmonary venous system, causing pulmonary edema as the hydrostatic pressure in the vessels exceeds the plasma oncotic pressure. Decreased pulmonary venous compliance exacerbates the pulmonary venous hypertension, though a concomitant decrease in microvascular permeability may

\(^{a}\)Valve gradients are flow dependent and when used as estimates of severity of valve stenosis should be assessed with knowledge of cardiac output or forward flow across the valve.
preclude pulmonary edema in the chronic setting.119 Patients may also develop pulmonary arterial hypertension, owing to vasoconstriction, intimal hyperplasia, and medial hypertrophy of the pulmonary arterioles in response to the increased pulmonary venous pressure. The secondary obstruction to flow caused by reactive pulmonary arterial hypertension may serve to protect against pulmonary edema, but it also exacerbates the intractable decrease in cardiac output that develops as stenosis worsens.120

Throughout the process, the left atrium becomes dilated and hypertrophied due to increased work in filling the ventricle against a fixed obstruction. Atrial fibrillation (AF) may develop, exacerbating the patient’s symptoms and increasing the risk of left atrial thrombus and subsequent embolization. Left ventricular structure and function are typically preserved owing to the protective effect of the stenotic valve.

Clinical Manifestations. The sudden opening of the thickened, nonpliable valve with left atrial contraction produces an opening snap, followed by a diastolic rumble caused by rapid entry of blood into the left ventricle. When diastole is complete, the MV subsequently closes very rapidly, causing an increased first heart sound. The murmur, classically known as the auscultatory triad, is best heard at the apex. Associated mitral and tricuspid insufficiencies are heard as a pansystolic murmur radiating to the axilla and a systolic murmur at the xiphoid process, respectively.

The first clinical signs of MS are those associated with pulmonary venous congestion, namely exertional dyspnea, decreased exercise capacity, orthopnea, and paroxysmal nocturnal dyspnea. Hemoptyisia and pulmonary edema may develop as the venous hypertension worsens. Advanced MS can also cause pulmonary arterial hypertension and subsequent right heart failure, manifested as jugular venous distention, hepatomegaly, ascites, and lower extremity edema.2

As mentioned previously, atrial fibrillation may develop as left atrial pathology worsens, causing atrial stasis and subsequent thromboembolism. Patients with MS may initially present with signs of arterial embolization, even rarely with angina from coronary occlusion.2

Diagnostic Studies. All patients with a clinical history and physical exam suggestive of MS should have an electrocardiogram (ECG) and chest X-ray. Abnormalities in the ECG may include atrial fibrillation, left atrial enlargement, or right axis deviation. Chest X-ray findings may include enlargement of the left atrium and pulmonary artery, creating a double contour behind the right atrial shadow and obliterating the normal concavity between the aorta and left ventricle. Findings consistent with pulmonary congestion may also be present.2

The diagnostic tool of choice is TTE, which not only confirms the diagnosis of MS, but also rules out other concomitant myocardial or valvular heart disease.121 Two-dimensional TTE can be used to calculate the MV area and to determine the morphology of the MV apparatus, including leaflet mobility and flexibility, leaflet thickness and calcification, subvalvular fusion, and the appearance of the commissures. Doppler TTE can also be used in combination with various equations to estimate the hemodynamic severity of MS in terms of the mean transmural pressure gradient, the MV area, and the pulmonary artery systolic pressure.

In most cases, further examinations are not necessary. A preoperative TEE may be utilized to rule out left atrial appendage thrombus, when the patient is being considered for percutaneous balloon mitral commissurotomy, or if the preoperative TTE is insufficient for diagnosis. Exercise TTE is indicated when resting TTE parameters are discordant with symptom severity.123 Routine coronary angiography is usually performed prior to valve surgery,98 except in young patients (≤30 years of age) with no risk factor for coronary artery disease.

Indications for Operation. Depending on the severity and the morphology of the diseased MV (see Table 21-8), balloon commissurotomy, surgical repair, or MV replacement may be indicated for the treatment of MS (Table 21-9).98

Mitrail Regurgiation

Etiology. The most important cause of MR in the United States is myxomatous degenerative disease of the MV, which occurs in 2% to 3% of the population.123 Other important causes of MR include rheumatic heart disease, infective endocarditis, ischemic heart disease, and dilated cardiomyopathies. Less frequently, MR can be caused by collagen vascular diseases, trauma, previous chest radiation, hypereosinophilic syndrome, carcinoid disease, and exposure to certain drugs.96

Pathology. The MV apparatus consists of the mitral leaflets, chordae tendineae, papillary muscles, and mitral annulus, and abnormalities in any one of these components has the potential to cause MR.124 The system for classifying MR proposed by Carpentier focuses on the functional and anatomic characteristics of the MV pathology and proposes three basic types of diseased valves based on the motion of the free edge of the leaflet relative to the plane of the mitral annulus.125

In Type I MR, valvular insufficiency occurs secondary to annular dilatation or leaflet perforation, and normal leaflet motion is maintained. Type II MR is seen in patients with mitral valve prolapse and is due to prolapse of often thickened excessive leaflet tissue that gives the valve a “billowing” appearance, in addition to ruptured or elongated chordae tendineae causing increased leaflet motion. Type III insufficiency, as seen in patients with rheumatic and ischemic heart disease, occurs from restricted leaflet motion, either during systole and diastole (Type IIIA) or during systole alone (Type IIIB).

Pathophysiology. The basic pathophysiologic abnormality of MR is the retrograde flow of a portion of the LV stroke volume into the left atrium during systole due to an incompetent MV or dilated MV annulus. Acute severe MR can result from ruptured chordae tendineae, a ruptured papillary muscle, or infective endocarditis and causes a sudden volume overload of both the left atrium and ventricle.96 Although an acute increase in preload provides a modest increase in overall stroke volume, the left atrium and ventricle are unable to fully accommodate the regurgitant volume or maintain forward stroke volume in the acute setting due to a lack of remodeling.

Chronic MR generally has a more indolent course, with increasing volume overload of the left atrium and ventricle as the effective regurgitant orifice size becomes larger. The resulting increase in left atrial and ventricular volume initially allows for an increase in the total stroke volume by Starling’s law and accommodation of the regurgitant volume, thus maintaining forward cardiac output and alleviating pulmonary congestion during the compensatory phase of chronic MR.126 However, as the left atrium becomes more dilated, the development of AF becomes more likely, disrupting atrioventricular synchrony and

LV = left ventricular; LVEF = left ventricular ejection fraction; MR = mitral regurgitation; MS = mitral stenosis; MV = mitral valve; MVr = mitral valve repair; MVR = mitral valve replacement; NYHA = New York Heart Association; PASP = pulmonary artery systolic pressure; PAWP = pulmonary artery wedge pressure; * = mitral valve repair should be performed when possible in this population.
predisposing to thrombus formation. Additionally, chronic volume overload may lead to LV contractile dysfunction, resulting in impaired ejection and end-systolic volume increases. LV dilatation and elevated LV end-diastolic pressures may also worsen throughout the progression of MR, reducing cardiac output and causing congestion of the pulmonary vasculature. These changes herald LV decompensation and heart failure and often indicate irreversible myocardial injury.

Clinical Manifestations. In cases of acute severe MR, patients are often symptomatic and present with pulmonary congestion and reduced forward stroke volume. In severe cases, patients may present with cardiogenic shock. Because the LV has not remodeled in the acute setting, a hyperdynamic apical impulse may not be present in the precordium. The typical systolic murmur of MR may be holosystolic or absent, with a third heart sound and/or diastolic flow murmur being the only auscultatory findings.

In cases of chronic MR, patients may remain asymptomatic for long periods of time due to the compensatory mechanisms of the remodeled LV. However, once the LV begins to fail, patients become increasingly symptomatic from exertional dyspnea, decreased exercise capacity, orthopnea, and eventually pulmonary hypertension and right heart failure. Physical examination may demonstrate displacement of the LV apical impulse due to cardiac enlargement from chronic volume overload, a third heart sound, or an early diastolic flow rumble. The characteristic auscultatory findings also include an apical systolic murmur, which is variably transmitted to the axilla or the left sternal border, depending on the location of the pathology. As mentioned previously, patients may present with AF due to dilatation of the left atrium. Findings consistent with pulmonary hypertension frequently indicate late-stage disease.

Diagnostic Studies. In the setting of acute heart failure, TTE should be performed and may demonstrate the anatomical location and severity of the MV pathology. However, TTE may underestimate lesion severity due to inadequate views of the color flow jet. In this case, severe MR should be suspected if hyperdynamic systolic function of the LV is visualized, and TEE may be used to confirm the diagnosis and direct repair strategies.

In cases of chronic MR, ECG and chest X-ray are performed to assess rhythm status and the degree of pulmonary vascular congestion. An initial 2D and Doppler TTE should be performed for a baseline estimation of LV and left atrial size, LV systolic function, pulmonary artery pressure, MV morphology, and MR severity. A central color flow jet in the setting of a structurally normal MV on TTE suggests functional MR, which may be due to LV dilatation or tethering of the posterior leaflet in patients with ischemic heart disease. In the setting of organic MR (i.e., rheumatic and degenerative MR), which is suggested by the presence of an eccentric color flow jet and morphological abnormalities in the MV apparatus on TTE, the presence of calcium in the annulus or leaflets, the redundancy of the leaflets, and the anatomy of the MV pathology should be assessed. Follow-up TTE is indicated on an annual or semiannual basis in patients with asymptomatic moderate to severe MR in order to assess changes from baseline parameters and direct the timing of surgery. Any abrupt change in signs or symptoms in a patient with chronic MR is also an indication for TTE examination.

Additional preoperative studies are variably indicated in certain patient populations. Preoperative TEE is indicated in patients with indications for surgery or poor windows on TTE in order to determine the severity and anatomic basis of MR and to evaluate LV systolic function. Preoperative TEE is also indicated in cases when a discrepancy exists between a patient’s functional status and the severity of MR on TTE. It is helpful for preoperative planning when assessing the feasibility of repair in the individual patient. Exercise stress-echoangiography may also be useful to detect LV systolic dysfunction in well-compensated patients, who may not demonstrate a rise in the end-systolic dimension of the heart or a drop in ejection fraction on routine TTE. Coronary angiography should be performed prior to valve surgery in patients with evidence of ischemia, decreased LV systolic function, a history of coronary artery disease or coronary risk factors, including postmenopausal status and age ≥40 in men and premenopausal women.

Indications for Operation. Based on the etiology, morphology, and severity of MR (see Table 21-8), MV repair, MV replacement with preservation of part or all of the mitral apparatus may be variably performed for the treatment of MR. As the intraoperative findings may dictate MV replacement whenever a MV repair is planned, current recommendations are for MV surgery in general (see Table 21-9).

Mitral Valve Operative Techniques and Results

Mitral valve surgery is performed on the arrested heart with the assistance of cardiopulmonary bypass. Traditionally, a median sternotomy incision has been used; however, the left atrium can also be approached via minimally invasive incisions, such as a right thoracotomy, or a fully endoscopic approach. The MV is commonly exposed through a left atrial incision placed posterior and parallel to the intra-atrial groove or via a transseptal approach through the right atrium.

Commissurotomy. Upon opening the left atrium, the MV is visualized and the left atrium is examined for thrombus. A nerve hook or right-angle clamp is subsequently introduced beneath the commissures and used to evaluate the MV apparatus for leaflet mobility, commissural fusion, and subvalvular chordal abnormalities. The commissure is then carefully incised in a slightly anterior direction 2 to 3 mm at a time, making sure with each extension of the incision that the chordae tendineae remain attached to the commissural leaflets. The commissurotomy is generally stopped 1 to 2 mm from the annulus where the leaflet tissue thins, indicating the transition to normal commissural tissue. The papillary muscles are subsequently examined and incised as necessary in order to maximize the mobility of the leaflets.

After the commissurotomy is complete and the associated chordae tendineae and papillary muscles are mobilized, leaflet mobility is assessed. The anterior leaflet is grasped with forceps and brought through its complete range of motion. If subvalvular restriction or leaflet rigidity is identified, further division or excision of fused chordae and debridement of calcium may be necessary. Occasionally, the leaflets can be debrided carefully to increase mobility. In rheumatic patients, the thickened leaflets can be thinned by careful dissection. Valve replacement may be more appropriate if extensive secondary mobilization is required. At the end of the procedure, competence of the valve is assessed with injection of cold saline into the ventricle.

Open surgical commissurotomy has an operative risk of <1%, and has been shown to have good long-term results, with freedom from reoperation as high as 88.5%, 80.3%, and 78.7% at 10, 20, and 30 years, respectively. The incidence of
postoperative thromboembolic complications is generally <1% per patient-year, and the lack of required systemic anticoagulation precludes the development of hemorrhagic complications long term.\textsuperscript{132} In some institutions, balloon valvuloplasty has replaced commissurotomy.

**Mitrval Valve Replacement.** After exposing the valve, an incision is made in the anterior mitral leaflet, in the midline. The chordal attachments are preserved if possible, with leaflet tissue being excised as needed. Attempts are made to preserve the annular and subvalvular apparatus when possible. If it is necessary to excise the anterior leaflet and chordae, the papillary muscles can be reattached to the annulus with PTFE suture. If possible, the posterior leaflet along with its associated subvalvular structures are preserved. The annulus is subsequently sized, and an appropriate mitral prosthesis is implanted using pledged horizontal mattress sutures. The annular sutures may be placed from the atrial to the ventricular side, seating the valve intra-annularly, or from the ventricular to the atrial side, seating the valve in a supra-annular position. When placing the mattress sutures, care must be taken to stay within the annular tissue, as excessively deep bites may cause injury to critical structures such as the circumflex coronary artery posterolaterally, the atrioventricular node anteromedially, or the aortic valve anterolaterally. The sutures are subsequently placed through the sewing ring, and the valve prosthesis is lowered onto the annulus, where it is secured (Fig. 21-8).

The factors associated with increased operative risk for MV replacement include age, left ventricular systolic dysfunction, emergent procedure status, NYHA functional status, previous cardiac surgery, associated coronary artery disease, and concomitant disease in another valve. However, for most patients, MV replacement is associated with an operative mortality between 2% to 6%, and 65% to 70% 5-year survival.\textsuperscript{133,134} Although preservation of the mitral apparatus during MV replacement is important for subsequent left ventricular function, there was no difference between complete and partial preservation with respect to 30-day and 5-year mortality.\textsuperscript{133} Mechanical valves are associated with increased durability compared to bioprosthetic valves, and they have demonstrated a freedom from reoperation of 98% vs. 79% at 15 years, respectively.\textsuperscript{135} Despite these findings, the choice of prosthetic valve depends on many factors and should be decided on a patient-by-patient basis.

**Mitrval Valve Repair.** There are many techniques available for MV repair that are variably used depending on the preoperative and intraoperative assessment of valvular pathology. On opening the atrium, the endocardium is examined for a jet lesion, a roughened area caused by a regurgitant jet striking the wall, in order to better localize the area of valvular insufficiency. The commissures are examined for evidence of prolapse, fusion, and malformation. The subvalvular apparatus and individual leaflets are subsequently examined, and areas of prolapse, restriction, fibrosis, and calcification are identified. Leaflet perforations are generally repaired primarily, or with a pericardial patch. The degree of annular dilation is also noted. The basic components of MV repair based on this assessment may include resection of the posterior and/or anterior leaflet, chordal shortening, chordal transposition, artificial chordal replacement, and annuloplasty. Recent trends have been toward leaflet preservation.

One of the mainstays of MV repair is triangular resection of the posterior leaflet. Excision of the diseased leaflet tissue extends downwards towards but generally not to the mitral annulus. After repair has been completed, valvular competency is evaluated by injecting saline into the ventricle with a bulb syringe and assessing leaflet mobility and apposition. If focal insufficiency is identified in other areas, additional procedures are performed.

The anterior leaflet may be repaired via chordal shortening, chordal transposition, artificial chordal replacement, and triangular resection of the anterior leaflet. Chordal shortening has generally been abandoned in favor of chordal replacement. During chordal transposition, a resected portion of the posterior leaflet with attached chordae is transposed onto the prolapsed portion of the anterior leaflet to provide structural support, and this is followed by posterior leaflet repair, as described previously. The procedure of artificial chordal replacement uses polytetrafluoroethylene sutures to attach the papillary muscle to the free edge of the prolapsing anterior leaflet. Triangular resection with primary repair of the anterior leaflet removes the prolapsing segment of the anterior MV leaflet, while preserving adjacent chordal tissue, and may be especially helpful in patients with a ruptured chord or large amount of redundant anterior leaflet tissue.

Annular dilation is generally corrected using a MV annuloplasty device, such as a ring or partial band. Annuloplasty is known to improve the durability of all types of MV repair (Fig. 21-9).\textsuperscript{138} A number of devices are available and include rigid or semirigid rings that geometrically remodel the annulus, flexible rings or bands that restrict annular dilation while maintaining the physiologic sphincter motion of the annulus, and semirigid bands that provide a combination of annular remodeling and support of physiologic motion.

Another technique known as the “double-orifice” or “edge-to-edge” repair was introduced by Alfieri in 1995, and it involves tacking the free edge of the anterior leaflet to the opposing free edge of the posterior leaflet.\textsuperscript{137} This procedure effectively gives the valve a double-orifice “bow tie” configuration, and it has been used as both a primary repair technique and an adjunct to other repair techniques, usually in cases of anterior leaflet pathology or Barlow’s disease. While some groups report excellent late results, its use remains controversial, and it is used mainly as a bail-out procedure of last resort in many centers.

ACQUIRED HEART DISEASE

CHAPTER 21

Figure 21-9. Mitral valve repair. The narrow arrow indicates the posterior leaflet repair, and the wide arrow indicates the ring annuloplasty as viewed through a left atriotomy.

Due to the variety in operations and etiologies of MV disease, there is heterogeneity in outcomes following MV repair. In general, the operative risk for elective, younger patients undergoing MV repair is <1%, and late results across a broad range of patients have demonstrated benefits in survival and valve-related complications, such as thromboembolic events, infective endocarditis, and anticoagulation-related hemorrhage, compared to MV replacement. Patients with MR due to degenerative disease have especially encouraging outcomes, demonstrating rates of survival and freedom from reoperation of >50% and >94% at 20 years, respectively. Historically, isolated anterior leaflet prolapse increased the risk of reoperation fivefold in this population. However, increasing experience and the expanded use of chordal replacement has greatly improved these results in recent series. Independent predictors of mortality have included higher NYHA class, lower left ventricular ejection fraction, renal dysfunction, and age. Older patients have demonstrated slightly worse outcomes overall, with an operative mortality of approximately 4%, and a 10-year survival of 54% in patients ≥65 years of age. However, the superiority of repair over replacement persists even for patients >80 years of age.

Patients with rheumatic disease have demonstrated slightly worse outcomes, with one study showing significantly better freedom from operation at 10 years in patients with non-rheumatic MV disease (88% vs. 73%, P < 0.005). Similarly, in patients with MR secondary to myocardial ischemia, there is growing recent evidence that mitral valve replacement may be significantly more durable than repair. Despite these differences in outcomes, MV repair remains the procedure of choice for the majority of patients with amenable MV disease.

Transcatheter Mitral Valve Repair and Replacement. Since the successful introduction of transcatheter aortic valve replacement, efforts have been made to translate the lessons learned to treatment of the mitral valve. The first device to receive FDA approval for repair of severe mitral regurgitation due to degenerative mitral disease was the MitraClip (Abbott, Abbott Park, IL), introduced in 2003. This device allows a surgeon or cardiologist to grasp the anterior and posterior leaflets of the mitral valve together, approximating the Alfieri double-orifice repair technique. Transcatheter mitral valve repair is now in clinical use in patients with chronic severe primary MR in whom surgery would be too great a risk, as judged by a heart team approach including a cardiologist skilled in structural heart intervention and an experienced mitral valve surgeon (see Table 21-9). In a recent randomized controlled trial comparing transcatheter mitral valve repair to open surgical mitral valve repair, 20.1% (n = 37) of patients who received transcatheter mitral valve repair (n = 184) underwent second intervention with surgical mitral valve repair or replacement within 12 months compared with 2% (n = 2) of patients who underwent surgical repair (n = 95) (P < 0.001). Surgical repair was associated with higher rates of blood transfusion and mechanical ventilation >48 hours but had otherwise equivalent safety. Other transcatheter techniques, including transcatheter mitral valve replacement, have begun clinical trials. This is an area of active research; however, at present, open surgical repair or replacement remains the standard of care for most patients.

AORTIC VALVE DISEASE

Aortic Stenosis

Etiology. The most common cause of adult aortic stenosis (AS) is calcification of a normal trileaflet or congenital bicuspid aortic valve, particularly in patients >70 years of age. Another important cause of AS is rheumatic heart disease, which is particularly common in developing countries (Fig. 21-10).

Pathology. Calcific aortic valve disease, also known as senile or degenerative disease, is an age-related disorder characterized by lipid accumulation, proliferative and inflammatory changes, upregulation of angiotensin-converting enzyme activity, oxidative stress, and infiltration of macrophages and T lymphocytes. This process, which closely resembles atherosclerotic vascular calcification, initially results in bone formation within the base of the cusps, reducing leaflet motion. Calcification progresses to involve the leaflets, and eventually results in obstructive

\(^a\)Valve gradients are flow dependent and when used as estimates of severity of valve stenosis should be assessed with knowledge of cardiac output or forward flow across the valve.

disease, with a reduced effective valve area without signs of leaflet fusion.

Pathophysiology. In general, once moderate AS is present, the average rate of progression includes an increase in jet velocity of 0.3 m/s per year, an increase in mean pressure gradient of 7 mmHg per year, and a decrease in valve area of 0.1 cm\(^2\) per year (Table 21-10).\(^{108}\) In most adult patients with AS, obstruction develops gradually and includes a long latent period free from symptoms. During this time, the LV typically hypertrophies in response to systolic pressure overload, and normal intracavitary volume is maintained.\(^{146}\) Afterload, which is defined as left ventricular systolic wall stress, and thus ejection fraction remain normal early in this process as the increase in myocardial thickness is usually enough to counter the increased intracavitary systolic pressures. Patients without a typical hypertrophic response to systolic pressure overload or with a depressed contractile state of the myocardium do not follow the common clinical course, but they experience an early decrease in ejection fraction due to excessively increased afterload without a compensatory response.\(^{147}\)

Concentric LV hypertrophy without chamber dilatation eventually leads to increased end-diastolic pressures and diastolic dysfunction. Forceful atrial contraction in the face of elevated end-diastolic pressures becomes an important component of ventricular filling, even as mean left atrial and pulmonary venous pressures remain in the normal range. Disorders such as atrial fibrillation that disrupt atrial contraction can lead to clinical deterioration. Although systolic function is generally preserved long into the natural history of the disease, left ventricular decompensation eventually occurs in the setting of longstanding increased afterload and is an indication for surgery even in the absence of other symptoms.

Although concentric hypertrophy is a compensatory mechanism to maintain ejection fraction in the face of high intracavitary pressures, the hypertrophied heart becomes increasingly vulnerable to ischemic injury. Coronary blood flow may become inadequate, despite the absence of epicardial coronary artery disease.\(^{148}\) Coronary vasodilation is mitigated by the hypertrophied myocardium, and the hemodynamic stress of exercise or tachyarrhythmias can lead to subendocardial ischemia and further systolic or diastolic dysfunction. When ischemic insults occur, patients with ventricular hypertrophy experience larger infarcts and higher mortality rates than those without hypertrophy.\(^{149}\) In some patients, ventricular hypertrophy occurs in excess of what is needed to compensate for increased intracavitary pressures, creating a high-output state that is also associated with increased perioperative morbidity and mortality.\(^{150}\)

Clinical Manifestations. The characteristic auscultatory findings of AS include a harsh, crescendo-decrescendo systolic murmur at the right second or third intercostal space, often with radiation to the carotid arteries.\(^2\) As the disease progresses, aortic valve closure may follow pulmonic valve closure, causing paradoxical splitting of the second heart sound. Other physical findings associated with AS include an apical impulse commonly described as a “prolonged heave,” and the presence of a narrow and sustained peripheral pulse, known as pulsus parvus et tardus.

The classic symptoms of AS are exertional dyspnea, angina, and syncope.\(^2\) Although many patients are diagnosed prior to the onset of symptoms, the most common clinical
presentation in patients with a known diagnosis of AS is worsening exertional dyspnea. Angina occurs in over half of patients with AS and is due to the increased oxygen demand of the hypertrophied myocardium in the setting of reduced oxygen supply secondary to coronary compression. Although some patients may have concomitant coronary disease, angina occurs without significant epicardial coronary artery disease in half of all patients with AS.\textsuperscript{153} Syncope is most common during exertion, as systemic vasodilation in the setting of a fixed cardiac output causes decreased cerebral perfusion. However, at times, it may occur at rest secondary to paroxysmal atrial fibrillation and subsequent loss of atrial booster pump function. Late findings of AS include atrial fibrillation, pulmonary hypertension, systemic venous hypertension, and, rarely, sudden death.

**Diagnostic Studies.** Evidence of LV hypertrophy is found in approximately 85\% of patients with AS on routine ECG, though the correlation between the absolute electrocardiographic voltages in precordial leads and the severity of AS is poor.\textsuperscript{2} ECG also may demonstrate signs of left atrial enlargement and various forms and degrees of atrioventricular and intraventricular block due to calcific infiltration of the conduction system. Routine chest X-ray usually demonstrates a normal heart size, with rounding of the left ventricular border and apex. A late finding on chest X-ray is cardiac enlargement, or cardiomegaly, a sign of LV failure.

Transesophageal echocardiography is indicated in all patients with a systolic murmur graded ≥2/6, a single second heart sound, or symptoms characteristic of AS.\textsuperscript{98} Initial TTE examinations are often diagnostic and provide an assessment of left ventricular size and function, the degree of left ventricular hypertrophy, the degree of valvular calcification, and the presence of other associated valvular disease. Doppler evaluation should be performed to define the maximum jet velocity, which is a useful measure for following disease severity and predicting clinical outcome.\textsuperscript{2} Additionally, color flow Doppler assesses the severity of the stenotic lesion by allowing calculation of the mean transvalvular pressure gradient and effective valve orifice area (see Table 21-10).\textsuperscript{98} Follow-up TTE is indicated depending on the severity of AS in order to assess changes from baseline parameters and direct the timing of surgery: yearly for severe AS; every 1 to 2 years for moderate AS; and every 3 to 5 years for mild AS. Any abrupt change in signs or symptoms in a patient with AS is an indication for TTE examination.

Additional preoperative studies may be necessary in some patients. Rarely, when TTE images are suboptimal, TEE or fluoroscopy may be indicated to assess the degree of valve calcification and effective valve orifice area. As in other patients with valvular heart disease, coronary angiography should be performed prior to aortic valve surgery in most patients.\textsuperscript{2} Since the symptoms of AS often mimic those of ischemic heart disease, left heart catheterization and coronary angiography may be necessary at the initial evaluation in patients with AS. Stress echocardiography may also be useful in the asymptomatic patient with AS in order to elicit exercise-induced symptoms or abnormal blood pressure responses during exertion. It is also useful in the evaluation of low-gradient AS in patients with depressed LV function.\textsuperscript{98} However, exercise stress-echocardiography is contraindicated in patients with ischemic heart disease.\textsuperscript{98} In patients with evidence of aortic root disease by TTE, chest computed tomography is useful in evaluating aortic dilatation at several anatomic levels and is necessary for clinical decision making and surgical planning.\textsuperscript{2}

**Indications for Operation.** Based on the severity of AS (see Table 21-10) and the predicted risk with surgical aortic valve replacement (SAVR) determined using the STS risk calculator, SAVR or transcatheter aortic valve replacement (TAVR) may be recommended for the treatment of AS (Table 21-11).\textsuperscript{98,152} As this field is rapidly evolving, attention to guideline updates and a multidisciplinary heart team approach to risk stratification and treatment selection are mandatory. In patients with severe calcific AS, AVR via either approach is the only effective treatment, though controversy exists as to the timing of intervention in asymptomatic patients. Balloon aortic valvuloplasty creates a modest hemodynamic effect and temporary symptom improvement in patients with calcific AS. However, the procedure has not been shown to affect long-term outcomes and is often used in hemodynamically unstable patients as a bridge to AVR.\textsuperscript{98}

**Aortic Insufficiency**

**Etiology.** The most common cause of isolated aortic insufficiency (AI) in patients undergoing AVR is aortic root disease, and it represents over 50\% of such patients in some studies.\textsuperscript{2} Other common causes of AI include congenital abnormalities of the aortic valve such as bicuspid aortic valve, calcific degeneration, rheumatic disease, infective endocarditis, systemic hypertension, myxomatous degeneration, dissection of the ascending aorta, and Marfan syndrome. Less common causes of AI include traumatic injuries to the aortic valve, ankylosing spondylitis, syphilitic aortitis, rheumatoid arthritis, osteogenesis imperfecta, giant cell aortitis, Ehlers-Danlos syndrome, Reiter’s syndrome, discrete subaortic stenosis, and ventricular septal defects with prolapse of an aortic cusp.\textsuperscript{96} Although most of these lesions produce chronic aortic insufficiency, rarely acute severe aortic regurgitation can result, often with devastating consequences.

**Pathology.** Regardless of its cause, AI produces volume overload with dilatation and hypertrophy of the left ventricle and subsequent dilatation of the MV annulus. Depending on the severity of AI, the left atrium may undergo dilatation and hypertrophy as well. Frequently, the regurgitant jet causes endocardial lesions at the site of impact on the left ventricular wall.

Diseases causing AI can be classified as primary disorders of the aortic valve leaflets and/or disorders involving the wall of the aortic root. Diseases causing dilatation of the ascending aorta are a more common indication for AVR due to isolated AI, and they include disorders such as age-related (degenerative) aortic dilatation, cystic medial necrosis of the aorta as is seen in Marfan syndrome, aortic dilatation secondary to bicuspid valves, and aortic dissection, to name a few.\textsuperscript{153} In these disorders, the aortic annulus becomes dilated, causing separation of the valve leaflets and subsequent AI. The diseased aortic wall may dissect secondarily and further escalate regurgitation across the valve, and secondary thickening and shortening of the valve cusps may occur due to undue tension placed on the valvular apparatus by the dilated aortic root. As the disease progresses, the valve leaflets become too small to close the aortic orifice, causing further aortic insufficiency and exacerbating dilatation of the ascending aorta.

There are also many primary valvular diseases that cause AI, generally in association with AS. One such disorder is age-related calcific AS, which causes some degree of AI in up to 75\% of patients.\textsuperscript{154} Infective endocarditis may involve the aortic valve apparatus and cause AI through direct destruction of the valve leaflets, perforation of a leaflet, or formation of vegetations that interfere with proper coaptation of the valve.
Pathophysiology. The basic pathophysiologic abnormality of AI is the retrograde flow of a portion of the LV stroke volume into the LV during diastole, producing volume overload. Acute severe AI results most commonly from infective endocarditis, acute aortic dissection, or trauma, and it causes a sudden volume overload of the left ventricle. Although an acute increase in preload provides a small increase in overall
stroke volume due to the Starling mechanism, the left ventricle often is unable to accommodate the large regurgitant volume and maintain forward stroke volume in the acute setting due to a lack of remodeling. Left ventricular end-diastolic and left atrial pressures increase dramatically as the LV is unable to develop compensatory chamber dilation. Although tachycardia develops as a compensatory mechanism to maintain forward flow, this attempt is often inadequate, and patients frequently present in heart failure and even cardiogenic shock. Moreover, subendocardial myocardial ischemia frequently develops as a result of decreased coronary diastolic perfusion pressures and increased LV end-diastolic pressure, as well as increased myocardial oxygen demand due to acute dilation. In the setting of a chronic ventricular hypertrophy and preexisting diastolic dysfunction, the pressure-volume relationship is even more extreme, exacerbating the hemodynamic derangements seen in acute AI.

Chronic AI generally has a more indolent course, with volume overload of the LV causing compensatory increases in left ventricular end-diastolic volume and chamber compliance as well as a combination of eccentric and concentric hypertrophy. Compensatory remodeling of the LV allows for accommodation of the regurgitant volume without a significant increase in filling pressures and maintains the preload reserve of the chamber. Eccentric left ventricular hypertrophy develops, permitting normal contractile performance across the enlarged chamber circumference and subsequent ejection of a larger total stroke volume in order to maintain forward flow, despite the regurgitant fraction. However, the enlarged chamber size results in an increase in systolic myocardial wall stress and causes further ventricular hypertrophy. As the disease progresses, recruitment of preload reserve and compensatory hypertrophy maintains ejection fraction within the normal range despite elevated afterload, causing many patients to remain asymptomatic throughout the compensatory phase.

Eventually, left ventricular compensatory mechanisms fail, and systolic dysfunction ensues. As the disease progresses, preload reserve may become exhausted, the hypertrophic response may become inadequate, and impaired myocardial contractility may develop so that ejection fraction begins to decline. Although left ventricular systolic dysfunction related to excessive afterload is reversible early in the course, irreversible damage occurs once chamber enlargement predominates as the primary cause of diminished myocardial contractility.

Clinical Manifestations. In cases of acute severe AI, patients are symptomatic and invariably present with compensatory tachycardia, often associated with acute pulmonary congestion and cardiogenic shock. Because the left ventricular and aortic pressures often equalize before the end of diastole, the diastolic murmur of AI may be short and/or soft. The reduced systolic pressure may attenuate the increase in peripheral pulse pressure seen in chronic AI, and early closing of the mitral valve due to elevated left ventricular end-diastolic pressures may diminish the intensity of the first heart sound in the acute setting.

In patients with chronic AI, symptoms of heart failure and myocardial ischemia develop after the compensatory phase. Patients gradually begin to complain of exertional dyspnea, fatigue, orthopnea, and paroxysmal nocturnal dyspnea, often after significant myocardial dysfunction has developed. Angina is a common complaint late in the course, especially during sleep when heart rate slows and arterial diastolic pressure falls. Patients also may experience exertional angina secondary to diminished coronary perfusion in the setting of myocardial hypertrophy. Occasionally, the compensatory tachycardia that develops with chronic AI will cause palpitations, and the increased pulse pressure will cause a sensation of pounding in the patient’s head. Peripherally, the widened pulse pressure causes a forceful, bounding, and quickly collapsing pulse known as Corrigan’s water-hammer pulse. Premature ventricular contractions have been reported to cause particularly troubling symptoms, owing to the heave of the volume-loaded left ventricle during the postextrasystolic beat. The classic auscultatory finding associated with AI is a high-pitched decrescendo diastolic murmur heard best in the left third intercostal space; an associated S gallop is often indicative of late disease. The Austin Flint murmur has also been described, and it is heard as a middiastolic rumble at the apex that simulates mitral stenosis and occurs in severe AI when the regurgitant jet impedes mitral valve leaflet opening.

Diagnostic Studies. In the acute setting, TTE should be performed to confirm the presence and severity of aortic regurgitation, the degree of pulmonary hypertension, and the cause of valvular dysfunction. When aortic dissection is suspected as the cause of acute AI, TEE or chest CT angiography may be substituted if more readily available. In these patients with confirmed aortic dissection, cardiac catheterization and coronary angiography are rarely indicated and can delay life-saving urgent surgical intervention.

In cases of chronic AI, the ECG frequently demonstrates left axis deviation and, late in the course, intraventricular conduction defects associated with left ventricular dysfunction. On chest X-ray, the left ventricle enlarges predominantly in an inferior and leftward direction, causing marked increase in the long axis diameter of the heart, frequently with little or no change in the transverse diameter. The chest X-ray should be examined for aneurysmal dilation of the aorta. An initial TTE should be performed to confirm the diagnosis and severity of AI, assess the cause of AI (including valve morphology and aortic root size and morphology), and assess the degree of left ventricular hypertrophy, volume, and systolic function. Follow-up TTE is indicated on an annual or semiannual basis in patients with asymptomatic moderate to severe AI in order to assess changes from baseline parameters and direct the timing of surgery. Any abrupt change in signs or symptoms in a patient with chronic AI is an indication for TTE examination.

Additional preoperative studies are indicated in certain patient populations. In patients with poor windows on TTE, TEE or MRI is indicated for initial and serial assessment of AI severity and left ventricular volume and function at rest. In symptomatic patients with chronic AI, it is reasonable to proceed directly to TEE or cardiac catheterization if TTE examinations are inadequate. Exercise stress testing may be helpful for an assessment of functional capacity and symptomatic responses in patients with equivocal symptoms. Coronary angiography should be performed prior to valve surgery in most patients.

Indications for Operation. Based on the morphology and severity of valve dysfunction (see Table 21-10), AV repair or replacement may be performed for the treatment of AI (see Table 21-11). Although the indications for AV repair and AV replacement do not differ, it is recommended that AV repair be performed only in those surgical centers that have developed the appropriate technical expertise, gained experience in patient selection, and which have demonstrated outcomes equivalent to those of valve replacement.
**Aortic Valve Operative Techniques and Results**

Aortic valve surgery has traditionally been performed through a median sternotomy with the assistance of cardiopulmonary bypass. However, minimally invasive incisions for aortic valve surgery have been introduced, including mini-sternotomy and mini-thoracotomy approaches. After the aorta is cross-clamped, cold blood cardiopulgia is delivered antegrade through the aortic root and/or retrograde through the coronary sinus.

**Aortic Valve Replacement.** During aortic valve replacement, an aortotomy is performed, extending medially from approximately 1 to 2 cm above the right coronary artery and inferiorly into the noncoronary sinus. The valve is completely excised. The annulus is thoroughly debrided of calcium deposits. At this point, the annulus is sized and an appropriate prostheses is selected. Pledged horizontal mattress sutures are then placed into the aortic valve annulus and subsequently through the sewing ring of the prosthetic valve, taking care to avoid damage to the coronary ostia, the conduction system, and the MV apparatus. The annular sutures may be placed from below the annulus, seating the valve supra-annularly, or from above the annulus for intra-annular placement (Fig. 21-11).

The major components to increased operative risk associated with surgical AVR include age, body surface area, diabetes, renal failure, hypertension, chronic lung disease, peripheral vascular disease, neurologic events, infectious endocarditis, previous cardiac surgery, myocardial infarction, cardiogenic shock, NYHA functional status, and pulmonary hypertension. For most patients, the risk of operative mortality associated with AVR is 1% to 5%, and 5-year survival has been reported to be >80%, even in patients >70 years of age. The choice of valve is dependent on many patient-related factors, and it is accompanied by the attendant postoperative risks of decreased durability and thromboembolic vs. hemorrhagic complications for biologic and mechanical valves, respectively.

**Aortic Valve Repair.** Although aortic valve replacement is performed more commonly, AV repair may be recommended at centers of excellence.

For patients with aortoannular ectasia, AI is due to annular dilatation and distortion of the sinotubular junction. For these patients, competence of the aortic valve can be achieved by functionally repairing the annulus in a method analogous to homograft implantation. The aneurysmal portion of the aortic root is excised, and the aortic valve is reimplemented inside a tubular Dacron graft, with concomitant reimplantation of the coronary arteries. Alternatively, the aneurysmal tissue and supravalvular tissue can be excised in their entirety, with subsequent implantation of the Dacron graft onto the superior aspect of the annulus and reimplantation of the coronary arteries.

Valve-sparing root replacement for root and annular stabilization in patients with AI due to aortoannular ectasia has led to a more durable outcome than is seen with subcommissural annuloplasty or leaflet-related procedures alone. One study demonstrated equivalent overall survival between patients undergoing subcommissural annuloplasty or aortic valve repair without annuloplasty and patients undergoing valve-sparing root replacement at 6 years. However, patients who underwent valve-sparing root replacement had higher freedom from reoperation and aortic insufficiency >2+ (100% vs. 90%, P = 0.03; and 100% vs. 77%, P = 0.002, respectively) at midterm follow-up.

For patients with AI associated with redundant leaflet tissue, aortic valve repair may be accomplished with free margin plication or resuspension of the valve cusps, with or without triangular resection of the redundant segment. Excision of the diseased portion of the involved valve cusp improves symmetry of the valve leaflets, and annular plication of one or both commissures helps to ensure adequate coaptation. Generally, the free margins of the excised leaflets are reaproximated primarily, but in the absence of adequate cusp tissue, a triangular autologous or bovine pericardial patch may be used for cusp restoration.

AV cusp repair with a free margin plication or resuspension technique has demonstrated encouraging results in expert centers, both in patients with tricuspid and bicuspid aortic valves. Freedom from AV reoperation in patients with a tricuspid AV has been reported to be 89% to 92% at 10 years, with a freedom from recurrent AI >2+ of 80% to 86% at the same time point. In patients with bicuspid aortic valves, who generally represent a younger cohort of patients, 10-year survival has been reported at 94% following AV repair, with a freedom from AV reoperation of 81% at the same time point.

**Ross Procedure.** As mentioned previously, the Ross procedure involves replacing the diseased AV with the patient’s native pulmonary valve as an autograft, which is in turn replaced with a homograft in the pulmonic position. The autograft may be implanted in the aortic position directly with resuspension of the valve commissures, or in association with a root replacement, which requires reimplantation of the coronary ostia.

The cylinder root replacement technique is most reproducible and involves transecting the native aorta approximately 5 mm above the sinotubular ridge, with subsequent excision of the aortic valve leaflets and supra-annular tissue. The main pulmonary artery is transected at the bifurcation, and the right ventricular outflow tract is incised, allowing the pulmonary valve and artery to be removed en bloc from the outflow tract. The annulus of the pulmonary autograft is sewn to the native aortic annulus with continuous or interrupted sutures, and the coronary ostia are reimplanted into the pulmonary artery graft. The pulmonary valve and right ventricular outflow tract are subsequently reconstructed using an aortic homograft.

![Figure 21-11. Aortic valve replacement. The stented porcine bioprosthesis as viewed through an aortotomy.](image-url)
The primary benefit of the Ross procedure compared to traditional AV surgery is a low risk of thromboembolism without the need for systemic anticoagulation. Although patients undergoing the Ross procedure are generally younger, perioperative mortality has been reported to be as low as 2.5% in this group, with an overall survival of 90% at 18-year follow-up. However, the long-term durability of the procedure is somewhat questionable. Although Ross reported a freedom from autograft replacement of 75% at 20 years, other groups have reported freedom from autograft reoperation and allograft reintervention of 51% and 82%, respectively, at 18-year follow-up. Progressive aortic insufficiency has been described as a cause of late failure in these patients, as well as calcification of the pulmonary homograft and pulmonary stenosis.

**Transcatheter Aortic Valve Replacement.** Transcatheter aortic valve replacement (TAVR) has proven beneficial for the treatment of AS in patients who are either moderate or high-risk candidates for conventional surgery. TAVR is now indicated for patients with severe AS with a STS score predicted risk of mortality of greater than or equal to 3%. Clinical trials in the low-risk population are currently underway.

There are two types of transcatheter valves that are approved for commercial use: a balloon-expandable valve (Edwards) and a self-expandable valve (CoreValve). A transcatheter valve may be inserted via the femoral artery, the left subclavian artery, the ascending thoracic aorta, or LV apex via a small left anterior thoracotomy. By far the most common route is transfemoral, making up the majority of TAVR in most centers. The principle of valves placed via these routes are to place the aortic prosthesis inside the patient’s native aortic valve. Rigorous preoperative planning is needed to ensure adequate sizing of the valve as well as placement to ensure there is no risk of coronary occlusion or malalignment of the valve.

A series of large, multicenter clinical trials have been performed investigating the role and safety of TAVR in patients with severe aortic stenosis requiring surgical treatment. The PARTNER I trial looked at mortality rate as the primary endpoint in patients with severe aortic stenosis who were not suitable candidates for surgery (high-risk patients). TAVR, as compared with standard surgical treatment (SAVR), significantly reduced the rates of death from any cause (30.7% vs. 50.7%, at 1 year, \( P < 0.001 \)), the composite endpoint of death from any cause or repeat hospitalization (42.5% vs. 71.6%, \( P < 0.001 \)), and cardiac symptoms (25.2% vs. 58.0%, \( P < 0.001 \)), despite the higher incidence of major strokes (5.0% vs. 1.1%, \( P = 0.06 \)) and major vascular events (16.2% vs. 1.1%, \( P < 0.001 \)). In the PARTNER II trial, 2032 intermediate-risk patients with severe aortic stenosis were randomly assigned to undergo either TAVR or SAVR. It was found that in intermediate-risk patients, TAVR was similar to SAVR with respect to the primary end point of death or disabling stroke (\( P = 0.001 \) for noninferiority). TAVR resulted in larger aortic valve areas than did surgery and also resulted in lower rates of acute kidney injury, severe bleeding, and new-onset atrial fibrillation; surgery resulted in fewer major vascular complications and less paravalvular aortic regurgitation.

Similarly, the Surgical or Transcatheter Aortic-Valve Replacement in Intermediate-Risk patients trial (SURTAVI) evaluated the clinical outcomes in intermediate-risk patients with severe, symptomatic aortic stenosis in a randomized trial comparing TAVR (performed with the use of a self-expanding prosthesis) with surgical aortic-valve replacement. TAVR was found to be a noninferior (i.e., similar composite endpoint of death from any cause or disabling stroke at 24 months) alternative to surgery in patients with severe aortic stenosis at intermediate surgical risk, with a different pattern of adverse events associated with each procedure. Surgery was associated with higher rates of acute kidney injury, atrial fibrillation, and transfusion requirements, whereas TAVR had higher rates of residual aortic regurgitation and need for pacemaker implantation. The PARTNER III trial, currently under investigation, is designed to establish the safety and effectiveness of TAVR in patients with severe, calcific aortic stenosis who are at low operative risk for standard surgical aortic valve replacement (SAVR). Ongoing trials will continue to define the roles for SAVR and TAVR in the future.

**TRICUSPID VALVE DISEASE**

**Tricuspid Stenosis and Insufficiency**

**Etiology.** Acquired tricuspid valve (TV) disease can be classified as either organic or functional and affects approximately 0.8% of the general population. Tricuspid stenosis (TS) is almost always a result of rheumatic heart disease or rarely endocarditis. In the case of rheumatic disease, tricuspid stenosis with or without associated insufficiency is invariably associated with mitral valve disease. Other less common causes of obstruction to right atrial emptying include congenital tricuspid atresia, right atrial tumors, and endomyocardial fibrosis.

Tricuspid insufficiency (TR), on the other hand, is most often a functional disease caused by secondary dilation of the tricuspid annulus due to pulmonary hypertension and/or right heart failure. This is most commonly caused by MV disease. Conditions such as right ventricular infarction and pulmonic stenosis can also lead to increased right ventricular pressures and functional TR. The less common causes of organic TR, with or without associated stenosis, include endocarditis, carcinoid syndrome, radiation therapy, trauma such as repeated endomyocardial biopsy, and Marfan syndrome.

**Pathology.** The changes associated with TS closely resemble those associated with MS, including fusion of the commissures. In the case of rheumatic disease, mixed TS and TR may result from fusion and shortening of the chordae tendineae, and fusion of the commissures, causing retraction of the valve leaflets. The right atrium is frequently dilated and thickened in chronic TS, and chronic obstruction to right ventricular filling often produces signs of systemic venous congestion such as hepatomegaly and splenomegaly.

In most cases of TR, dilation and deformation of the tricuspid annulus is the most prominent feature; the valve leaflets oftentimes appear stretched but are otherwise pliable and normal in appearance. When TR is caused by carcinoid syndrome, white fibrous carcinoid plaques are found on the ventricular surfaces of the TV, causing the cusps to adhere to the underlying right ventricular wall and stenting the valve open.

**Pathophysiology.** The basic pathophysiologic abnormality of both TS and severe TR is elevated right atrial pressure, producing systemic congestion and right heart failure. Severe TS is marked by a valve area <1.0 cm², and severe TR is defined as a vena contracta width of >0.7 cm in combination with systolic flow reversal in the hepatic veins. However, in patients with TS, a diastolic pressure gradient of only 5 mmHg, or a TV
orifice <1.5 cm², is frequently enough to cause jugular venous
distention, organomegaly, and peripheral edema. In severe
cases, cardiac output is compromised, especially during exercise
when the fixed obstruction prevents an increase in forward flow.
Patients with severe insufficiency and pulmonary hypertension
experience similar hemodynamic derangements.

Clinical Manifestations. Patients with TS and severe TR
develop symptoms of right heart failure associated with chroni-
cally elevated right atrial pressures. The classic clinical signs
and symptoms of TS and severe TR are jugular venous disten-
tion, hepatomegaly, splenomegaly, ascites, and lower extremity
dema. Uncomfortable fluttering in the neck has been reported
in patients with TV disease, and sensations of throbbing in the
eyeballs and pulsatile varicose veins have been reported to
occur, especially in patients with severe TR.

The low cardiac output syndrome occasionally associated
with TS and severe TR can cause fatigue, weakness, and exercise
intolerance in these patients. In the absence of pulmonary
hypertension, dyspnea is not a prominent feature of tricuspid
disease. The auscultatory findings associated with TS include
a presystolic and middiastolic murmur characterized by a tri-
cuspid opening snap that increases on inspiration. The lower
left parasternal murmur of TR may be holosystolic or less than
holosystolic, depending on the degree of regurgitation, may be
associated with a middiastolic murmur in severe cases, and may
increase on inspiration.

Diagnostic Studies. In patients with TV disease, chest
X-ray frequently demonstrates enlargement of the right atrium
and ventricle. Patients with TS demonstrate an exaggerated a
wave and a diminished rate of y descent in the jugular venous
pulse, while patients with TR have abnormal systolic c and v
waves. TTE examination should be performed in patients with
TV disease in order to characterize the structure and motion
of the TV, the size of the tricuspid anulus, and other cardiac
abnormalities that may affect TV function. In patients with a
pulmonary artery systolic pressure >55 mmHg, TI commonly
occurs in the setting of structurally normal valves; however,
structural derangement of the TV apparatus is frequently present
if TR is documented with a pulmonary artery systolic pressure
<40 mmHg. Doppler TTE allows estimations of the severity of
TR, the right ventricular systolic pressure, and the TV diastolic
gradient.

Indications for Operation. As an isolated lesion, mild or
moderate TV disease does not require surgical correction. How-
ever, patients with severe TV disease should be considered for
surgical intervention, especially in the setting of right ventricu-
lar enlargement and impaired systolic function, as this improves
life expectancy and the development of sequelae such as heart
failure and atrial fibrillation. Depending on the patient’s clini-
cal status and the cause of TV dysfunction, TV repair and TV
replacement be variably recommended for the treatment of TV
dysfunction (Table 21-12). In patients with TR, the valve can
usually be repaired with modern techniques.

Operative Techniques and Results. The TV can be
approached through a median sternotomy, a right thoracotomy,
or port-based techniques. Surgery is performed with the assist-
ance of cardiopulmonary bypass and, though TV surgery is
usually performed on the beating heart, a brief period of car-
dioplegic arrest may be rarely needed to allow for complete
inspection of the interatrial septum and to close any defects that
may be present. TV repair may include a suture or ring annuloplasty as well
as valvuloplasty, and multiple methods have been described.
Historically, bicuspidization of the TV was accomplished by a
figure-of-eight suture plication of the annulus of the posterior
leaflet; however, this technique has been essentially replaced
by suture or ring annuloplasty. Suture annuloplasty is gener-
ally performed by placing pledged suture along the base of
the anterior and posterior leaflets, partially encircling the annulus.
Ring annuloplasty can be accomplished by suturing the TV
annulus to a variety of rigid or semirigid annuloplasty rings,
which generally have an opening at the level of the anterospe-
tal commissure to avoid passing the anchoring sutures near to
the conduction system. Most surgeons favor ring over suture
annuloplasty. In severe annular dilatation, augmentation of the
anterior leaflet with autologous pericardium has been used with
some success. Tricuspid valvuloplasty is infrequently performed
and may include commissurotomy, triangular leaflet resection,

MV = mitral valve; PASP = pulmonary artery systolic pressure; TI = tricuspid insufficiency; TV = tricuspid valve; TVr = tricuspid valve repair; TVR = tricuspid valve replacement.
primary perforation repair, and traditional leaflet repair techniques such as chordal transfer, shortening, and replacement, papillary muscle plication, tricuspid leaflet augmentation, and the edge-to-edge repair technique used in MV prolapse.

For patients with functional TV disease, TV repair is generally preferred to replacement due to favorable results without the associated risks of thrombosis and the need for anticoagulation. In the setting of concomitant mitral valve surgery, TV repair has not been associated with additional perioperative complications, and 5-year freedom from reoperation has been impressive at 98%. However, a subgroup of patients report late failure following TV repair, and this may be worse following suture annuloplasty compared with ring annuloplasty.117

Prosthetic valve replacement may be necessary due to extensive leaflet destruction, as may be seen in patients with endocarditis, or marked annular dilatation not amenable to repair. In some cases, the valve prosthesis may be anchored directly to the leaflet tissue instead of the valve annulus, reducing the risk of injury to the conduction system.106 If this technique is used, it should be confirmed that the residual tissue does not interfere with the movement of the prosthetic leaflets after implantation. Pledgeted sutures should be used and may be placed on the ventricular or atrial side of the annulus.

Outcomes data following TV replacement are difficult to interpret, as most reports are in patients with previous TV surgery and/or signs of severe right heart failure. Operative mortality has been ≥20% in some studies.106 One study of 87 patients undergoing TV replacement between 1994 and 2007 showed an in-hospital mortality of only 1.4%. The choice of prosthetic valve is also somewhat controversial. Though bioprosthetic valves are more durable in the tricuspid than mitral or aortic positions, valve degeneration is an important cause of bioprosthetic valve dysfunction at reoperation. The ability to replace a degenerated tricuspid valve bioprosthesis with a transcatheter valve has led some surgeons to favor biological valves in this position. This is particularly true since the increased risk of valve thrombosis seen with mechanical valves mandates rigorous systemic anticoagulation. Even with these precautions, mechanical tricuspid valves are associated with an increased risk of hemorrhagic and thrombotic complications. The choice of valve is usually decided on a case-by-case basis, and late outcomes have been similar with biological and mechanical valves in this position. In general, TV replacement may be a reasonable choice in select patients, though more data are needed regarding long-term outcomes in the modern era.

### Multivalve Disease

Pathology involving multiple valves is relatively common and may result from diseases such as rheumatic fever, calcific disease, Marfan syndrome, and other connective tissue disorders. However, multivalve disease may also be caused by secondary valvular dysfunction due to a distal valvular lesion, as in the case of myxomatous degeneration of the mitral valve, resulting in pulmonary hypertension, dilation of the tricuspid annulus, and functional TR. If the primary pathology is corrected early in the disease course, these secondary functional changes may resolve without the need for intervention.

In patients with multivalve disease, the clinical manifestations may be dependent on the severity of each individual valve lesion, but this is not always the case.2 In patients with concomitant mitral and tricuspid dysfunction, the prominent symptoms of dyspnea, paroxysmal nocturnal dyspnea, and orthopnea commonly associated with MV dysfunction are sometimes diminished by associated TV dysfunction. Symptoms of multivalve disease are most commonly masked when valvular abnormalities are of approximately equal severity, highlighting the importance of careful examination of each valve both preoperatively and in the operating room.

Surgery for multivalve disease is associated with a higher perioperative mortality than single-valve procedures, and this risk is exacerbated by factors such as pulmonary artery hypertension, age, triple-valve procedures, concomitant coronary artery bypass grafting, previous heart surgery, renal insufficiency, and diabetes.170 Failing to recognize significant concomitant valvular dysfunction at the time of surgery is also associated with higher perioperative mortality. For this reason, patients suspected of having multivalve involvement should undergo full preoperative Doppler TTE or TEE evaluation and heart catheterization.18 In selected patients, procedures correcting multivalve disease demonstrate significant clinical improvement in symptoms and quality of life, as well as acceptable mortality and survival rates.170

### SURGICAL THERAPY FOR THE FAILING HEART

#### Epidemiology of Heart Failure

Heart failure affects approximately 5 million patients in the United States, with >550,000 new cases diagnosed annually.171 The disorder is the primary reason for 12 to 15 million office visits and >1 million hospitalizations each year. Overall 1-year mortality is estimated to be around 25%, but this can increase to as high as 75% for patients with more advanced heart failure (NYHA class IV).172 While heart transplantation remains the gold standard for the treatment of end stage disease, an increasing number of patients deteriorate while on the waiting list, and up to 30% die before transplantation.173 The total direct and indirect costs associated with the treatment of heart failure are estimated to be $32 billion, and this is projected to increase to $70 billion by 2030.174 Advances in the surgical management of heart failure over the two decades have pushed surgery for CHF into the mainstream. As a result, there is an increasing number of patients with late- or end-stage disease who are being considered for surgical therapies.

#### Etiology and Pathophysiology

Heart failure can be classified as acute or chronic, genetic or acquired, left-sided and/or right-sided, and systolic and/or diastolic dysfunction. The underlying causes and treatments for each of these vary considerably. In the Framingham Heart Study, coronary artery disease accounted for 67% of heart failure cases, valvular heart disease accounted for 10%, and 20% of cases were attributable to primary myocardial diseases, of which dilated cardiomyopathy predominated.175 In all cases, heart failure is a progressive disorder that through complex mechanisms of ventricular remodeling, altered hemodynamics, neurohumoral activation, cytokine overexpression, and vascular and endothelial dysfunction either disrupts the ability of the myocardium to generate force or results in a loss of functioning cardiac myocytes, thereby preventing normal myocardial contraction.

#### CABG for Ischemic Cardiomyopathy

Surgical coronary revascularization is among the most commonly performed procedures for CHF. CABG is beneficial as it protects from further myocardial infarction and/or malignant...
ventricular arrhythmias. It is most successful when treating hibernating as opposed to infarcted myocardium. While the majority of evidence supporting CABG for patients with ischemic cardiomyopathy comes from nonrandomized, retrospective studies, the prospective, randomized, multicenter international Surgical Treatment of Ischemic Heart Failure (STICH) trial compared CABG with medical therapy to medical therapy alone. Entry criteria included an EF ≤35% with CAD and anatomy suitable for CABG. No significant difference was seen in overall mortality by study completion, but patients who underwent CABG did have fewer deaths or hospitalizations from cardiovascular causes (58% vs. 68%, P < 0.001).

Myocardial viability testing has been shown by multiple studies to be pivotal in identifying patients that will have improved outcomes following CABG for ischemic cardiomyopathy. A meta-analysis performed by Allman et al demonstrated an 80% reduction in mortality in patients who underwent revascularization with viable myocardium compared to patients who received medical therapy alone (3.2% vs. 16%, P < 0.0001). Most importantly, in this analysis, CABG had no benefit over medical therapy for patients without viable myocardium. A more recent study by Gerber et al prospectively compared CABG and medical therapy to medical therapy alone in 114 patients with CAD and low EF (24% ± 8%) who underwent viability testing using delayed-enhancement cardiac MRI. This study demonstrated worse 3-year survival in medically treated patients with dysfunctional but viable myocardium than in medically treated patients with nonviable myocardium (48% vs. 77%, P = 0.02). This corresponded with a 4.56 times increased hazard of death when medical treatment was selected over full revascularization. In contrast, survival after CABG was not significantly different whether myocardium was viable or not (88% vs. 71%, P = NS). These studies underscore both the importance of viable myocardium as well as the adverse consequences of not offering a patient with viability surgical intervention.

Patients with ischemic cardiomyopathy are a heterogeneous group, and, as with any surgery, appropriate patient selection is central to success. In one retrospective study of 96 patients with ischemic cardiomyopathy (EF ≤25%), age and poor distal vessel quality were predictors of poor outcomes. Mortality in patients with poor vessel quality was 100%, compared with 90% when vessel quality was fair and 10% when it was good. Therefore, poor vessel quality should be considered a contraindication to surgical revascularization even in the presence of angina.

LV size and LV dyssynchrony are also risk factors for adverse short- and intermediate-term outcomes. A LV end-diastolic dimension of >100 mL/m² is associated with a significantly reduced 5-year survival following CABG (85% vs. 53%, P < 0.05), as well as worse 5-year freedom from recurrent CHF (85% vs. 31%). Moreover, LV dyssynchrony has been shown to have a significant impact on mortality in patients undergoing moderate- to high-risk revascularization and may compound risk in patients with nonviable myocardium. In patients with severe preoperative LV dyssynchrony, the 30-day mortality was 27% vs. 3% in patients without significant dyssynchrony (P < 0.001). Similar differences were seen with the presence of postoperative LV dyssynchrony, and outcomes were worse when patients also had fewer segments of viable myocardium.

Secondary Mitral Regurgitation
Secondary mitral regurgitation describes MR that results from damage to the left ventricle as a result of either ischemia or dilated cardiomyopathy rather than from a problem with the valve itself. Ischemic MR (IMR) typically results from systolic restriction of the mitral leaflets due to tethering of the subvalvular apparatus. This occurs mainly from regional wall motion abnormalities in areas of the LV adjacent to papillary muscle attachments. Alterations in the size and shape of the mitral annulus and posterior displacement of the posteroendocardial papillary muscle, which occurs primarily after an infarcted posterior MI, may also contribute. Additionally, functional MR (FMR) is caused by LV dilatation and increased sphericity, which displace the papillary muscles apically and radically, creating lateral forces on the valve that lead to increased retraction of the mitral leaflets by the chordae tendineae. LV dyssynchrony may also contribute to FMR through poor coordination of the contraction of the septum and lateral walls, producing MR that may vary in intensity during the cardiac cycle. Functional MR is usually referred to as a Carpentier class I/IIib lesion due to the presence of both annular dilatation (Carpentier type I) and systolic restriction of the mitral leaflets due to LV dysfunction (Carpentier type IIib). Ultimately, increased regurgitation leads to increased preload, LV wall tension, and LV work load, all of which contribute to progressive dysfunction of the LV and worsening heart failure.

Several observational and population-based studies have demonstrated a significant impact of secondary MR on long-term survival. Following MI, the 5-year survival rate dropped significantly from 61% in patients who did not have MR to 47% and 29% in patients with mild and moderate to severe MR, respectively. Similarly, in a series of 2057 patients with symptomatic heart failure and an LVEF <40%, the 5-year survival rate for patients without MR was 54%, and it decreased to 40% in patients with moderate to severe secondary MR. Moreover, medical therapy and PCI have not reduced the impact of IMR on late mortality.

Although specific recommendations to intervene for secondary MR are controversial and have not been rigorously defined, guidelines are available (Table 21-13). Some surgeons initially advocated performing only revascularization in cases of moderate ischemic MR with the idea that revascularizing viable myocardium would lead to improvements in LV function and effect reverse remodeling, ultimately contributing to a decrease in MR. While several studies, including a recent large, multicenter, randomized, controlled trial, have shown that MR often persists following revascularization alone, the addition of a mitral valve annuloplasty in those studies did not improve long-term functional status or survival in patients with ischemic MR. Nevertheless, other studies have shown that the persistence of MR after CABG is associated with a decreased survival rate and that CABG alone only has modest effects on reducing MR at 1 month follow-up. As a result, some centers continue to repair moderate MR in this patient population. Indications for surgery in ischemic MR patients in the absence of revascularization options are even less well defined.

For patients with functional MR, the goal of mitral valve surgery is to avoid or postpone transplantation in eligible patients. Mitral valve repair has been considered the procedure of choice when surgery is indicated for secondary MR. However, in patients with severe ischemic MR, a recent randomized, multicenter trial showed improved late freedom from moderate or severe recurrent MR with mitral valve replacement compared to repair (2.3% vs. 32.6%, P < 0.001). There was not a significantly higher mortality in the replacement group in this study.
In patients with poor LV function, dilated LV, and severe MR with significant leaflet tethering, we favor MV replacement with preservation of the subvalvular apparatus. Bioprosthetic valve is usually used due to the poor late survival in this group of patients. Currently, for patients undergoing repair recommendations are to use a semirigid or rigid annuloplasty ring to downsize the mitral annulus. There have also been various techniques proposed to correct the papillary muscle displacement, but most reports are single center, retrospective, and small. Mitral valve replacement with preservation of the subvalvular apparatus is indicated when repair is not feasible due to severe tethering of the leaflets or massive LV dilation.

Outcomes from surgery vary among centers and among patients in this heterogeneous group. Operative mortality ranges between 0% and 9% in most modern series. Generally speaking, mortality and recurrence rates are higher and long-term prognosis is worse compared to outcomes for primary MR. Recurrent MR is as high as 15% to 30% in some series, and 5-year mortality is between 44% and 48%. Some reductions in left atrial dimension and LV reverse remodeling may be achieved.

**Left Ventricular Aneurysmmorphy and Surgical Ventricular Restoration**

**Pathophysiology of Ventricular Aneurysms.** A transmural infarction of approximately 5% to 10% of the myocardium may result in formation of an LV aneurysm as necrotic myocardium is replaced by fibrous tissue. This usually occurs 4 to 8 weeks following the infarct. In the last decade, prompt revascularization of the culprit artery by either surgical or interventional techniques generally results in sparing of the subepicardial muscle while the subendocardial muscle remains necrotic. Therefore, it is not uncommon for the LV wall to show both living myocardium during thallium testing and an akinetic zone on echocardiogram or angiogram. It has been demonstrated that once more than 20% of the myocardium is necrosed there is irreversible progression to ventricular dilation and failure. Once heart failure develops after postinfarction remodeling, the 1-year mortality reaches 32% despite current therapies. The classic aneurysm is a 4 to 6 mm thick scar, which bulges outward in paradoxical motion as the LV contracts during systole. More than 80% develop in the anteroseptal and apical portions of the left ventricle as a result of left anterior descending artery occlusion. The rest are inferior in location and the result of circumflex or right coronary occlusion.

This patient population typically suffers from associated ventricular arrhythmias for several reasons. First, electrical dysynchrony results from postinfarction remodeling, and triggers for ventricular arrhythmias typically occur in the scar border zone in patients with ischemic cardiomyopathy. Second, increased ventricular volume causes high wall stress and stretch, and stretch has been shown to be arrhythmogenic. Third, LV aneurysms represent an independent risk factor for SCD after MI. Surgical ventricular restoration (SVR) addresses each of these issues by removing the anatomic substrate during resection of the postinfarct scar and/or aneurysm, accomplishing volume reduction and mechanical resynchronization and relieving ischemia through complete revascularization and reduction in myocardial wall tension and oxygen demand.

**Clinical Presentation and Diagnosis.** Symptoms of LV aneurysms include angina, CHF, ventricular arrhythmias, and rarely, embolic phenomenon. Rupture is extremely uncommon. Patients generally present for coronary artery bypass or during evaluation of CHF or arrhythmias. While transthoracic echocardiography gives pertinent information regarding LV function, size, mitral valve function, and the presence of thrombus, it is generally accepted that cardiac MRI is the best diagnostic modality to accurately identify areas of scar and viable tissue and to best define ventricular geometry.

**Surgical Treatment and Results.** In 1985, Vincent Dor described a surgical technique called the endoventricular circular patch plasty that was intended to improve geometric reconstruction compared with the standard linear repair in LV aneurysm surgery. SVR is a somewhat broader term that arose from surgical repair of ventricular aneurysms and has now come to be applied to a group of surgical procedures designed to correct the effects of postinfarction ventricular remodeling. It is also sometimes referred to as surgical ventricular remodeling or reconstruction, surgical anterior ventricular endocardial reconstruction (SAVER), or the Dor procedure. SVR is specifically intended to reduce the size and sphericity of the LV by...
excluding akinetic and dyskinetic areas, most often by using a circular patch inserted inside the ventricle on contractile myocardium (Fig. 21-12A,B).

Candidates for SVR are typically patients who have had a remote anterior or anteroseptal myocardial infarction, significant ventricular enlargement with a significant area of akinetic or dyskinetic myocardium, a discrete aneurysm, a clinical picture consistent with heart failure (LVEF <40%), retained function of the basilar and lateral portions of the heart, and good right ventricular function. These patients should also be candidates for repair of any other concomitant cardiac disease. Dor currently emphasizes the importance of complete revascularization and repair of any mitral pathology at the time of operative SVR. In patients with spontaneous (13%) or inducible (25%) ventricular tachycardia (VT), it is additionally necessary to perform nonguided endocardial resection and cryoablation encircling the resected area.197

Results with this approach have been good in treating both heart failure and its sequelae, such as VT. In Dor’s series of 1150 patients, the operative mortality varied based on the LVEF, ranging from 1% (patients with EF >40%) to 13% (patients with EF <30%), and the 5-year survival approached 85%.197 Overall, more than 80% of survivors either stabilized or improved, and the quality of life was shown to improve significantly by 6 months after the Dor procedure.203 This is likely due in part to the fact that the Dor procedure restores LV geometry, resulting in a mean ejection fraction increase between 10% and 15%, with significant alleviation of symptoms.197,204-206 These data are reinforced by the international RESTORE group, which examined SVR in a registry of 1198 postinfarction patients between 1998 and 2003.207 They found that 5-year overall freedom from hospital readmission for CHF was 78%. Moreover, 67% of patients had preoperative NYHA class III or IV symptoms, whereas 85% of patients were NYHA functional class I or II postoperatively.

With respect to VT, Dor et al reported on 106 patients with ischemic ventricular arrhythmias that underwent reconstruction for postinfarction LV aneurysm and visually directed endocardectomy plus or minus cryoablation and coronary revascularization.208 At a mean follow-up of 21.3 months, only 10.8% of patients had inducible VT, and no spontaneous VT was documented. Results from similar series have also been excellent,197,206,209 but the efficacy of left ventricular restoration alone has been controversial.209,211 Inferior results seen in some series have been attributed to failure to perform endocardial resection and/or cryoablation at the border of the transitional zone, as well as differences in stimulation protocols and possible inadequate volume reduction of the ventricle.

A large, randomized, multicenter study, the STICH trial, concluded that adding SVR to reduce ventricular volume to CABG does not improve symptoms or exercise tolerance and fails to lower death rate or cardiac rehospitalization compared to CABG alone.199 While this trial has some shortcomings, it has resulted in a marked decrease in referrals for this procedure. The main problem is that the LV volume was reduced by only 19% in the STICH trial, reflecting an inadequate repair as determined by the Surgery Therapy Committee, whose “acceptable STICH procedure” guideline required a 30% reduction at the 4-month postoperative cardiac MRI.212 Previous studies have reported an average reduction of end-systolic volume index (ESVI) of 40% with a range between 30% and 58%, suggesting that the STICH SVR procedure may have involved an inadequately small LV plication or limited intracavitary reconstruction.212 Moreover, this trial enrolled 13% of patients who had never had an MI and changed criteria such that enrollment required documented LV anterior wall dysfunction rather than demonstration of scar. This could have captured patients with hibernating myocardium that would recover following CABG alone. Dor subsequently published the results of 117 patients who would have been eligible for the STICH trial and demonstrated durable improvement in left ventricular function.213 However, this was a single-center, retrospective experience. Caution should be exercised so as not to broadly extrapolate the results of the STICH trial and inappropriately deny appropriate patients effective treatment. This remains an area of controversy.

With the recent advances in percutaneous interventions, the Parachute device has been trialed in human subjects. It is composed of a self-expanding nitinol frame covered with an impermeable fluoropolymer that is deployed into the LV apex walling off akinetic or dyskinetic segments of the LV. The PARACHUTE trial reported 3-year echocardiographic and clinical outcomes of patients with ischemic heart failure who underwent placement of the Parachute device as a feasibility and safety study. They demonstrated that of the 31 patients who received the device, there was improvement or maintenance of NYHA functional class in 85% as well as significant reduction of the LV EDV index.198
Mechanical Circulatory Support

Intra-Aortic Balloon Pump. The intra-aortic balloon pump (IABP) is a commonly used device for mechanical circulatory support and has been in use since 1968. The device is inserted percutaneously through a peripheral artery into the thoracic aorta. The balloon is synchronized so that it inflates during diastole and deflates during systole, resulting in augmentation of diastolic perfusion of the coronary arteries and decreased afterload. Typically, this improves cardiac index and decreases both preload and myocardial oxygen consumption.

Common indications for use of an IABP are cardiogenic shock during or following cardiac catheterization or cardiac surgery. It is also utilized for preoperative stabilization of high-risk patients with either severe coronary artery disease, LV dysfunction, or refractory, unstable angina. Kang et al have reported that risk-adjusted mortality was significantly lower for selected high-risk patients undergoing open heart surgery when a preoperative IABP was used. In 2012, Thiele et al reported their data following a randomized, prospective, multicenter clinical trial looking at the outcome of using intra-aortic balloon pump in the treatment of cardiogenic shock complicating acute myocardial infarction in patients who underwent early revascularization (by means of percutaneous coronary intervention or bypass surgery) (IABP-SHOCK II trial). IABP did not significantly reduce 30-day mortality in this group of patients. Additionally, they reported no significant differences in secondary end points, including the time to hemodynamic stabilization, the length of stay in the intensive care unit, serum lactate levels, and major complications including major bleeding and peripheral ischemia.

Generally, an IABP is used for a few days and the amount of support is weaned as the patient’s condition improves. Mortality associated with device use is typically minimal; however, in one series of 911 patients undergoing CABG who received an IABP, there was a 12% incidence of minor or major vascular complications, including an approximately 3% incidence of limb ischemia requiring thromboembolectomy. This is the most serious complication of IABP placement. To prevent this problem, frequent lower extremity neurovascular checks are necessary while an IABP is in place.

Ventricular Assist Device Indications and Cannulation. Patients in need of ventricular assist devices (VADs) may have preexisting chronic heart failure, refractory ventricular arrhythmias, or acute heart failure following an MI, cardiopulmonary arrest, viral illness, pregnancy, or cardiomyopathy. Device therapy is intended to preserve end-organ perfusion and function and may be categorized as short- or long-term support for the left heart, the right heart, or both. In general, VADs may be used rarely for support while the heart recovers (bridge to recovery, BTR), while the patient waits for a heart transplant (bridge to transplant, BTT) or increasingly more commonly to treat a chronic heart failure patient who is not a transplant candidate (destination therapy, DT). The Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) database, a joint effort by the NHLBI, FDA, CMS, academia, and industry to prospectively track patient outcomes, reported that in 2015 and 2016 indications for device implantation were BTR (0.2%), BTT listed (26.4%), BTT likely (15.5%), BTT moderate (7.7%), BTT unlikely (2.5%), DT (49.2%), and rescue therapy (0.5%). The percentage of patients receiving a VAD as destination therapy has markedly increased over the last decade as results and devices improved.

Left ventricular assist devices (LVADs) provide support for the failing heart by unloading blood from the left ventricle and pumping it into the aorta. Cannulas may be inserted into the LV apex or the left atrium for inflow into the pump, and return is through an arterial cannula or graft sewn to either the ascending or descending aorta. For right-sided devices, inflow drainage is most often from a cannula in the right atrium, and blood is returned through a graft sewn to the pulmonary artery or right ventricular outflow tract.

Left Ventricular Assist Devices. The first generation LVADs were pulsatile devices. They provided adequate support for the heart but were limited by their large size and durability. More recently, continuous-flow LVADs based on rotary pump technology have been introduced. These devices are smaller, quieter, and durable enough for long term support. The two most commonly used devices today are the HeartMate II (Thoratec, Pleasanton, CA) and the HeartWare HVAD (HeartWare, Inc., Framingham, MA) (Figs. 21-13A,B and 21-14A,B). These devices differ in that the HeartMate II is implanted subdiaphragmatically, whereas the smaller HeartWare HVAD is implanted within the pericardium. Frequently used short-term support devices include the Abiomed BVS 5000 (Abiomed, Inc., Danvers, MA) and the CentriMag (Thoratec), which are both extracorporeal pumps, as well as the Impella (Abiomed), which may be inserted percutaneously. These devices are commonly used in either post-MI or postcardiotomy heart failure. They have the benefit of faster and easier insertion, making them ideal rescue devices and allowing time for patient transfer to a tertiary referral center, device weaning, transplantation, or transition to a permanent VAD as DT or BTT.

Bridge to Recovery. The ideal clinical situation would be for all LVADs to be temporary with the goal of myocardial recovery. However, as noted previously, this is rare with only 0.2% of devices in the most recent INTERMACS data placed with intent for bridge to recovery. The LVAD Working Group Recovery Study, a prospective multicenter trial investigating myocardial recovery in BTT patients, has shown significant improvements in left ventricular ejection fraction and significant reductions in left ventricular end-diastolic diameter following support with continuous flow pumps, but myocardial recovery resulting in device explantation was still only seen in six patients (9%). Current data suggest that significant reverse remodeling is more likely to occur in the young and those with myocarditis.

Nevertheless, some encouraging results have been reported using a combination of treatment modalities. In a few small studies of patients with LVADs inserted for nonischemic cardiomyopathy, deliberate and aggressive medical therapy, including the β2-agonist clenbuterol, resulted in successful LVAD explantation in 69% to 73% of patients but these results have been difficult to replicate. Moreover, early results from clinical trials using stem cell therapy to treat patients with ischemic cardiomyopathy suggest that stem cells may be another adjuvant treatment with potential to aid in myocardial recovery.

Bridge to Transplant. LVADs are used as a bridge to transplant in patients who are candidates for heart transplantation but are not predicted to survive the waiting list period due to sequelae of cardiac failure, including end-organ dysfunction, rising pulmonary artery pressures, escalating inotrope
Figure 21-13. The HeartMate II LVAD viewed from the (A) outside and (B) inside. The device is an axial flow, rotary pump that produces no pulsatile action. The pump contains a magnet, and the rotor assembly functions by the electromotive force generated by the motor. The result is that blood is propelled from the inflow cannula to systemic circulation at flows up to 10 L/min. Figure 21-14. The HeartWare HVAD system. A. Both the device controller and batteries are held in a wearable carrying case and connected to the ventricular assist device through the driveline. B. The main component is a centrifugal blood pump, called the HVAD, which is implanted within the pericardium. The only moving part in the device, the impeller, is suspended within the pump using magnets and thrust bearings. Similar to the HeartMate II, it can deliver a flow rate of up to 10 L/min. (Reproduced with permission of Medtronic, Inc.)
Most recently, in 2017, Mehra et al reported their multicenter outcome (Mechanical Circulatory Support Therapy with HeartMate 3 trial—MOMENTUM 3) comparing the safety and effectiveness of centrifugal-flow pump (HeartMate 3) to the axial-flow pump (HeartMate II). Implantation of a fully magnetically levitated centrifugal-flow pump (HeartMate 3) was associated with better outcomes at 6 months than was implantation of an axial-flow pump (HeartMate II). The improved outcomes were primarily due to the lower rate of reoperation for pump malfunction. Additionally, no patients in the HeartMate 3 group were suspected or found to have pump thrombosis.

**Destination Therapy.** The Randomized Evaluation of Mechanical Assistance for Treatment of Congestive Heart Failure (REMATCH) trial was conducted to compare the efficacy of LVAD insertion against optimal medical management in patients with NYHA class IV heart failure. While the pulsatile devices used in this trial had high failure rates, poor durability, and high associated mortality, there was still a clear survival benefit in patients treated with LVADs. This led to the FDA approval of the first LVADs for destination therapy in 2002.

Subsequent trials have proven the increased efficacy of second-generation devices for DT. In one such landmark trial, patients with advanced heart failure who were ineligible for transplantation were randomized in a 2:1 ratio to either a HeartMate II or HeartMate XVE. While both groups showed significant improvements in functional capacity and quality of life, actuarial survival at 2 years was superior for HeartMate II patients (58% vs. 24%, $P = 0.008$) and adverse event rates were significantly lower. These data established the benefit of continuous flow LVADs over optimal medical management for end-stage heart failure, and led to FDA approval of the HeartMate II for DT in 2010. In certain populations, 2-year survival with the HeartMate II is now 80%. Several smaller third-generation devices are in various stages of development or clinical trials. Some of these devices eliminate the drive line by using alternative energy sources, thereby removing a significant nidus for device infections. Long-term outcomes with these devices are expected to continue to improve, approaching that of cardiac transplantation and providing a viable solution to organ shortage for many patients.

In 2013, Slaughter et al reported their multicenter clinical trial outcome to evaluate the HeartWare Ventricular Assist Device (HVAD) system for BTT in patients with advanced heart failure in the United States (ADVANCE BTT trial). The use of the HeartWare pump as a BTT continued to come into the light, and the use of the HeartMate XVE was approved for Destination Therapy. However, the HVAD system was limited due to longer survival and lower transplant rates. Current eligibility criteria for mechanical support as destination therapy include (a) NYHA class III or IV heart failure despite guideline-directed medical therapy including cardiac resynchronization therapy if indicated; (b) peak oxygen consumption <12 mL/kg per min or failure to wean from continuous IV inotropes; (c) left ventricular ejection fraction <25%; and (d) presence of a contraindication for heart transplantation (i.e., age >65 years, irreversible pulmonary hypertension, chronic renal failure, insulin-dependent diabetes with end-organ damage, or other clinically significant comorbidities).

Once a patient has an LVAD inserted as DT, close and intensive follow-up by a multidisciplinary heart failure team is required in order to optimize medical therapy, reduce device-related morbidity, and improve survival.

It is also important to keep in mind that while some contraindications to transplantation are irreversible, others can be modified. As such, approximately 10% of patients implanted with an initial strategy of destination therapy become BTT patients, and in some patients, the LVAD itself facilitates this transition. For example, an improvement in mean pulmonary vascular resistance was reported following implantation of the HeartMate II in patients with end-stage heart failure (2.1 vs. 3.6 Woods units, $P < 0.001$). These data are also relevant to patients that receive LVADs as a bridge to decision.

**Right Ventricular Assist Devices and Biventricular Assist Devices**

Most patients who present with advanced heart failure and a failing left ventricle also have some degree of right ventricular dysfunction, but the majority of these patients do well with only an LVAD. However, implantation of an LVAD may cause acute worsening of tricuspid regurgitation and exacerbations of right heart failure through leftward deviation of the intraventricular septum and as a result of the significant volume-loading and transfusion requirement that is often necessary to achieve adequate flows postoperatively. Overall, approximately 20% of HeartMate II BTT patients had persistent right ventricular failure (RVF) requiring either a subsequent RVAD (6%) or intravenous inotropic support for >14 days (14%), and these patients had significantly worse 6-month survival compared to those without RVF (71% vs. 89%, $P < 0.001$). Typically, mechanical right-ventricular support is temporary with intent to wean the device, and isolated right-ventricular assist devices are unusual.

Biventricular support is most commonly indicated for acute cardiogenic shock after an MI or postcardiotomy heart failure. Biventricular support is temporary, although some patients may be successfully bridged to transplant or permanent left-sided assist devices. There is currently no destination therapy device for biventricular failure.

**Total Artificial Heart**

The total artificial heart (TAH, SynCardia Systems, Tucson, AZ) is currently indicated as a bridge to transplant for patients in biventricular failure, particularly for those who are critically ill and too large for extracorporeal BiVAD support. Unlike ventricular assist devices, the TAH replaces the entire heart. The ventricles of the TAH are implanted orthotopically to the atrial cuffs on the ventricular side of the AV groove, and the outflow conduits are attached to the great vessels. This approach has the benefit of obviating the hemodynamic influence of pulmonary hypertension, right heart failure, myocardial or valvular problems, cardiac arrhythmias, and inotropic agents. While this device has failed to reach its potential as a replacement for cardiac transplantation, the TAH has achieved favorable results as a BTT with a >70% survival in selected centers. However, at most centers results with the TAH have been suboptimal, and it is not frequently used. A total of 226 TAH implants between 2013 and 2016 were reported to INTERMACS database. One-year and 2-year survival was reported at 52% and 37%, respectively. Compare to the previously reported survival (2006 through 2012), no significant improvement in survival was noted with time.

**Surgery for Arrhythmias**

The success of catheter-based ablation and implantable cardioverter defibrillators (ICDs) has significantly diminished referrals for the surgical treatment of arrhythmias such as ventricular...
tachycardia, Wolff-Parkinson-White syndrome, atrial flutter, and atrioventricular nodal reentry. On the other hand, the introduction of surgical ablation modalities such as radiofrequency and cryothermal energy, has simplified the surgical treatment of atrial fibrillation and has led to an increase in the number of surgical procedures performed annually for AF, although this has plateaued in recent years.241,242

**Atrial Fibrillation**

**Epidemiology of Atrial Fibrillation.** AF remains the most common arrhythmia in the world with an overall prevalence of 0.4% to 1% that increases to 8% in those older than 80 years old.243 The most serious complication of AF is thromboembolism with resultant stroke,244 but serious morbidity and mortality may also result from hemodynamic compromise due to loss of atrial contraction and exacerbations of CHF from atrioventricular asynchrony and tachycardia-induced cardiomyopathy.

**Medical Management.** Most patients are treated medically, but the shortcomings of pharmacological management have left an important role for interventional therapies. Antiarrhythmic medications have been limited by modest efficacy and significant proarhythmic and systemic toxicities.245 Conversely, rate control strategies leave the patient in AF, do not address the impaired hemodynamics or symptoms associated with this arrhythmia, and may render subsequent attempts at rhythm control therapies less effective for younger patients who may suffer irreversible cardiac remodeling due to the prolonged period of time in AF. Additionally, AF is associated with a fivefold greater risk of ischemic stroke or systemic embolism compared with normal sinus rhythm. Annual risk of major bleeding in those on anticoagulation is estimated at 1.2%.246

Restoration of normal sinus rhythm has several potential benefits over other strategies.247-249 These include improvement in atrial systolic function, which improves cardiac output and often symptoms of CHF; lowered risks of stroke; potential freedom from anticoagulation; and likely reversal of atrial structural and/or electrical remodeling.

**Indications for Surgical Management.** Consensus guidelines published by the Heart Rhythm Society state that surgical ablation for atrial fibrillation is indicated for (a) all symptomatic AF patients undergoing other cardiac surgery; (b) selected asymptomatic AF patients undergoing cardiac surgery in which the ablation can be performed with minimal additional risk; and (c) symptomatic patients with lone AF who have failed medical therapy and prefer a surgical approach, have failed one or more attempts at catheter ablation, or are poor candidates for catheter ablation.243 At our institution, relative indications for surgical ablation in patients with permanent AF that were not included in the consensus statement are (a) a contraindication to long term anticoagulation for patients at high risk for stroke (CHADS2 score ≥2) and (b) a history of stroke while on therapeutic anticoagulation. Since the consensus statement was released, a multicenter, randomized, controlled trial of surgical ablation in patients undergoing mitral valve surgery showed a significant improvement in freedom from atrial fibrillation in patients receiving surgical ablation (63% vs. 29%, *P* <0.001).250 Controversially, this trial did not show a difference between left atrial and bilateral lesion; this may have been due to technical issues with the operations.251 The STS has recently released guidelines for surgical ablation that give a Class I Level A recommendation for concomitant surgical ablation at the time of mitral valve surgery and a Class I Level B-NR recommendation for concomitant surgical ablation at the time of AVR, CABG, or AVR-CABG.252

**The Cox-Maze IV Procedure.** The first successful operation for atrial fibrillation, the Cox-Maze procedure, was introduced clinically in 1987 by James Cox. The procedure involved the completion of a maze-like pattern of surgical incisions across both the right and left atrial that were designed to interrupt the multiple macroreentrant circuits thought to be responsible for AF, while still allowing propagation of the sinus impulse, restoring atrioventricular synchrony, and preserving atrial transport function. While effective at eliminating AF and reducing the risk of thromboembolism, it was not widely performed because it was technically difficult and significantly prolonged time on cardiopulmonary bypass. In 2002, the Cox-Maze IV, was introduced. The Cox-Maze IV uses a combination of bipolar radiofrequency (RF) ablation and cryoablation to effectively replace the majority of incisions that comprise the Cox-Maze III while significantly shortening cross-clamp time and reducing operative complexity.

The Cox-Maze IV is performed on cardiopulmonary bypass through either a median sternotomy, often in combination with other cardiac surgery or a right minithoracotomy.253,254 In most cases, the right atrial lesion set performed on the beating heart, whereas the left atrial lesions are performed during cardioplegic arrest (Fig. 21-15).

**Results from the Cox-Maze IV procedure have been excellent.** The Washington University group reported a series of 576 consecutive patients in 2015, demonstrating freedom from atrial tachyarrhythmias in 92% of patients at 1 year and 73% of patients at 5 years postoperatively.255 Additionally, freedom from atrial tachyarrhythmias and antiarrhythmic drugs was 81% at 1 year and 61% at 5 years. A recent propensity-matched analysis showed that the addition of the Cox-Maze IV procedure to a routine cardiac surgery did not significantly increase postoperative morbidity or mortality and was associated with improved late survival compared with patients with untreated AF and a similar survival to patients without a history of AF.256 A propensity analysis has shown that results are similar between the traditional “cut-and-sew” maze (Cox-Maze III) and the Cox-Maze IV.257 This procedure is often successful in patients who are poor candidates for catheter-based ablation, such as those with large left atria and patients with long-standing persistent AF.

The combination of surgical management of the left atrial appendage (LAA) and restoration of normal sinus rhythm after the Cox-Maze procedure significantly reduces stroke risk. It is our practice to stop warfarin at 3 months postoperatively in patients who are in normal sinus rhythm and without another indication for anticoagulation, regardless of CHA2DS2-VASc score. With this approach, the stroke rate following the Cox-Maze procedure off anticoagulation has been remarkably low (annual risk = 0.2%).258 In contrast, in one report the annual rate of intracranial hemorrhage in anticoagulated patients with AF was 0.9% per year, and the overall rate of major bleeding complications was 2.3% per year.259

**Left Atrial Lesion Sets.** Some surgeons perform more limited ablation procedures, such as isolated pulmonary vein isolation or lesion sets that are limited to the left side of the heart. This is done in order to further reduce the complexity of the procedure and takes advantage of the fact that in most patients AF
Pulmonary Vein Isolation. Pulmonary vein isolation (PVI) is an attractive therapeutic option because it can be performed off of cardiopulmonary bypass (CPB) through small or thoracoscopic incisions. The results of PVI have been variable and highly dependent on patient selection since outcomes are consistently worse in patients with longstanding persistent AF. In a study from Edgerton et al, only 56% of patients were free from AF at 6 months (35% off antiarrhythmic drugs), and with concomitant procedures, the success rate of PVI has been even lower.267 Several devices are available to close the LAA at the time of PVI. These include staplers and epicardial clips that can be placed without the need for CPB.263

While surgical PVI has had poorer results than a Cox-Maze procedure, it has had superior results to catheter-based PVI. The Atrial Fibrillation Catheter Ablation Versus Surgical Ablation Treatment (FAST) Trial, which was a two-center, randomized clinical trial, compared catheter-based ablation to thoracoscopic PVI in patients with antiarrhythmic drug-refractory AF and either left atrial dilatation and hypertension or failed prior catheter-ablation.264 This study demonstrated that the 12-month freedom from AF and antiarrhythmic drugs was 37% for the catheter ablation group and 66% for the PVI group (P = 0.002).264

**Surgery for Pericardial Disease**

**Acute Pericarditis**

Pericarditis is characterized by infiltration of the cellular and fibrous pericardium by inflammatory cells. The exact incidence and prevalence of pericarditis is unknown, but it is estimated that pericarditis is found in approximately 1% of autopsies and accounts for up to 5% of presentations of nonischemic chest pain.265,266 The etiologies of acute pericarditis are diverse and may result from primary pericardial disorders or occur secondary to a systemic illness.267 In developed countries, 80% to 90% of cases are now considered idiopathic or related to a viral pathogen, but nonviral infection, autoimmune diseases, myocardial infarction, radiation, malignancy, endocrinopathy, myocarditis, aortic dissection, uremia, trauma, pharmacologic side effects, and previous cardiothoracic surgery must be included in the differential diagnosis. The relative incidences of peri-infarction pericarditis, which was once common, and postcardiac injury syndrome have been dramatically reduced with the advent of thrombolytics and coronary angioplasty.267

**Clinical Presentation and Diagnosis**

Diagnosis of acute pericarditis typically requires the identification of at least two of four cardinal features (Table 21-14). The presentation may be confused with several more common cardiopulmonary conditions, particularly myocardial infarction, making a careful history and physical critical. Patients with pericarditis classically complain of sudden onset, retrosternal pain that may be pleuritic in nature. The pain may also be positional, with alleviation of pain when the patient is upright and leaning forward. Pain from pericarditis is typically sharp or stabbing, as opposed to the dull pain or pressure that is common with angina, and it typically does not crescendo. While both conditions cause pain that often radiates to the neck, arms, and shoulders, pericarditis pain may
uniquely radiate to the trapezius ridge due to innervation from the phrenic nerve.\textsuperscript{268-269}

The presence of a pericardial friction rub is pathognomonic for pericarditis, but it tends to vary in intensity over time and may be absent in 15\% to 65\% of patients.\textsuperscript{265,268} As such, the sensitivity of this physical finding is dependent on the frequency and quality of auscultation. A pericardial friction rub is best heard at the left lower sternal border and is typically described as a high-pitched scratchy or squeaky sound with a triphasic cadence corresponding to the movement of the heart during atrial systole, ventricular systole, and early ventricular diastole. However, it may be monophonic or biphasic in up to 50\% of patients.

Electrocardiogram changes typically progress through four stages representing global subepicardial myocarditis and subsequent recovery. Pericarditis patients may have concave ST deflections with diffuse changes, spanning the leads of multiple coronary artery distributions, but ST segment abnormalities are absent in 20\% to 40\% of patients.\textsuperscript{270,271} Acute pericarditis should not result in the development of infarct patterns, such as Q waves or loss of R waves, and T-wave inversions from pericarditis tend to result later in the disease process after the ST segment has returned to baseline.

Echocardiography is routinely performed in the evaluation of acute pericarditis. Its role is primarily to assess for a pericardial effusion. However, in a patient who can be demonstrated to have previously had normal cardiac function, it may be used to exclude segmental wall motion abnormalities that may suggest ischemia.

The remaining workup should attempt to determine the underlying cause of the pericarditis and should be directed by the history and physical. Most inflammatory markers and laboratory tests are nonspecific, but C-reactive protein may be useful in predicting recurrence risks and in guiding the duration of anti-inflammatory medications.\textsuperscript{272} Rarely, other imaging modalities, such as CT scanning, pericardial biopsies, or pericardiocentesis may aid in diagnosis.

Treatment. The preferred treatment depends on the underlying cause of the pericarditis. The disease usually follows a self-limited and benign course and can be successfully treated with a short course of nonsteroidal anti-inflammatory agents (NSAIDs). The addition of colchicine may be beneficial.\textsuperscript{273} Some patients may require judicious use of steroids or IV antibiotics. In cases of purulent pyogenic pericarditis, surgical exploration and drainage are occasionally necessary. Rarely, accumulation of fluid in the pericardium may lead to tamponade, requiring prompt evacuation of the pericardial space. While pericardiocentesis will typically suffice, surgical drainage may be required for thick, viscous, or clotted fluid or in patients with significant scarring from previous operations. More commonly, surgical intervention is required to manage recurrent disease.

Relapsing Pericarditis

As many as one-third of patients with acute pericarditis will develop at least one episode of relapse.\textsuperscript{267} While many of these patients can be treated medically during their initial relapse and do not experience further episodes, a subset of patients experience chronic relapsing pericarditis that can significantly impact their quality of life. Recurrence may develop either from the original etiology or from an autoimmune process that occurs as a consequence of damage from the initial episode. Relapsing pericarditis normally responds to a longer course of NSAIDS ± colchicine. While steroids may induce rapid symptomatic response, their use should be limited to patients who have multiple relapses and are unresponsive to first-line agents, as several studies have suggested that steroid administration may favor relapse.\textsuperscript{273,274}

Pericardiectomy may be considered a last resort treatment in patients with relapsing pericarditis who are severely symptomatic despite optimal medical management, are unable to tolerate steroids, or have recurrence with tamponade. Evidence for this approach is lacking, as few studies have described pericardiectomy in this population.\textsuperscript{275-277} The largest study and the only one to compare surgical treatment with medical management for patients with persistent relapsing pericarditis was a report of 184 patients from the Mayo Clinic.\textsuperscript{276} About 58 patients were identified as having undergone a pericardiectomy after failed medical treatment, whereas the remainder were treated with medical management only. Compared to medical treatment only, pericardiectomy resulted in significantly fewer relapses (8.6\% vs. 28.6\%, $P = 0.009$) at long term follow-up, as well as a nonsignificant trend towards less medication and corticosteroid usage. Of note, 80\% of patients in the pericardiectomy group who had relapses reported significant improvements in their symptoms and had fewer relapses than before pericardiectomy. No perioperative deaths were observed, and only two patients (3\%) had major complications. Hence, at experienced centers pericardiectomy may be a safe and viable option in select patients with relapsing pericarditis.

Chronic Constrictive Pericarditis

**Etiology, Pathology, and Pathophysiology.** Constrictive pericarditis can occur after any pericardial disease process but remains a rare outcome of recurrent pericarditis. It results when chronic pericardial scarring and fibrosis cause adhesion of the visceral and parietal layers and resultant obliteration of the pericardial space. While the pericardium is often grossly thickened with either focal or diffuse calcification in chronic disease, constriction may occur with normal pericardial thickness in approximately 20\% of cases.\textsuperscript{267,278} In developed nations, idiopathic causes and cardiac surgery (accounting for almost 40\% of cases in some series) are the predominant underlying etiologies, followed by mediastinal radiation, pyogenic infections (i.e., Staphylococcus), and other miscellaneous causes. Tuberculosis is an additional common cause in immunosuppressed patients and in developing or underdeveloped countries.

Clinically, pericardial constriction limits diastolic filling of the ventricles and mimics right heart failure since the right-sided chambers are more affected by a rise in filling pressures. Subsequent increases in central venous pressure result in the progressive development of hepatomegaly, ascites, peripheral edema, abdominal pain, dyspnea on exertion, anorexia, and nausea (in part due to hepatic and bowel congestion). In many patients, these symptoms develop insidiously over a course
of years. Since many of these symptoms are similar to those seen in patients with restrictive cardiomyopathy, the distinction between the two entities is difficult, but it remains critical because the treatment is completely different for restriction. The primary difference is that restrictive cardiomyopathy is defined by a nondilated ventricle with a rigid myocardium that causes a significant decrease in myocardial compliance, which is not seen in constrictive pericarditis.

**Clinical and Diagnostic Findings.** Classic physical exam findings include jugular venous distention with Kussmaul’s sign, diminished cardiac apical impulses, peripheral edema, ascites, pulsatile liver, a pericardial knock, and, in advanced disease, signs of liver dysfunction, such as jaundice or cachexia. The “pericardial knock” is an early diastolic sound that reflects a sudden impediment to ventricular filling, similar to an S3 but of higher pitch.

Several findings are characteristic of noninvasive and invasive testing. CVP is often elevated 15 to 20 mmHg or higher. ECG commonly demonstrates nonspecific low voltage QRS complexes and isolated repolarization abnormalities. Chest X-ray may demonstrate calcification of the pericardium, which is highly suggestive of constrictive pericarditis in patients with heart failure, but this is present in only 25% of cases. Cardiac CT or MRI (cMRI) typically demonstrate increased pericardial thickness (>4 mm) and calcification, dilation of the inferior vena cava, deformed ventricular contours, and flattening or leftward shift of the ventricular septum. Pericardial adhesions may also be seen on tagged cine MRI studies.

As discussed, it is most important to distinguish pericardial constriction from restrictive cardiomyopathy, which is best done with either echocardiography or right heart catheterization. Findings favoring constriction on echocardiography include respiratory variation of ventricular septal motion and mitral inflow velocity, preserved or increased mitral annulus early diastolic filling velocity, and increased hepatic vein flow reversal with expiration. Cardiac catheterization will show increased atrial pressures, equalization of end-diastolic pressure and early ventricular diastolic filling with a subsequent plateau, called the “square-root sign.” Additional findings upon catheterization that would favor constriction include respiratory variation in ventricular filling and increased ventricular interdependence, manifest as a discordant change in the total area of the LV and RV systolic pressure curve with respiration.

**Surgical Treatment.** Transient constrictive pericarditis may occur weeks to months after an initial injury and follows a self-limiting course of weeks to a few months. These patients are best treated with medical therapy alone. They often lack calcification of their pericardium, and the degree of late gadolinium enhancement of the pericardium on cardiac MRI has shown promise in predicting which patients may have resolution of the process. Still, there is no ideal way to distinguish these patients from those who will develop chronic constrictive pericarditis, which is permanent. Therefore, if a newly diagnosed patient is hemodynamically stable, it is recommended that conservative management is attempted for 2 to 3 months prior to performing a pericardectomy. Surgical therapy should not be delayed indefinitely, however, as results are improved when the operation is performed earlier in the course of the disease. A series of 938 patients undergoing pericardiectomy reported by the Mayo Clinic, 355 of whom underwent pericardiectomy for constrictive pericarditis, showed significantly lower survival in patients with constrictive pericarditis compared with patients with effusive/relapsing pericarditis. Patients with left ventricular systolic dysfunction or right ventricular dilatation are at increased risk of early mortality. Additional factors that predict adverse long-term outcomes include older age and prior ionizing radiation, as well as cardiopulmonary and renal dysfunction. Surgery should therefore be approached cautiously in patients with advanced, “end-stage” constrictive pericarditis, mixed constrictive-restrictive disease (often from radiation), and significant myocardial or renal dysfunction, as those patients are at increased risk from surgery and may not experience improvement of symptoms.

In order to minimize recurrence following pericardiectomy, complete pericardial resection is desirable. This is typically performed through either a median sternotomy or left anterolateral thoracotomy while on cardiopulmonary bypass. Radical pericardiectomy involves wide resection of the constricting pericardium from the anterior surface of the heart between the phrenic nerves and the diaphragmatic surface. Decortication of the right atrium and vena cavae is not universally performed, but doing so improves the risk of persistent disease or relapse.

The extent of myocardial involvement may also affect long-term outcomes, and, thus, the depth of decortication is an important consideration. Even when an adequate pericardiectomy is performed, epicardial sclerosis can cause persistent hemodynamic instability or a delayed response to surgery. Sclerotic epicardium is often thin and nearly transparent, but in cases of severe chronic constrictive pericarditis it can be difficult to remove it without injury to the heart.

**Surgical Results.** While most patients experience significant improvement in their symptoms following pericardiectomy, symptomatic relief may take several months. Since there is a significant perioperative morbidity and mortality, pericardiectomy is best performed by experienced surgeons at high-volume centers. Between 1970 and 1985, the operative mortality was reported to be 12%, but a lower mortality of approximately 4% to 8% was noted between 1977 and 2006 at several experienced centers.

Long-term survival is in part determined by etiology of the disease. In a report from the Cleveland Clinic, 7-year survival rates following pericardiectomy for idiopathic, postsurgical, and radiation-induced constrictive pericarditis were 88%, 66%, and 27%, respectively. Results are worst for radiation-induced disease because ionizing radiation is often associated with myocardial injury as well as pericardial disease.

Despite the risks, many patients experience significant benefits from surgical treatment. In one large series, 83% of patients were reported to be free of symptoms at last follow-up. This is in agreement with other studies that have shown a significant improvement in NYHA functional status from class III/IV preoperatively to class I/II following pericardiectomy in >95% of patients.

**CARDIAC NEOPLASMS**

**Overview and General Clinical Features**

Cardiac neoplasms are rare, with an incidence ranging from 0.001% to 0.3% in autopsy studies and a 0.15% incidence in major echocardiographic series. In one large autopsy series, 99.2% of cardiac tumors were metastatic in origin; however,
these patients almost never present for surgical management as they usually have fatal diffuse metastatic disease. As a result, a majority of surgical series describe management of primary cardiac neoplasms. Benign cardiac tumors are most common and account for 75% of primary neoplasms. Approximately 50% of benign cardiac tumors are myxomas, with the remainder being papillary fibroelastomas, lipomas, rhabdomyomas, fibromas, hemangiomas, teratomas, lymphangiomas, and others, in order of decreasing frequency. Most malignant primary cardiac tumors are sarcomas (angiosarcoma, rhabdomyosarcoma, fibrosarcoma, leiomyosarcoma, and liposarcoma), with a small incidence of malignant lymphomas.

**Clinical Presentation.** The clinical presentation of cardiac neoplasms varies greatly depending on the location of the tumor, as well as its size, rate of growth, invasiveness, and friability. While as many as 10% of patients are asymptomatic, most manifest some combination of symptoms from the classic triad resulting from blood flow obstruction, tumor embolization, and constitutional symptoms. Systemic manifestations of disease include fever, myalgias, chills, night sweats, weight loss, and fatigue and occur in up to one-third of patients.

Obstruction of cardiac blood flow accounts for the majority of presenting symptoms. When the tumor is located in the left atrium, symptoms tend to mimic mitral valve disease with dyspnea and pulmonary edema; although more severe presentations with syncopal episodes, hypotension, and sudden cardiac death have been reported from temporary valve orifice occlusion. When the tumor is located in the right atrium, symptoms may mimic right heart failure and include hepatomegaly, ascites, and peripheral edema. Outflow tract obstruction is rare but may be caused by large ventricular tumors.

Tumor lysis and embolization may also lead to neurologic presentations such as stroke, retinal artery occlusion, or cerebral aneurysms, particularly in the case of pedunculated tumors and those with frond-like projections. Embolic tumor cells are able to lodge and penetrate distant vessel walls via subintimal growth, which leads to weakening of the arterial wall and subsequent aneurysm formation. This has been documented as late as 5 years after successful primary myxoma resection. Alternatively, embolic implants may metastasize and create space occupying lesions. While rare, myxomatous tumor emboli have also been identified in the coronary arteries, common iliac and femoral arteries, kidney, spleen, pancreas, and liver.

Certain clinical features may be helpful in distinguishing benign from malignant primary cardiac tumors. Malignant tumors, primarily sarcomas, do not demonstrate a gender preference and tend to present after the fourth decade of life. They are often multifocal within the right atrium, and intramyocardial invasion can lead to refractory congestive heart failure, arrhythmias, hemopericardium, and ischemia. Conversely, benign tumors, primarily myxomas, are typically unifocal in the left atrium, have a 3:1 female preference, and occur in younger patients. Arrhythmias and pericardial effusions are very rare in this population.

**Diagnosis and Characterization of Cardiac Masses.** Trans-thoracic echocardiography is the mainstay imaging technique for the detection of cardiac tumors. However, echocardiography is limited by dependence on an acoustic window, suboptimal visualization of extracardiac extension, and poor soft-tissue visualization. TEE is generally only beneficial for small localized tumors due to its limited field of view. cMRI is therefore the current standard for delineating the anatomical extent of the tumor and assessing the paracardiac space and great vessels. Advantages of cMRI over CT scans include better soft-tissue evaluation without the need for iodinated contrast and no exposure to ionizing radiation.

It is important in the initial workup to distinguish a cardiac tumor from an intracardiac thrombus, which may be common in the atria of patients with AF and can mimic echocardiographic features of atrial myxomas. This determination is critical, as an atrial thrombus may be expected to resolve with anticoagulation, whereas a tumor requires surgical intervention. Moreover, anticoagulation can potentially increase the risk of peripheral embolization in patients with cardiac tumors. Delayed enhancement cMRI is the best modality to separate these two entities. cMRI may show vascularization, areas of necrosis, hemorrhage, or calcification in cardiac tumors that are not present in thrombi.

**Myxoma**

**Pathology and Genetics.** Cardiac myxomas are the most common primary cardiac tumor and are characterized by several distinguishing features. About 75% of the time, they arise from the interatrial septum near the fossa ovalis in the left atrium. Most others will develop in the right atrium, but, less commonly, they can arise from valvular surfaces and the walls of other cardiac chambers. Macroscopically, these tumors are pedunculated with a gelatinous consistency, and the surface may be smooth (65%), villous, or friable. Size varies greatly with these tumors and ranges from 1 to 15 cm in diameter. Internally, myxomas are heterogeneous and often contain hemorrhage, cysts, necrosis, or calcification. Histologically, these tumors contain cells that arise from a multipotent mesenchyme and are contained within a mucopolysaccharide stroma.

While the majority of myxomas occur spontaneously with the highest incidence in women aged 40 to 60 years old, approximately 7% of cases are familial as part of Carney complex. Carney complex is an autosomal dominant disorder characterized by two or more of the following conditions: atrial and extracardiac myxomas, schwannomas, cutaneous lentiginosis, spotty pigmentation, myxoid fibroadenomas of the breast, endocrine overactivity (pituitary adenomas or primary adrenal hyperplasia with Cushing’s syndrome), and testicular tumors. Compared to sporadic myxomas, those that occur as part of Carney complex are more commonly found in the right atrium (37% vs. 18%) or one of the ventricles (25% vs. 0%), more often multicentric (33% vs. 6%) and more likely to recur (20% vs. 3%). They also present earlier at an average age of 24 years old (range 4–48 years).

**Pathophysiology.** Larger tumors are more likely to be associated with cardiovascular symptoms from obstruction, and embolic symptoms tend to occur from organized thrombi present on friable or villous tumors (Fig. 21-16). The relative frequencies of symptoms was illustrated by a series of 112 patients who reported cardiovascular symptoms (67%), most commonly resembling mitral valve obstruction; systemic embolization (29%); neurologic deficits (20%); and constitutional symptoms (34%). Similar incidences of symptoms have been reported in other large studies.

**Treatment.** Cardiac myxomas should be promptly excised after diagnosis due to the significant risk of embolization and cardiovascular complications, including sudden death. Resection may be performed through either a median sternotomy or...
a minimally invasive right thoracotomy while on cardiopulmonary bypass. Care is taken not to manipulate the tumor before cross clamping of the aorta in order to avoid embolization. Left atrial tumors may be approached through a standard left atriotomy. Exposure of large tumors attached to the interatrial septum may be facilitated by an additional parallel incision in the right atrium, but this is rarely necessary. An ideal resection encompasses both the tumor and a portion of the cardiac wall or interatrial septum to which it is attached. In order to prevent recurrence, a full thickness excision of the attachment site is preferred, but partial thickness excisions and cryoablation of the base have been performed with good late results. The defect created in the atrial septum can either be repaired primarily or with a small patch. Finally, patients with valvular involvement may require additional valvular reconstruction or replacement, and rare cases of cardiac autotransplantation (with atrial reconstruction) or transplantation have been reported as strategies for complex cases of recurrent atrial myxoma.

Short- and long-term results following excision are excellent for benign cardiac myxomas. Operative mortality is low, and the probability of disease-free survival at 20 years has been reported to be as high as 92% for benign, sporadic myxomas. Risk of recurrence is significantly higher for familial cases. Other risk factors for recurrence include younger age, smaller tumor mass, and ventricular tumor location.

Other Benign Cardiac Tumors
There are several benign cardiac tumors apart from myxomas that are infrequent but have distinct pathophysiologic features. Papillary fibroelastomas are the second most common primary cardiac tumor, representing approximately 8% of all cases. These tumors typically occur in more elderly patients; are small (<1 cm in diameter) sessile, pedunculated masses that arise from the mitral or aortic valves; and frequently result in embolization. Fibroelastomas can almost always be resected with preservation of the native valve leaflets, and cryoablation of the valve leaflet after resection can help prevent recurrence. Lipomas are encapsulated tumors that usually arise from the epicardium and remain asymptomatic in most patients. Hemangiomas, which may arise from any cardiac structure, including the pericardium, account for 2% of benign cardiac tumors, and atrioventricular node tumors, which often lead to sudden cardiac death from heart block and ventricular fibrillation, are exceedingly rare.

In children, rhabdomyomas are the most common primary cardiac tumor, whereas fibromas are the most commonly resected cardiac tumor. Rhabdomyomas are myocardial hamartomas that are often multicentric in the ventricles. About 50% of cases are associated with tuberous sclerosis, and while resection is occasionally necessary, most disappear spontaneously. Fibromas are congenital lesions that one-third of the time are found in children younger than 1-year old. These tumors, conversely, are ordinarily solitary lesions found in the inner interventricular septum, and they may present with heart failure, cyanosis, arrhythmias, syncopal episodes, chest pain, or sudden cardiac death.

Malignant Cardiac Tumors
Primary cardiac malignancies are very rare, but when they occur they tend to have a right-sided predominance and frequently demonstrate extracardiac extension and involvement. Malignant cardiac tumors include intimal sarcoma, angiosarcoma, osteosarcoma, leiomysarcoma, rhabdomyosarcoma, liposarcoma, and primary cardiac lymphomas. Intimal sarcoma is the most common subtype. Angiosarcomas are aggressive, rapidly invading adjacent structures, and 47% to 89% of patients present with lung, liver, or brain metastases by the time of diagnosis. Leiomyosarcomas are sessile masses with a mucous appearance that are typically found in the posterior wall of the left atrium. Rhabdomyosarcomas are bulky (>10 cm in diameter) tumors that usually occur in children and do not have a predilection for any particular chamber. They frequently invade nearby cardiac structures and are multicentric in 60% of cases. Finally, while not as frequent as secondary cardiac lymphomas, primary cardiac lymphomas are increasing in frequency due to lymphoproliferative disorders caused by Epstein-Barr virus in immunosuppressed patients. The absence of necrotic foci in lymphomas can be used to differentiate these tumors from cardiac sarcomas.

Metastatic Cardiac Tumors
Cardiac metastases have been found in approximately 10% of autopsies performed for malignant disease. Secondary cardiac tumors, unlike primary tumors, are therefore relatively common. They may arise from direct extension of mediastinal tumors, hematological spread, intracavitary extension from the inferior vena cava or lymphatic extension, although the latter is the most common mechanism.

While they can occur with most any primary tumor, they are generally observed late in the course of disease. Malignant melanomas have a high potential for cardiac involvement, but...
other soft tissue tumors such as lung cancer, breast cancer, sarcomas, renal carcinoma, esophageal cancer, hepatocellular carcinoma, and thyroid cancer may all progress to cardiac involvement. Cardiac metastases may also develop from leukemia and lymphoma in 25% to 40% of cases.304

Metastatic cardiac tumors are typically found in random locations, excluding the valvular tissue where lymphatics are absent, and they may be multifocal or diffusely extend along the epicardial surface. Signs of malignant cardiac involvement in cancer patients include pericardial effusion or tamponade, tachyarrhythmias, and heart failure symptoms. Workup is similar to other cardiac tumors. Treatment is generally with combined chemotherapy and radiation and is rarely effective.

ANATOMY OF THE AORTA

The aorta consists of two major segments—the proximal aorta and the distal aorta—whose anatomic characteristics affect both the clinical manifestations of disease in these segments and the selection of treatment strategies for such disease (Fig. 22-1). The proximal aortic segment includes the ascending aorta and the transverse aortic arch. The ascending aorta begins at the aortic valve and ends at the origin of the innominate artery. The first portion of the ascending aorta is the aortic root, which includes the aortic valve annulus and the three sinuses of Valsalva; the coronary arteries originate from two of these sinuses. The aortic root joins the tubular portion of the ascending aorta at the sinotubular ridge. The transverse aortic arch is the area from which the brachiocephalic branches arise. The distal aortic segment includes the descending thoracic aorta and the abdominal aorta. The descending thoracic aorta begins distal to the origin of the left subclavian artery and extends to the diaphragmatic hiatus, where it joins the abdominal aorta. The descending thoracic aorta gives rise to multiple bronchial and esophageal branches, as well as to the segmental intercostal arteries, which provide circulation to the spinal cord.

The volume of blood that flows through the thoracic aorta at high pressure is far greater than that found in any other vascular structure. For this reason, any condition that disrupts the integrity of the thoracic aorta, such as aortic dissection, aneurysm rupture, or traumatic injury, can have catastrophic consequences.

Historically, open surgical repair of such conditions has been an intimidating undertaking associated with significant morbidity and mortality. Strategies for protecting the brain and spinal cord during such repairs have become critical in preventing devastating complications. Endovascular therapy for such conditions in selected patients has become accepted practice, producing fewer adverse outcomes than traditional approaches.

THORACIC AORTIC ANEURYSMS

Aortic aneurysm is defined as a permanent, localized dilatation of the aorta to a diameter that is at least 50% greater than is normal at that anatomic level. The annual incidence of thoracic aortic aneurysms is estimated to be 5.9 per 100,000 persons. The clinical manifestations, methods of treatment, and treatment results in patients with aortic aneurysms vary according to the cause and the aortic segment involved. Causes of thoracic aortic aneurysms include degenerative disease of the aortic wall, aortic dissection, aortitis, infection, and trauma. Aneurysms can be localized to a single aortic segment, or they can involve multiple segments. Thoracoabdominal aortic aneurysms, for example, involve both the descending thoracic aorta and the abdominal aorta. In the most extreme cases, the entire aorta is aneurysmal; this condition is often called mega-aorta.

Aortic aneurysms can be either “true” or “false.” True aneurysms can take two forms: fusiform and saccular. Fusiform aneurysms are more common and can be described as symmetrical dilatations of the aorta. Saccular aneurysms are localized outpouchings of the aorta. False aneurysms, also called pseudoaneurysms, are leaks in the aortic wall that are contained by the outer layer of the aorta and/or the periaortic tissue; they are caused by disruption of the aortic wall and lead blood to collect in pouches of fibrotic tissue.

Aneurysms of the thoracic aorta consistently increase in size and eventually progress to cause serious complications. These include rupture, which usually is a fatal event. Therefore, aggressive treatment is indicated in all but the poorest surgical candidates. Small, asymptomatic thoracic aortic aneurysms can be followed, especially in high-surgical-risk patients, and can be treated surgically later if symptoms or complications develop, or if progressive enlargement occurs. Meticulous control of hypertension is the primary medical treatment for patients with small, asymptomatic aneurysms.

Elective resection with graft replacement is indicated in asymptomatic patients with an aortic diameter of at least twice...
**Key Points**

1. Assessing urgency of repair is essential to developing the appropriate management plan. Although emergent repair carries greater operative risk than does elective repair, any inappropriate delay of repair risks death.

2. The clinical progression of an aortic aneurysm is continued expansion and eventual dissection or rupture. Hence, regular noninvasive imaging studies, as part of a lifelong surveillance plan, are necessary to ensure long-term patient health. Even small asymptomatic aneurysms should be routinely imaged to assess overall size and yearly rate of expansion.

3. Endovascular repair devices are approved for the treatment of descending thoracic aortic aneurysms, descending thoracic aortic dissections, aortic trauma, and penetrating aortic ulcer.

4. Practice guidelines have been published to help standardize the decision-making process and select an appropriate surgical intervention, as well as to standardize the use of imaging studies for patients with thoracic aortic disease.

5. Ascending aortic aneurysms that are symptomatic or \(\geq 5.5\) cm in diameter should be repaired regardless of whether normal in the involved segment (5 to 6 cm in most thoracic segments). Elective repair is contraindicated by extreme operative risk due to severe coexisting cardiac or pulmonary disease and by other conditions that limit life expectancy, such as malignancy. An emergency operation is performed for any patient in whom a ruptured aneurysm is suspected.

Patients with thoracic aortic aneurysm often have coexisting aneurysms of other aortic segments. A common cause of death after repair of a thoracic aortic aneurysm is rupture of a different aortic aneurysm. Therefore, staged repair of multiple aortic segments often is necessary. As with any major operation, careful preoperative evaluation for coexisting disease and subsequent medical optimization are important for successful surgical treatment.

An alternative to traditional open repair of a descending thoracic aortic aneurysm is endovascular stent grafting. Certain anatomic criteria for use—such as a landing zone that includes at least 2 cm of landing zone of healthy aortic tissue proximal and distal to the targeted aneurysm—are preferable, but not absolutely necessary. Although few data on long-term outcomes have recently been published, endovascular repair of descending thoracic aortic aneurysm has become an accepted practice that produces excellent midterm results.

3. Ascending aortic aneurysms that are symptomatic or \(\geq 5.5\) cm in diameter should be repaired regardless of whether normal in the involved segment (5 to 6 cm in most thoracic segments). Elective repair is contraindicated by extreme operative risk due to severe coexisting cardiac or pulmonary disease and by other conditions that limit life expectancy, such as malignancy. An emergency operation is performed for any patient in whom a ruptured aneurysm is suspected.

Patients with thoracic aortic aneurysm often have coexisting aneurysms of other aortic segments. A common cause of death after repair of a thoracic aortic aneurysm is rupture of a different aortic aneurysm. Therefore, staged repair of multiple aortic segments often is necessary. As with any major operation, careful preoperative evaluation for coexisting disease and subsequent medical optimization are important for successful surgical treatment.

An alternative to traditional open repair of a descending thoracic aortic aneurysm is endovascular stent grafting. Certain anatomic criteria for use—such as a landing zone that includes at least 2 cm of landing zone of healthy aortic tissue proximal and distal to the targeted aneurysm—are preferable, but not absolutely necessary. Although few data on long-term outcomes have recently been published, endovascular repair of descending thoracic aortic aneurysm has become an accepted practice that produces excellent midterm results.

Causes and Pathogenesis

**General Considerations.** The normal aorta derives its elasticity and tensile strength from the medial layer, which contains approximately 45 to 55 lamellae of elastin, collagen, smooth muscle cells, and ground substance. Elastin content is highest within the ascending aorta, as would be expected because of its compliant nature, and decreases distally into the descending and abdominal aorta. Maintenance of the aortic matrix involves complex interactions among smooth muscle cells, macrophages, proteases, and protease inhibitors. Any alteration in this delicate balance can lead to aortic disease.

Thoracic aortic aneurysms have a variety of causes (Table 22-1). Although these disparate pathologic processes differ in biochemical and histologic terms, they share the final common pathway of progressive aortic expansion and eventual rupture.

Hemodynamic factors clearly contribute to the process of aortic dilatation. The vicious cycle of increasing diameter and increasing wall tension, as characterized by Laplace’s law (tension = pressure × radius), is well established. Turbulent
blood flow also is recognized as a factor. Poststenotic aortic dilatation, for example, occurs in some patients with aortic valve stenosis or coarctation of the descending thoracic aorta. Hemodynamic derangements, however, are only one piece of a complex puzzle.

Atherosclerosis is commonly cited as a cause of thoracic aortic aneurysms. However, although atherosclerotic disease often is found in conjunction with aortic aneurysms, the notion that atherosclerosis is a distinct cause of aneurysm formation has been challenged. In most thoracic aortic aneurysms, atherosclerosis appears to be a coexisting process, rather than the underlying cause.

Research into the pathogenesis of abdominal aortic aneurysms has focused on the molecular mechanisms of aortic wall degeneration and dilatation. For example, imbalances between proteolytic enzymes (e.g., matrix metalloproteinases) and their inhibitors contribute to abdominal aortic aneurysm formation. Building on these advances, current investigations are attempting to determine whether similar inflammatory and proteolytic mechanisms are involved in thoracic aortic disease, in hope of identifying potential molecular targets for pharmacologic therapy.

**Nonspecific Medial Degeneration.** Nonspecific medial degeneration is the most common cause of thoracic aortic disease. Histologic findings of mild medial degeneration, including fragmentation of elastic fibers and loss of smooth muscle cells, are expected in the aging aorta. However, an advanced, accelerated form of medial degeneration leads to progressive weakening of the aortic wall, aneurysm formation, and eventual dissection, rupture, or both. The underlying causes of medial degenerative disease remain poorly understood.

**Aortic Dissection.** An aortic dissection usually begins as a tear in the inner aortic wall, which initiates a progressive separation of the medial layers and creates two channels within the aorta. This event profoundly weakens the outer wall. As the most common catastrophe involving the aorta, dissection represents a major, distinct cause of thoracic aortic aneurysms and is discussed in detail in the second half of this chapter.

**Heritable Conditions.** Several heritable conditions cause thoracic aortic aneurysms. To better characterize these disorders, the National Institutes of Health (NIH) sponsored a longitudinal registry for individuals affected by genetically triggered thoracic aneurysms and cardiovascular conditions (GenTAC) more than a decade ago. The registry enrollment includes adults and children in 13 clinical categories, including Marfan syndrome, Ehlers-Danlos syndrome, Loeys-Dietz syndrome, familial thoracic aortic aneurysms and dissections, aneurysms-osteoarthritis syndrome, and congenital bicuspid aortic valve.

**Marfan Syndrome** Marfan syndrome is an autosomal dominant genetic disorder characterized by a specific connective tissue defect that leads to aneurysm formation. The phenotype of patients with Marfan syndrome typically includes a tall stature, high palate, joint hypermobility, eye lens disorders, mitral valve prolapse, and aortic aneurysms. The aortic wall is weakened by fragmentation of elastic fibers and deposition of extensive amounts of mucopolysaccharides (a process previously called cystic medial degeneration or cystic medial necrosis). Patients with Marfan syndrome have a mutation in the fibrillin gene located on the long arm of chromosome 15. The traditional view has been that abnormal fibrillin in the extracellular matrix decreases connective tissue strength in the aortic wall and produces abnormal elasticity, which predisposes the aorta to dilatation from wall tension caused by left ventricular ejection impulses. More recent evidence, however, shows that the abnormal fibrillin causes degeneration of the aortic wall matrix by increasing the activity of transforming growth factor beta (TGF-β). Between 75% and 85% of patients with Marfan syndrome have dilatation of the ascending aorta and annuloaortic ectasia (dilatation of the aortic sinuses and annulus). Marfan syndrome also is frequently associated with aortic dissection, and aortic complications are the most common cause of death among patients with Marfan syndrome.

**Loeys-Dietz Syndrome** Loeys-Dietz syndrome is phenotypically distinct from Marfan syndrome. It is characterized as an aneurysmal syndrome with widespread systemic involvement. Loeys-Dietz syndrome is an aggressive, autosomal dominant condition that is distinguished by the triad of arterial tortuosity and aneurysms, hypertelorism (widely spaced eyes), and bifid uvula or cleft palate. It is caused by heterozygous mutations in the genes encoding TGF-β receptors. Patients with Loeys-Dietz syndrome—including young children—are at increased risk of aortic rupture and aortic dissection; diameter-based thresholds of repair tend to be lower for patients with this syndrome than for patients with other heritable disorders.

**Ehlers-Danlos Syndrome** Ehlers-Danlos syndrome includes a spectrum of inherited disorders of collagen synthesis. The subtypes represent differing defective steps of collagen production. Vascular type Ehlers-Danlos syndrome is characterized by an autosomal dominant defect in type III collagen synthesis, which can have life-threatening cardiovascular manifestations. Spontaneous arterial rupture, usually involving the mesenteric vessels, is the most common cause of death in these patients. Thoracic aortic aneurysms and dissections are less commonly associated with Ehlers-Danlos syndrome, but when they do occur, they pose a particularly challenging surgical problem because of the reduced integrity of the aortic tissue. An Ehlers-Danlos variant of periventricular heterotopia associated with joint and skin hyperextensibility and aortic dilation has been described as being caused by mutations in the gene encoding filamin A.
(FLNA), an actin-binding protein that links the smooth muscle cell contractile unit to the cell surface.\textsuperscript{12}

**Familial Thoracic Aortic Aneurysm and Dissection** Families without the heritable syndromes described earlier also can be affected by genetic conditions that cause thoracic aortic aneurysm. In fact, it is estimated that at least 20% of patients with thoracic aortic aneurysms and dissections have a genetic predisposition to them. The involved mutations are characterized by autosomal dominant inheritance with decreased penetrance and variable expression. The number of genes for which mutations have been identified as causes of familial thoracic aortic aneurysm and dissection is expanding rapidly; involved genes include those related to TGF-β receptors (TGFBR1 and TGFBR2), TGF-β ligands (TGFβ2 and TGFβ3), myosin (MYH11 and MYLK), elastin (ELN), elastin microfibril interfacial 1 (EMLI1), microfibril-associated glycoprotein 2 (MFAP5), fibrillin-2 (FBN2), fibulin-4 (FBLN4), lysyl oxidase (LOX), and α-smooth muscle cell actin (ACTA2).\textsuperscript{3,13-16} ACTA2 mutations are present in approximately 14% of families with familial thoracic aortic aneurysms and dissections.

**Aneurysms-Osteoarthritis Syndrome** Aneurysms-osteoarthritis syndrome is an autosomal dominant disorder characterized by aortic and arterial aneurysms, arterial tortuosity, aortic dissection, mild craniofacial abnormalities, and early-onset osteoarthritis. Aneurysms-osteoarthritis syndrome is caused by mutations in the gene encoding SMAD3, a transcription factor for TGF-β. Affected patients have a high incidence of aortic dissection, which often occurs in a mildly dilated aorta and causes sudden death.\textsuperscript{17}

**Congenital Bicuspid Aortic Valve** Bicuspid aortic valve is the most common congenital malformation of the heart or great vessels, affecting up to 2% of Americans.\textsuperscript{18} Compared to patients with a normal, trileaflet aortic valve, patients with bicuspid aortic valve have an increased incidence of ascending aortic aneurysm formation and, often, a more rapid rate of aortic enlargement.\textsuperscript{19} The location of the fused leaflet, or raphe, may be predictive of aortic dilation and other abnormalities.\textsuperscript{20} Fifty to 70% of adults with bicuspid aortic valve, but without significant valve dysfunction, have echocardiographically detectable aortic dilatation.\textsuperscript{21,22} This dilatation usually is limited to the ascending aorta and root.\textsuperscript{23} Dilation occasionally is found in the arch and only rarely in the descending or abdominal aorta. In addition, aortic dissection occurs 10 times more often in patients with bicuspid valves than in the general population.\textsuperscript{24} Recent findings suggest that aneurysms associated with bicuspid aortic valve have a fundamentally different pathobiologic cause than aneurysms that occur in patients with trileaflet valves.\textsuperscript{25}

Although the exact mechanism responsible for aneurysm formation in patients with bicuspid aortic valve remains unclear, evidence suggests that these patients have a congenital connective tissue abnormality that predisposes the aorta to medial degeneration.\textsuperscript{25-31} For example, fibrillin-1 content is significantly lower and matrix metalloproteinase activity is significantly higher in the aortic media in patients with bicuspid aortic valve than in persons with a normal, tricuspid aortic valve.\textsuperscript{26-27} Further, the process of medial degeneration in patients with bicuspid aortic valve may be exacerbated by the presence of chronic turbulent flow through the deformed valve.

**Bovine Aortic Arch** Bovine aortic arch—a common origin of the innominate and left common carotid arteries—has been considered a normal anatomic variant. Studies from Yale University have identified a higher prevalence of bovine aortic arch in patients with thoracic aortic disease; an association was found between this anomaly and a generalized increase in aortic aneurysmal disease (without any predisposition to a particular aortic region). However, bovine aortic arch was not associated distinctly with bicuspid aortic valve or aortic dissection, but with a higher mean aortic growth rate: 0.29 cm per year in patients with bovine aortic arch, compared with 0.09 cm per year in controls. Therefore, bovine aortic arch may be better characterized as a precursor of aortic aneurysm than as a simple normal anatomic variant.\textsuperscript{32} Further studies are needed to delineate the underlying mechanism for this association.

**Infection.** Primary infection of the aortic wall resulting in aneurysm formation is rare. Although these lesions are termed mycotic aneurysms, the responsible pathogens usually are bacteria rather than fungi. Bacterial invasion of the aortic wall may result from bacterial endocarditis, endothelial trauma caused by an aortic jet lesion, or extension from an infected laminar clot within a preexisting aneurysm. The most common causative organisms are *Staphylococcus aureus, Staphylococcus epidermidis, Salmonella,* and *Streptococcus.*\textsuperscript{33,34} Unlike most other causes of thoracic aortic aneurysms, which generally produce fusiform aneurysms, infection often produces saccular aneurysms located in areas of aortic tissue destroyed by the infectious process.

Although syphilis was once the most common cause of ascending aortic aneurysms, the advent of effective antibiotic therapy has made syphilitic aneurysms a rarity in developed nations. In other parts of the world, however, syphilitic aneurysms remain a major cause of morbidity and mortality. The spirochete *Treponema pallidum* causes an obliteratorative endarteritis of the vasa vasorum that results in medial ischemia and loss of the elastic and muscular elements of the aortic wall. The ascending aorta and arch are the most commonly involved areas. The emergence of HIV infection in the 1980s was associated with a substantial increase in the incidence of syphilis in both HIV-positive and HIV-negative patients. Because syphilitic aortitis often presents 10 to 30 years after the primary infection, the incidence of associated aneurysms may increase in the near future.

**Aortitis.** In patients with preexisting degenerative thoracic aortic aneurysms, localized transmural inflammation and subsequent fibrosis can develop. The dense aortic infiltrate responsible for the fibrosis consists of lymphocytes, plasma cells, and giant cells. The cause of the intense inflammatory reaction is unknown. Although the severe inflammation is a superimposed problem rather than a primary cause, its onset within an aneurysm can further weaken the aortic wall and precipitate expansion.

Systemic autoimmune disorders also cause thoracic aortitis. Aortic Takayasu arteritis generally produces obstructive lesions related to severe intimal thickening, but associated medial necrosis can lead to aneurysm formation. In patients with giant cell arteritis (temporal arteritis), granulomatous inflammation may develop that involves the entire thickness of the aortic wall, causing intimal thickening and medial destruction. Rheumatoid aortitis is an uncommon systemic disease that is associated with rheumatoid arthritis and ankylosing spondylitis. The resulting medial inflammation and fibrosis can affect the aortic root, causing annular dilatation, aortic valve regurgitation, and ascending aortic aneurysm formation.

**Pseudoaneurysms.** Pseudoaneurysms of the thoracic aorta usually represent chronic leaks that are contained by surrounding...
tissue and fibrosis. By definition, the wall of a pseudoaneurysm is not formed by intact aortic tissue; rather, the wall develops from organized thrombus and associated fibrosis. Pseudoaneurysms can arise from primary defects in the aortic wall (e.g., after trauma or contained aneurysm rupture) or from anastomotic or cannulation site leaks that occur after cardiovascular surgery. Anastomotic pseudoaneurysms can be caused by technical problems or by deterioration of the native aortic tissue, graft material, or suture. Commonly, they occur in patients with Marfan syndrome, Loeys-Dietz syndrome, or other heritable conditions that markedly weaken the vessel wall. Tissue deterioration usually is related to either progressive degenerative disease or infection. Improvements in sutures, graft materials, and surgical techniques have decreased the incidence of thoracic aortic pseudoaneurysm. Should thoracic aortic pseudoaneurysms occur, they typically require expeditious open surgical or catheter-based repair because they are associated with a high incidence of morbidity and rupture.

Clinical History
Treatment decisions in cases of thoracic aortic aneurysm are guided by our current understanding of the clinical history of these aneurysms, which classically is characterized as progressive aortic dilatation and eventual dissection, rupture, or both.

An analysis by Elefteriades of data from 1600 patients with thoracic aortic disease has helped quantify these well-recognized risks. Average expansion rates were 0.07 cm per year in ascending aortic aneurysms and 0.19 cm per year in descending thoracic aortic aneurysms. As expected, aortic diameter was a strong predictor of rupture, dissection, and mortality. For thoracic aortic aneurysms >6 cm in diameter, annual rates of catastrophic complications were 3.6% for rupture, 3.7% for dissection, and 10.8% for death. Critical “hinge-point” diameters, at which the incidence of expected complications significantly increased, were 6.0 cm for aneurysms of the ascending aorta and 7.0 cm for aneurysms of the descending thoracic aorta; the corresponding risks of rupture after reaching these diameters were 31% and 43%, respectively.

Certain types of aneurysms have an elevated propensity for expansion and rupture. For example, aneurysms in patients with Marfan or Loeys-Dietz syndrome tend to dilate at an accelerated rate and rupture or dissect at smaller diameters than sporadic, nonheritable aneurysms. Before the era of surgical treatment for aortic aneurysms, the aggressive form of aortic disease in Marfan patients resulted in an average life expectancy of 32 years, with aortic root complications causing the majority of deaths. Saccular aneurysms, which commonly are associated with aortic infection and typically affect only a discrete small section of the aorta, tend to grow more rapidly than fusiform aneurysms, which are associated with more widespread degenerative changes and generally affect a larger section of the aorta.

One common clinical scenario deserves special attention. A moderately dilated ascending aorta (i.e., 4 to 5 cm) often is encountered during aortic valve replacement or coronary artery bypass operations. The clinical history of these ectatic ascending aortas has been defined by several studies. Michel and colleagues studied patients whose ascending aortic diameters were >4 cm at the time of aortic valve replacement; 25% of these patients required reoperation for ascending aortic replacement. Prenger and colleagues reported that aortic dissection occurred in 27% of patients who had aortic diameters of >5 cm at the time of aortic valve replacement. Attention has been directed toward whether or not a mildly dilated aortic root should be replaced in patients with bicuspid aortic valve who are undergoing isolated valve replacement, and at what threshold to intervene. Although this is a controversial issue, many surgeons believe that the tendency toward late aortic dilatation in these patients warrants aggressive treatment. According to a recent guidelines clarification, in patients with bicuspid aortic valve who are undergoing aortic valve replacement or repair, replacing the ascending aorta is reasonable when the diameter of the ascending aorta is greater than 4.5 cm (Class Ila, Level C recommendation).

Clinical Manifestations
In many patients with thoracic aortic aneurysms, the aneurysm is discovered incidentally when imaging studies are performed for unrelated reasons. Therefore, patients often are asymptomatic at the time of diagnosis. However, thoracic aortic aneurysms that initially go undetected eventually create symptoms and signs that correspond with the segment of aorta that is involved. These aneurysms have a wide variety of manifestations, including compression or erosion of adjacent structures, aortic valve regurgitation, distal embolism, and rupture.

Local Compression and Erosion. Initially, aneurysmal expansion and impingement on adjacent structures causes mild, chronic pain. The most common symptom in patients with ascending aortic aneurysms is anterior chest discomfort; the pain is frequently precordial in location but may radiate to the neck and jaw, mimicking angina. Aneurysms of the ascending aorta and transverse aortic arch cause symptoms related to compression of the superior vena cava, the pulmonary artery, the airway, or the sternum. Rarely, these aneurysms erode into the superior vena cava or right atrium, causing acute high-output failure. Expansion of the distal aortic arch can stretch the recurrent laryngeal nerve, which results in left vocal cord paralysis and hoarseness. Descending thoracic and thoracoabdominal aneurysms frequently cause back pain localized between the scapulae. When the aneurysm is largest in the region of the aortic hiatus, it may cause middle back and epigastric pain. Thoracic or lumbar vertebral body erosion typically causes severe, chronic back pain; extreme cases can present with spinal instability and neurologic deficits from spinal cord compression. Although mycotic aneurysms have a peculiar propensity to destroy vertebral bodies, spinal erosion also occurs with degenerative aneurysms. Descending thoracic aortic aneurysms may cause varying degrees of airway obstruction, manifesting as cough, wheezing, stridor, or pneumonitis. Pulmonary or airway erosion presents as hemoptysis. Compression and erosion of the esophagus cause dysphagia and hematemesis, respectively. Thoracoabdominal aortic aneurysms can cause duodenal obstruction or, if they erode through the bowel wall, gastrointestinal bleeding. Jaundice due to compression of the liver or porta hepatitis is uncommon. Erosion into the inferior vena cava or iliac vein presents with an abdominal bruit, widened pulse pressure, edema, and heart failure.

Aortic Valve Regurgitation. Ascending aortic aneurysms can cause displacement of the aortic valve commissures and annular dilatation. The resulting deformation of the aortic valve leads to progressively worsening aortic valve regurgitation. In response to the volume overload, the heart remodels and becomes increasingly dilated. Patients with this condition may present with progressive heart failure, a widened pulse pressure, and a diastolic murmur.

Distal Embolization. Thoracic aortic aneurysms—particularly those involving the descending and thoracoabdominal aorta—are commonly lined with friable, atheromatous plaque and
mural thrombus. This debris may embolize distally, causing occlusion and thrombosis of the visceral, renal, or lower-extremity branches.

**Rupture.** Patients with ruptured thoracic aortic aneurysms often experience sudden, severe pain in the anterior chest (ascending aorta), upper back or left chest (descending thoracic aorta), or left flank or abdomen (thoracoabdominal aorta). When ascending aortic aneurysms rupture, they usually bleed into the pericardial space, producing acute cardiac tamponade and death. Descending thoracic aortic aneurysms rupture into the pleural cavity, producing a combination of severe hemorrhagic shock and respiratory compromise. External rupture is extremely rare; saccular syphilitic aneurysms have been observed to rupture externally after eroding through the sternum.

**Diagnostic Evaluation**

Diagnosis and characterization of thoracic aneurysms require imaging studies, which also provide critical information that guides the selection of treatment options. Although the best choice of imaging technique for the thoracic and thoracoabdominal aorta is somewhat institution-specific, varying with the availability of imaging equipment and expertise, efforts have been made to standardize key elements of image acquisition and reporting. Recent practice guidelines recommend that aortic imaging reports plainly state the location of aortic abnormalities (including calcification and the extent to which abnormalities extend into branch vessels), the maximum external aortic diameters (rather than internal, lumen-based diameters), internal filling defects, and any evidence of rupture. Whenever possible, all results should be compared with those of prior imaging studies.

**Plain Radiography.** Plain radiographs of the chest, abdomen, or spine often provide enough information to support the initial diagnosis of thoracic aortic aneurysm. Ascending aortic aneurysms produce a convex shadow to the right of the cardiac silhouette. The anterior projection of an ascending aneurysm results in the loss of the retrosternal space in the lateral view. An aneurysm may be indistinguishable from elongation and tortuosity. Importantly, chest radiographs (CXRs) may appear normal in patients with thoracic aortic disease and thus cannot exclude the diagnosis of aortic aneurysm. Aortic root aneurysms, for example, often are hidden within the cardiac silhouette. Plain CXRs may reveal convexity in the right superior mediastinum, loss of the retrosternal space, or widening of the descending thoracic aortic shadow, which may be highlighted by a rim of calcification outlining the dilated aneurysmal aortic wall. Aortic calcification also may be seen in the upper abdomen on a standard radiograph made in the anteroposterior or lateral projection (Fig. 22-2). Once a thoracic aortic aneurysm is detected on plain radiographs, additional studies are required to define the extent of aortic involvement.

**Echocardiography and Abdominal Ultrasonography.** Ascending aortic aneurysms are commonly discovered during echocardiography in patients presenting with symptoms or signs of aortic valve regurgitation. Both transthoracic and transesophageal echocardiography provide excellent visualization of the ascending aorta, including the aortic root. Transesophageal echocardiography also allows visualization of the descending thoracic aorta but is not ideal for evaluating the transverse aortic arch (which is obscured by air in the tracheobronchial tree) or the upper abdominal aorta. Effective echocardiography requires considerable technical skill, both in obtaining adequate images and in interpreting them. This imaging modality has the added advantage of being less expensive than CT or MRI and providing real-time imaging during intervention. Advantages of abdominal ultrasonography include the ability to identify mural thrombus, intraluminal thrombus, and atheroemboli, as well as the location of an aneurysm.

**Figure 22-2.** Chest radiographs showing a calcified rim (arrows) in the aortic wall of a thoracoabdominal aortic aneurysm. A. Anteroposterior view. B. Lateral view.
benefit of assessing cardiac function and revealing any other abnormalities that may be present. During ultrasound evaluation of a suspected infrarenal abdominal aortic aneurysm, if a definitive neck cannot be identified at the level of the renal arteries, the possibility of thoracoabdominal aortic involvement should be suspected and investigated by using other imaging modalities. Caution should be exercised while interpreting aneurysm dimensions from ultrasound imaging because intraluminal measurements are often reported, whereas external measurements are usually used in other imaging modalities.

**Computed Tomography.** Computed tomographic (CT) scanning is widely available, provides visualization of the entire thoracic and abdominal aorta, and permits multplanar and 3-dimensional aortic reconstructions. Consequently, CT is the most common—and arguably the most useful—imaging modality for evaluating thoracic aortic aneurysms. In addition to establishing the diagnosis, CT provides information about an aneurysm’s location, extent, anatomic anomalies, and relationship to major branch vessels. CT is particularly useful in determining the absolute diameter of the aorta, especially in the presence of laminated clot, and also detects aortic calcification. Contrast-enhanced CT provides information about the aortic lumen and can detect mural thrombus, aortic dissection, inflammatory periaortic fibrosis, and mediastinal or retroperitoneal hematoma due to contained aortic rupture. To increase consistency and ensure uniform reporting, current practice guidelines suggest that measurements be taken perpendicular to blood flow and at standard anatomic locations, (Fig. 22-3); this should reduce the likelihood of erroneous measurements, especially during serial imaging surveillance.

The major disadvantage of contrast-enhanced CT scanning is the possibility of contrast-induced acute renal failure in patients who are at risk (e.g., patients with preexisting renal disease or diabetes) even though the risk is smaller than was assumed in the past. If possible, surgery is performed at least 1 day after contrast administration to allow time to observe renal function and to permit diuresis. If renal insufficiency occurs or is worsened, elective surgery is postponed until renal function returns to normal or stabilizes.

**Magnetic Resonance Angiography.** Magnetic resonance angiography (MRA) is becoming widely available and can facilitate visualization of the entire aorta. This modality produces aortic images comparable to those produced by contrast-enhanced CT but does not necessitate exposure to ionizing radiation. In addition, MRA offers excellent visualization of branch-vessel details, and it is useful in detecting branch-vessel stenosis. However, MRA is limited by high expense and a susceptibility to artifacts created by ferromagnetic materials, and gadolinium—the contrast agent for MRA—may be linked to nephrogenic systemic fibrosis and acute renal failure in patients with advanced renal insufficiency. Furthermore, the MRA environment is not appropriate for many critically ill patients, and unlike CT imaging, MRA imaging is suboptimal in patients with extensive aortic calcification.

**Invasive Aortography and Cardiac Catheterization.** Although catheter-based contrast aortography was previously considered the gold standard for evaluating thoracic aortic disease, cross-sectional imaging (i.e., CT and MRA) has largely replaced this modality. Technologic improvements have enabled CT and MRA to provide excellent aortic imaging while causing less morbidity than catheter-based studies do, so CT and MRA are now the primary modes for evaluating thoracic aortic disease. Today, the use of invasive aortography in patients with thoracic aortic disease is generally limited to those undergoing endovascular therapies or when other types of studies are contraindicated or have not provided satisfactory results.

Unlike standard aortography, cardiac catheterization continues to play an important role in diagnosis and preoperative planning, especially in patients with ascending aortic involvement. Proximal aortography can reveal not only the status of the coronary arteries and left ventricular function but also the degree of aortic valve regurgitation, the extent of aortic root involvement, coronary ostial displacement, and the relationship of the aneurysm to the arch vessels.

The value of the information one can obtain from catheter-based diagnostic studies should be weighed against
the established limitations and potential complications of such studies. A key limitation of aortography is that it images only the lumen and may therefore underrepresent the size of large aneurysms that contain laminated thrombus. Manipulation of intraluminal catheters can result in embolization of laminated thrombus or atheromatous debris. Proximal aortography carries a 0.6% to 1.2% risk of stroke. Other risks include allergic reaction to the contrast agent, iatrogenic aortic dissection, and bleeding at the arterial access site. In addition, the volumes of contrast agent required to adequately fill large aneurysms can cause significant renal toxicity. To minimize the risk of contrast nephropathy, patients receive periprocedural intravenous (IV) fluids for hydration, mannitol for diuresis, and acetylcysteine. As with contrast-enhanced CT, surgery is performed ≥1 day after angiography whenever possible to ensure that renal function has stabilized or returned to baseline.

**Treatment**

**Selecting the Appropriate Treatment.** Once a thoracic aortic aneurysm is detected, management begins with patient education, particularly if the patient is asymptomatic, because aortic disease may progress rapidly and unexpectedly in some patients. A detailed medical history is collected, a physical examination is performed, and a systematic review of medical records is carried out to clearly assess the presence or absence of pertinent symptoms and signs, despite any initial denial of symptoms by the patient. Signs of heritable conditions such as Marfan syndrome or Loey-Dietz syndrome are thoroughly reviewed. If clinical criteria are met for a heritable condition, confirmatory laboratory tests are conducted. Patients with heritable disorders are best treated in a dedicated aortic clinic where they can be appropriately followed up. Surveillance imaging and aggressive blood pressure control are the mainstays of initial management for asymptomatic patients. When patients become symptomatic or their aneurysms grow to meet certain size criteria, the patients become surgical candidates.

Endovascular therapy has become an accepted treatment for descending thoracic aortic aneurysm. Its role in treating proximal aortic disease and thoracoabdominal aortic aneurysm remains experimental; nonetheless, endoluminal stenting is approved by the U.S. Food and Drug Administration for the treatment of isolated descending thoracic aortic aneurysm, and several different devices have been approved for the treatment of blunt aortic injury and penetrating aortic ulcer. In practice, however, the off-label application of aortic stent grafts is widespread and accounts for well over half their use; endovascular approaches may be helpful in emergent aneurysm repair, such as for patients with aortic rupture. Endovascular therapy has evolved to include hybrid repairs, which combine open “debranching” techniques (to reroute branching vessels) with endovascular aortic repair. Despite these advances, for the repair of aneurysms with proximal aortic involvement and of thoracoabdominal aortic aneurysms, open procedures remain the gold standard and preferred approach.

**Determination of the Extent and Severity of Disease.** Cross-sectional imaging with reconstruction is critical when one is evaluating a thoracic aneurysm, determining treatment strategy, and planning necessary procedures. Note that patients with a thoracic aortic aneurysm may also have a second, remote aneurysm. In such cases, the more threatening lesion is addressed first. In many patients, staged operative procedures are necessary for complete repair of extensive aneurysms involving the ascending aorta, transverse arch, and descending thoracic or thoracoabdominal aorta. When the descending segment is not disproportionately large (compared with the proximal aorta) and is not causing symptoms, the proximal aortic repair is carried out first. An important benefit of this approach is that it allows treatment of valvular and coronary artery occlusive disease at the first operation.

Proximal aneurysms (proximal to the left subclavian artery) usually are addressed via a sternotomy approach. Aneurysms involving the descending thoracic aorta are evaluated in terms of criteria (described in the following section) for potential endovascular repair; those unsuitable for an endovascular approach are repaired with open techniques through a left thoracotomy. A CT scan can reveal detailed information about aortic calcification and luminal thrombus. These details are important in preventing embolization during surgical manipulation.

**Indications for Operation**

Thoracic aortic aneurysms are repaired to prevent fatal rupture. Therefore, on the basis of clinical history studies and other data, practice guidelines for thoracic aortic disease recommend elective operation in asymptomatic patients when the diameter of an ascending aortic aneurysm is ≥5.5 cm, when the diameter of a descending thoracic aortic aneurysm is ≥6.0 cm, or when the rate of dilatation is ≥0.5 cm per year. In patients with heritable disorders such as Marfan and Loey-Dietz syndromes, the threshold for operation is based on a smaller aortic diameter (5.0 cm for the ascending aorta in patients with Marfan syndrome, 4.4 to 4.6 cm for the ascending aorta in patients with Loey-Dietz syndrome, and <6.0 cm for the descending thoracic aorta in patients with either disorder). For women with heritable disorders who are considering pregnancy, prophylactic aortic root replacement is considered because the risk of aortic dissection or rupture increases at an aortic diameter of 4.0 cm and greater. For patients with ascending aortic aneurysm and bicuspid aortic valve, repair is recommended if aortic diameter is 5.0 cm or greater and additional risk factors are present (e.g., family history of dissection, expansion rate exceeding 0.5 cm per year), if aortic diameter is 5.5 cm or larger and no additional risk factors are present, or if aortic diameter exceeds 4.5 cm and the patient is undergoing aortic valve replacement or repair. For low-risk patients with chronic aortic dissection, descending thoracic repair is recommended at an aortic diameter of 5.5 cm or greater.

The acuity of presentation is a major factor in decisions about the timing of surgical intervention. Many patients are asymptomatic at the time of presentation, so there is time for thorough preoperative evaluation and improvement of their current health status, such as through smoking cessation and other optimization programs. In contrast, patients who present with symptoms may need urgent operation. Symptomatic patients are at increased risk of rupture and warrant expeditious evaluation. The onset of new pain in patients with known aneurysms is especially concerning because it may herald significant expansion, leakage, or impending rupture. Emergent intervention is reserved for patients who present with aneurysm rupture or superimposed acute dissection.

**Open Repair vs. Endovascular Repair** As noted earlier, endovascular repair has become the standard approach for patients with isolated degenerative descending thoracic aortic aneurysm; in fact, practice guidelines recommend that endovascular repair be strongly considered for patients with descending thoracic aneurysm at an aortic diameter of 5.5 cm (which is slightly below the 6.0-cm threshold for open repair). For endovascular
reparis to produce optimal outcomes, several anatomic criteria must be met. For one, the proximal and distal neck diameters should fall within a range that will allow proper sealing. Also, the proximal and distal landing zones should ideally be at least 20 mm long so that an appropriate seal can be made. Note that the limiting structures proximally and distally are the brachiocephalic vessels and celiac axis, respectively. Vascular access continues to be one of the most important determinants of successful deployment of the current endovascular devices. The femoral and iliac arteries have to be wide enough to accommodate the sheaths used to deploy the stent grafts. As endovascular technology evolves, newer devices are being used for smaller sheaths (or are “sheathless” self-deployed stent grafts) to accommodate smaller arteries. Tortuosity of the iliac vessels and abdominal aorta can make these procedures technically challenging. Occasionally, an 8- or 10-mm polyester “side graft” is anastomosed to the iliac artery through a retroperitoneal incision if the femoral vessels are too small to access easily.

Of note, attempts have been made to extend the use of endovascular therapy to aortic arch aneurysms and thoracoabdominal aortic aneurysms. Although reports of purely endovascular repair of the aortic arch remain limited, Greenberg and colleagues have reported their experience with a large series of purely endovascular thoracoabdominal aortic repairs. Additionally, there have been numerous reports of small series of off-label, experimental hybrid procedures that involve debranching of the aortic arch or the visceral vessels of the abdominal aorta, followed by endovascular exclusion of the aneurysm. The majority of hybrid approaches involve repairing the aortic arch. In its simplest form, hybrid arch repair involves an open bypass from the left subclavian to the left common carotid artery, which is followed by deliberate coverage of the origins of the left subclavian artery by the stent graft. In its most complex form, hybrid arch repair involves rerouting all of the brachiocephalic vessels, followed by proximal placement of the stent graft in the ascending aorta and extending repair distally into the aortic arch and descending thoracic aorta.

The patients who theoretically benefit the most from an endovascular approach are those who are of advanced age or have significant comorbidities, as many of these patients face substantial risks when undergoing traditional open repair. For example, with regard to open repair of a descending thoracic aortic aneurysm, significant pulmonary morbidity can occur postoperatively; therefore, patients with borderline pulmonary reserve may better tolerate an endovascular procedure than a standard open repair. Patients with heritable syndromic conditions generally are not considered candidates for elective endovascular repair except in specific circumstances. Endovascular repair in patients with heritable syndromic conditions have produced poor results, which are mainly due to progressive dilatation, stent graft migration, and endoleak.

Preoperative Assessment and Preparation. Given the impact of comorbid conditions on perioperative complications, a careful preoperative assessment of physiologic reserve is critical in assessing operative risk. Therefore, most patients undergo a thorough evaluation—with emphasis on cardiac, pulmonary, and renal function—before undergoing elective surgery.

Cardiac Evaluation Coronary artery disease is common in patients with thoracic aortic aneurysm and is responsible for a substantial proportion of early and late postoperative deaths in such patients. Similarly, valvular disease and myocardial dysfunction have important implications when one is planning anesthetic management and surgical approaches for aortic repair. Transthoracic echocardiography is a satisfactory noninvasive method for evaluating both valvular and biventricular function. Dipyridamole-thallium myocardial scanning identifies regions of myocardium that have reversible ischemia, and this test is more practical than exercise testing in older patients with concomitant lower-extremity peripheral vascular disease. Cardiac catheterization and coronary arteriography are performed in patients who have evidence of coronary disease—as indicated by either the patient’s history or the results of noninvasive studies—or who have a left ventricular ejection fraction of ≤30%. If significant valvular or coronary artery disease is identified before a proximal aortic operation, the disease can be addressed directly during the procedure. Patients who have asymptomatic distal aortic aneurysms and severe coronary occlusive disease undergo percutaneous transluminal angioplasty or surgical revascularization before the aneurysmal aortic segment is replaced.

Pulmonary Evaluation Pulmonary function screening with arterial blood gas measurement and spirometry is routinely performed before thoracic aortic operations. Patients with a forced expiratory volume in 1 second of >1.0 L and a partial pressure of carbon dioxide of <45 mmHg are considered appropriate candidates for open surgical repair. In suitable patients, borderline pulmonary function can be improved by implementing a regimen that includes smoking cessation, weight loss, exercise, and treatment of bronchitis for a period of 1 to 3 months before surgery. Although surgery is not withheld from patients with symptomatic aortic aneurysms and poor pulmonary function, adjustments in operative technique should be made to maximize these patients’ chances of recovery. In such patients, preserving the left recurrent laryngeal nerve, the phrenic nerves, and diaphragmatic function is particularly important.

Renal Evaluation Renal function is assessed preoperatively by measuring serum electrolyte, blood urea nitrogen, and creatinine levels. Information about kidney size and perfusion can be obtained from the imaging studies used to evaluate the aorta.

Obtaining accurate information about baseline renal function has important therapeutic and prognostic implications. For example, perfusion strategies and perioperative medications are adjusted according to renal function. Patients with severely impaired renal function frequently require at least temporary hemodialysis after surgery. These patients also have a mortality rate that is significantly higher than normal. Patients with thoracoabdominal aortic aneurysms and poor renal function secondary to severe proximal renal occlusive disease undergo renal artery endarterectomy, stenting, or bypass grafting during the aortic repair.

Operative Repair Proximal Thoracic Aortic Aneurysms

Open Repair Traditional open operations to repair proximal aortic aneurysms—which involve the ascending aorta, transverse aortic arch, or both—are performed through a midsternal incision and require cardiopulmonary bypass. The best choice of aortic replacement technique depends on the extent of the aneurysm and the condition of the aortic valve. The spectrum of operations (Fig. 22-4) ranges from simple graft replacement of the tubular portion of the ascending aorta only (Fig. 22-4A) to replacement of the ascending aorta and the proximal aortic arch (Fig. 22-4B) to graft replacement of the entire proximal aorta, including the aortic root, and reattachment of the coronary
Figure 22-4. Illustrations of proximal aortic repairs in which the native aortic root is left intact. A. ar teries and brachi o cephalic branches. The options for treating aortic valve disease, repairing aortic aneurysms, and maintaining perfusion during repair procedures each deserve detailed consideration (Table 22-2).

### Options for graft repair of the aortic aneurysm
- Patch aortoplasty
- Ascending replacement only
- Beveled hemiarch replacement
- Total arch replacement with reattachment of brachi o cephalic branches (island technique)
- Elephant trunk technique with island reattachment
- Total arch repair with bypass grafts to the brachi o cephalic branches (including Y-graft approaches)
- Elephant trunk technique with Y-graft approach
- Hybrid aortic arch repairs (including “frozen elephant trunk technique”)

### Perfusion options
- Standard cardiopulmonary bypass
- Profound hypothermic circulatory arrest without adjuncts
- Hypothermic circulatory arrest with adjuncts
- Retrograde cerebral perfusion
- Antegrade cerebral perfusion
- Balloon perfusion catheters
- Right axillary artery cannulation
- Innominate artery cannulation

### Options for treating aortic valve disease
- Aortic valve annuloplasty (annular plication)
- Aortic valve replacement (with mechanical or biologic prosthesis)
- Aortic root replacement
  - Composite valve graft (with mechanical or biologic valve)
  - Aortic homograft
  - Stentless porcine root
  - Pulmonary autograft (Ross procedure)
- Valve-sparing techniques

### Options for open surgical repair of proximal aortic aneurysms

Aortic Valve Disease and Root Aneurysms

Many patients undergoing proximal aortic operations have aortic valve disease that requires concomitant surgical correction. When such disease is present and the sinus segment is normal, separate repair or replacement of the aortic valve and graft replacement of the tubular segment of the ascending aorta are carried out. In such cases, mild to moderate valve regurgitation with annular dilatation can be addressed by plicating the annulus with mattress sutures placed below each commissure, thereby preserving the native valve. In patients with more severe valvar regurgitation or with valvular stenosis, the valve is replaced with a stented biologic or mechanical prosthesis; mechanical prostheses necessitate following a lifelong anticoagulation regimen.

Separate replacement of the aortic valve and ascending aorta is not performed in patients with Marfan syndrome or Loeys-Dietz syndrome, because progressive dilatation of the remaining sinus segment eventually leads to complications that necessitate reoperation. Therefore, patients with Marfan syndrome, Loeys-Dietz syndrome, or annuloaortic ectasia require some form of aortic root replacement.

In many cases, the aortic root is replaced with a mechanical or biologic prosthesis that has both a valve and an aortic conduit. Currently, the following graft options are commercially available: composite valve grafts with a mechanical valve, which consist of a bileaflet mechanical valve attached to a polyester tube graft; composite valve grafts with a biological valve (available in Europe only at this point); aortic root homografts, which are harvested from cadavers; and stentless porcine root grafts. In the United States, because no biologic composite valve grafts are commercially available, another option for surgeons is to construct a bioprosthetic composite valve graft during the operation by suturing a stented tissue valve to a polyester tube graft.

Although select patients may be offered the Ross procedure—in which the patient’s pulmonary artery root is excised and placed in the aortic position and then the right ventricular outflow tract is reconstructed by using a cryopreserved pulmonary homograft—this option is rarely used. This is largely because it is a technically demanding procedure, and there are concerns about the potential for autograft dilatation in patients with heritable conditions.

An additional option is valve-sparing aortic root replacement, which has evolved substantially during the past decade. The valve-sparing technique that is currently favored is called aortic root reimplantation and involves excising the aortic sinuses, attaching a prosthetic graft to the patient’s annulus (Fig. 22-5), and resuspended the native aortic valve inside the graft. The superior hemodynamics of the native valve and the avoidance of anticoagulation are major advantages of the valve-sparing approach. Long-term results in carefully selected patients have been excellent. Although the durability of this procedure in patients with Marfan syndrome has been satisfactory in some centers, it remains uncertain whether long-term durability can be reliably achieved with this approach. Further, acceptable mid-term outcomes have been reported for patients with bicuspid aortic valve. Patients who have structural leaflet deterioration or excessive annular dilatation are typically deemed unsuitable for valve-sparing repair.

Regardless of the type of conduit used, aortic root replacement requires reattaching the coronary arteries to openings in the graft. In the original procedure described by Bentall and De Bono, this was accomplished by suturing the intact aortic wall surrounding each coronary artery to the openings in the graft. The aortic wall was then wrapped around the graft to establish hemostasis. However, this technique frequently produced leaks at the coronary reattachment sites that eventually led to pseudoaneurysm formation. Cabrol’s modification, in which a separate, small tube graft is sutured to the coronary ostia and the main aortic graft, achieves tension-free coronary anastomoses, and reduces the risk of pseudoaneurysm formation. Kouchoukos’ button modification of the Bentall procedure is currently the most widely used technique. The aneurysmal aorta is excised, and buttons of aortic wall are left surrounding both coronary arteries, which are then mobilized and sutured to the aortic graft (Fig. 22-6). The coronary suture lines may be reinforced with polytetrafluoroethylene felt or pericardium...
Figure 22-5. Illustration of our current valve-sparing procedure for replacing the aortic root and ascending aorta for treatment of (A) aortic root aneurysm. B. The ascending aorta is opened after cardiopulmonary bypass and cardioplegic arrest are established and the distal ascending aorta is clamped. The diseased aortic tissue (including the sinuses of Valsalva) is excised. Buttons of surrounding tissue are used to mobilize the origins of the coronary arteries. C. A synthetic graft is sewn to the distal ascending aorta with continuous suture. D. After the distal anastomosis is completed, six sutures reinforced with Teflon pledgets are placed in the plane immediately below the aortic valve annulus. E. The subannular sutures are placed through the base of a synthetic aortic root graft, which is then is parachuted down around the valve. F. After the root graft is cut to an appropriate length, the valve commissures and leaflets are positioned within the graft. The annular sutures are then tied. G. Each of the three commissures is then secured near the top of the graft. H. The supra-annular aortic tissue is sewn to the graft in continuous fashion. I. The button surrounding the origin of the left main coronary artery is sewn to an opening cut in the root graft. J. The two aortic grafts are sewn together with continuous suture. K. The button surrounding the origin of the right coronary artery is sewn to an opening cut in the root graft. L. The completed valve-sparing aortic root replacement and graft repair of the ascending aorta are shown. (Used with permission of Baylor College of Medicine.)

to enhance hemostasis. When the coronary arteries cannot be mobilized adequately because of extremely large aneurysms or scarring from previous surgery, the Cabrol technique or a related modification can be used. Another option, originally described by Zubiate and Kay, is the construction of bypass grafts by using interposition saphenous vein or synthetic grafts.

Aortic Arch Aneurysms Several options are also available for handling aneurysms that extend into the transverse aortic arch.
with arch debranching followed by exclusion of the aneurysm with an endovascular graft. For fusiform aneurysms, when the distal portion of the arch is a reasonable size, a single, beveled replacement of the lower curvature (hemiarch) is performed. More extensive arch aneurysms require total replacement involving a distal anastomosis to the proximal descending thoracic aorta and separate reattachment of the brachiocephalic branches. The brachiocephalic vessels can be reattached to one or more openings made in the graft, or if these vessels are aneurysmal, they can be replaced with separate, smaller grafts. Alternatively, a Y-graft approach can be used to debranch the brachiocephalic vessels and move them forward, thereby permitting the distal anastomosis to be brought forward, which aids in hemostasis. When the aneurysm involves the entire arch and extends into the descending thoracic aorta, it is approached by using Borst’s elephant trunk technique of staged total arch replacement. The distal anastomosis is performed such that a portion of the graft is left suspended within the proximal descending thoracic aorta (Fig. 22-7). A collared graft can be used to accommodate any discrepancy in aortic diameter. During a subsequent operation, the suspended “trunk” is used to facilitate repair of the remaining descending thoracic or thoracoabdominal aortic aneurysm by an endovascular technique or by open repair through a thoracotomy incision, depending on the extent of disease and other factors. The elephant trunk technique permits access to the distal portion of the graft during the second operation without the need for dissection around the distal transverse aortic arch; this reduces the risk of injuring the left recurrent laryngeal nerve, esophagus, and pulmonary artery if an open approach is used at the second stage. As described in the section on hybrid repair of arch aneurysms (see later), the elephant trunk can be completed by using a hybrid endovascular approach (Fig. 22-8) in certain settings. A newer technique that is currently under investigation involves using a graft comprising a conventional polyester proximal portion and a stent graft into the distal transverse arch. This “frozen elephant trunk” technique can enable treatment of the entire aortic pathology during a single procedure or can facilitate a subsequent endovascular procedure (Fig. 22-9).

**Cardiopulmonary Bypass Perfusion Strategies** Like the operations themselves, perfusion strategies used during proximal aortic surgery depend on the extent of the repair. Aneurysms that are isolated to the ascending segment can be replaced by using standard cardiopulmonary bypass and distal ascending aortic clamping. This provides constant perfusion of the brain and other vital organs during the repair. Aneurysms involving the transverse aortic arch, however, cannot be clamped during the repair, which necessitates the temporary withdrawal of cardiopulmonary bypass support; this is called *circulatory arrest*. To protect the brain and other vital organs during the circulatory arrest period, hypothermia must be initiated before pump flow is stopped. However, the deep levels of hypothermia (below 20°C) that have been traditionally used in open arch repair are not without risk, and pure hypothermic circulatory arrest continues to have substantial limitations. Importantly, although brief periods of total circulatory arrest generally are well tolerated at cold temperatures, as the duration of circulatory arrest increases, the well-recognized risks of brain injury and death increase dramatically. Additionally, deep levels of hypothermia are associated with coagulopathy.

Because of the inherent complexity of aortic arch repairs and their general tendency to require longer periods
of hypothermic circulatory arrest, two cerebral perfusion strategies—retrograde cerebral perfusion (RCP) and antegrade cerebral perfusion (ACP)—were developed to supplement this process by delivering cold, oxygenated blood to the brain and further reduce the risks associated with repair. Retrograde cerebral perfusion involves directing blood from the cardiopulmonary bypass circuit into the brain through the superior vena cava. However, RCP is thought to be less beneficial than ACP, and although it may be helpful in the retrograde flushing of air and debris from the arch, many centers have stopped using RCP.

In contrast, ACP delivers blood directly into the brachiocephalic arteries to maintain cerebral flow. Although its use was cumbersome in the past, contemporary ACP techniques have been simplified and commonly involve cannulating either the right axillary artery or the innominate artery and subsequent connection to the cardiopulmonary bypass circuit. Often, a small section of graft is used as a conduit to ease cannulation, but there remains a small procedure-related risk of brachial plexus or vascular injury. Upon initiation, cold blood is delivered into the brain via the right common carotid artery and, if bilateral ACP is desired, the left common carotid artery. Note that, with the unilateral ACP technique, blood flow to the left side of the brain requires collateral circulation, ideally through an intact circle of Willis.

Methods to help determine the adequacy of unilateral ACP to deliver cerebral cross-circulation include preoperative imaging and intraoperative monitoring. A commonly used method (Fig. 22-10) have been simplified and commonly involve cannulating either the right axillary artery or the innominate artery and subsequent connection to the cardiopulmonary bypass circuit. Often, a small section of graft is used as a conduit to ease cannulation, but there remains a small procedure-related risk of brachial plexus or vascular injury. Upon initiation, cold blood is delivered into the brain via the right common carotid artery and, if bilateral ACP is desired, the left common carotid artery. Note that, with the unilateral ACP technique, blood flow to the left side of the brain requires collateral circulation, ideally through an intact circle of Willis. Methods to help determine the adequacy of unilateral ACP to deliver cerebral cross-circulation include preoperative imaging and intraoperative monitoring. A commonly used method

Figure 22-7. Illustration of a contemporary Y-graft approach to total arch replacement for aortic arch aneurysm. A. The proximal portions of the brachiocephalic arteries are exposed. B. The first two branches of the graft are sewn end-to-end to the transected left subclavian and left common carotid arteries. The proximal ends of the transected brachiocephalic arteries are ligated. C. A balloon-tipped perfusion cannula is placed inside the double Y-graft and used to deliver antegrade cerebral perfusion. After systemic circulatory arrest is initiated, the innominate artery is clamped, transected, and sewn to the distal end of the main graft. D. The proximal aspect of the Y-graft is clamped. This directs flow from the axillary artery to all three brachiocephalic arteries. The arch is then replaced with a collared elephant trunk graft. E. The distal anastomosis between the elephant trunk graft and the aorta is created between the innominate and left common carotid arteries. The collared graft accommodates any discrepancy in aortic diameter. F. The aortic graft is clamped, and a second limb from the arterial inflow tubing of the cardiopulmonary bypass circuit is used to deliver systemic perfusion through a side-branch of the arch graft while the proximal portion of the ascending aorta is replaced. Once the proximal aortic anastomosis is completed, the main trunk of the double Y-graft is cut to an appropriate length, and the beveled end is then sewn to an oval opening created in the right anterolateral aspect of the ascending aortic graft, which completes the repair (G). (Modified with permission from LeMaire SA, Price MD, Parenti JL, et al. Early outcomes after aortic arch replacement by using the Y-graft technique, Ann Thorac Surg. 2011 Mar;91(3):700-707.)
Figure 22-8. Illustration of Borst’s elephant trunk technique using a contemporary Y-graft approach. A. Stage 1: The proximal repair includes replacing the ascending aorta and entire arch, with Y-graft reattachment of the brachiocephalic vessels. The distal anastomosis is facilitated by using a collared elephant trunk graft to accommodate the larger diameter of the distal aorta. A section of the graft is left suspended within the proximal descending thoracic aorta. B. Stage 2: The distal repair uses the floating “trunk” for the proximal anastomosis. C. An alternate “hybrid” approach may be used in patients with less extensive distal aortic disease. Endovascular stent grafts are placed within the elephant trunk to complete the repair. (Used with permission of Baylor College of Medicine.)

Figure 22-9. Illustration of a frozen elephant trunk repair, which is a hybrid approach to repair that combines open aortic replacement with endovascular aortic repair. A. Extensive aortic disease affects the proximal and distal aorta. B. Aortic repair is extended into the proximal portion of the descending thoracic aorta after the transverse aortic arch is fully replaced. (Used with permission of Baylor College of Medicine.)
of intraoperative monitoring is brain near-infrared spectroscopy (NIRS), which measures cerebral oxygenation. If NIRS monitoring indicates inadequate perfusion, an additional perfusion catheter can be inserted into the left common carotid artery to provide blood flow to the left side of the brain.

Because ACP provides excellent brain protection, many surgeons now use more moderate levels of hypothermia (often between 22°C and 24°C) to decrease the risks associated with deep hypothermia.67 However, some authors have raised the concern that reducing the degree of hypothermia increases the risk of ischemic complications involving the spinal cord, kidneys, and other organs that are ischemic (without the benefit of deep hypothermia) during the systemic circulatory arrest period.98 Consequently, some groups supplement ACP with additional perfusion strategies that provide flow to the descending aorta during arch repair.99,100

**Endovascular Repair** Experience with purely endovascular treatment of proximal aortic disease remains limited and only investigational.101 The unique anatomy of the aortic arch and the need for uninterrupted cerebral perfusion pose difficult challenges. There are reports of the use of “homemade” grafts to exclude arch aneurysms; however, these grafts are experimental at this time. For example, in 1999, Inoue and colleagues102 reported placing a triple-branched stent graft in a patient with an aneurysm of the aortic arch. The three brachiocephalic branches were positioned by placing percutaneous wires in the right brachial, left carotid, and left brachial arteries. The patient underwent two subsequent procedures: surgical repair of a right brachial pseudoaneurysm and placement of a distal stent graft extension to control a major perigraft leak. Since then, efforts to employ endovascular techniques in the treatment of the proximal aorta have been essentially limited to the use of approved devices for off-label indications, such as the exclusion of pseudoaneurysms in the ascending aorta.

**Hybrid Repair** In June 1991, the Ukrainian surgeon Nikolay Volodos and his colleagues performed the first hybrid aortic arch repair103,104; 22 years later, Volodos reported that the patient was still alive.105 Unlike purely endovascular approaches, hybrid repairs of the aortic arch have entered the mainstream clinical arena, although they remain controversial. Hybrid arch repairs involve some form of “debranching” of the brachiocephalic vessels (which are not unlike Y-graft approaches), followed by endovascular exclusion of some or all of the aortic arch (Fig. 22-11). Although this technique has many variants, they often involve sewing a branched graft to the proximal ascending aorta with the use of a partial aortic clamp. The branches of the graft are then sewn to the arch vessels. Once the arch is “debranched,” the arch aneurysm can be excluded with an endograft. Commonly, a zone 0 approach (Fig. 22-12) is undertaken in which the proximal end of the endograft is secured within the ascending aorta. Other hybrid approaches aim to extend repair into the distal arch and descending thoracic aorta (see the following section). The arguments for using a hybrid approach to treat aortic arch aneurysm include the potential to avoid using cardiopulmonary bypass, circulatory arrest, and cardiac ischemia.59,60

It is not yet clear whether hybrid repairs are as durable as traditional ones because little mid- or long-term data have been published, and there are very few comparative studies.65 Procedure-related risks include the risk of embolization and stroke due to wire and device manipulation within the aortic arch (this risk appears to be greatest in zone 0 repairs106), retrograde acute aortic dissection,107 type I endoleak,108 and paraplegia.27 Because iatrogenic retrograde dissection of the ascending aorta is a particularly lethal complication, special considerations, including careful blood pressure management and wire manipulation, are recommended to avoid this problem in patients who are undergoing hybrid arch zone 0 stent deployment.109 Notably, patients with an ascending aortic diameter greater than 4.2 cm may be more susceptible to retrograde dissection. In an effort to
reduce the risk of iatrogenic dissection, some centers have begun to replace a small section of the ascending aorta with a standard polyester graft such that the endograft’s proximal landing zone comprises prosthetic material rather than native aortic tissue.107

**Distal Thoracic Aortic Aneurysms**

**Open Repair** In patients with descending thoracic or thoracoabdominal aortic aneurysms, several aspects of treatment—including preoperative risk assessment, anesthetic management, choice of incision, and use of protective adjuncts—are dictated by the overall extent of aortic involvement. By definition, descending thoracic aortic aneurysms involve the portion of the aorta between the left subclavian artery and the diaphragm. Thoracoabdominal aneurysms can involve the entire thoracoabdominal aorta, from the origin of the left subclavian artery to the aortic bifurcation. Surgical repair of thoracoabdominal aortic aneurysms is categorized by the extent of aortic replacement according to the Crawford classification scheme (Fig. 22-13). Extent I thoracoabdominal aortic aneurysm repairs involve most of the descending thoracic aorta, usually beginning near the left subclavian artery, and extend down into the suprarenal abdominal aorta. Extent II repairs also begin near the left subclavian artery but extend distally into the infrarenal abdominal aorta, and they often reach the aortic bifurcation. Extent III repairs extend from the lower descending thoracic aorta (below the sixth rib) and into the abdomen. Extent IV repairs begin at the diaphragmatic hiatus and often involve the entire abdominal aorta.

Descending thoracic aortic aneurysms not amenable to endovascular therapy are currently repaired through a left thoracotomy. In patients with thoracoabdominal aortic aneurysm, the thoracotomy is extended across the costal margin and into the abdomen.110 Using a double-lumen endobronchial tube allows selective ventilation of the right lung and deflation of the left lung. Transperitoneal exposure of the thoracoabdominal aorta is achieved by performing medial visceral rotation and circumferential division of the diaphragm. During a period of aortic clamping, the diseased segment is replaced with a polyester tube graft. Important branch arteries—including intercostal arteries and the celiac, superior mesenteric, and renal arteries—are reattached to openings made in the side of the graft. In patients with Marfan syndrome and other heritable conditions, separate (8- and 10-mm) grafts to the visceral branches are often used to prevent subsequent “patch aneurysms” that can develop in residual aortic tissue.111 Visceral and renal artery occlusive disease is commonly encountered during aneurysm repair; options for correcting branch-vessel stenosis include endarterectomy, direct arterial stenting, and bypass grafting.

Clamping the descending thoracic aorta causes ischemia of the spinal cord and abdominal viscera. Clinically significant manifestations of hepatic, pancreatic, and bowel ischemia are relatively uncommon. However, both acute renal failure and spinal cord injury resulting in paraplegia or paraparesis remain major causes of morbidity and mortality after these operations. Therefore, several aspects of the operation are devoted to minimizing spinal and renal ischemia (Table 22-3). Our multimodal approach to spinal cord protection includes expeditious repair to minimize aortic clamping time, moderate systemic heparinization (1.0 mg/kg) to prevent small-vessel

Crawford extent I and II thoracoabdominal repairs

- Cerebrospinal fluid drainage
- Left heart bypass during proximal anastomosis
- Selective perfusion of celiac axis and superior mesenteric artery during intercostal and visceral anastomoses

Thrombosis, mild permissive hypothermia (32°C to 34°C [89.6°F to 93.2°F] nasopharyngeal temperature), and reattachment of segmental intercostal and lumbar arteries. As the aorta is replaced from proximal to distal, the aortic clamp is moved sequentially to lower positions along the graft to restore perfusion to newly reattached branch vessels. During extensive thoracoabdominal aortic repairs (i.e., Crawford extent I and II repairs), cerebrospinal fluid drainage is used to improve spinal perfusion by reducing cerebrospinal fluid pressure. Because the benefits of this adjunct have been confirmed in a randomized clinical trial, its use is recommended in current guidelines (Class I, Level B recommendation). During cerebral spinal fluid drainage, the cerebral spinal fluid pressure is closely monitored, and the amount of fluid that is removed is carefully limited to avoid the devastating complication of intracranial hemorrhage. Motor evoked potentials are used by some groups to monitor the spinal cord throughout the operation. Left heart bypass, which provides perfusion of the distal aorta and its branches during the clamping period, is also used during extensive thoracoabdominal aortic repairs. Because left heart bypass unloads the heart, it is also useful in patients with poor cardiac reserve. Balloon perfusion cannulas connected to the left heart bypass circuit can be used to deliver blood directly to the celiac axis and superior mesenteric artery during their reattachment. The potential benefits of reducing hepatic and bowel ischemia include reduced risks of postoperative coagulopathy and bacterial translocation, respectively. Whenever possible, renal protection is achieved by perfusing the kidneys with cold (4°C [39.2°F]) crystalloid. In a randomized clinical trial, reduced kidney temperature was found to be associated with renal protection, and the use of cold crystalloid independently predicted preserved renal function. Hypothermic circulatory arrest can also be used during descending thoracic or thoracoabdominal aortic repairs. At our center, the primary indication for this approach is the inability to clamp the aorta because of rupture, extremely large aneurysm size, or extension of the aneurysm into the distal transverse aortic arch, or because a prior endovascular repair hinders clamping.

As discussed previously, complete repair of extensive aneurysm involving the ascending aorta, transverse arch, and descending thoracic aorta generally requires staged open
operations or a hybrid approach. In such procedures, when the descending or thoracoabdominal component is symptomatic (e.g., causes back pain or has ruptured) or is disproportionately large (compared with the ascending aorta), the distal segment is treated during the initial operation, and repair of the ascending aorta and transverse aortic arch is performed as a second procedure. A reversed elephant trunk repair, in which a portion of the proximal end of the aortic graft is inverted down into the lumen, can be performed during the first operation; this technique facilitates the second-stage repair of the ascending aorta and transverse aortic arch (Fig. 22-14).\(^{121}\)

Although spinal cord ischemia and renal failure receive the most attention, several other complications warrant consideration. The most common complication of extensive repairs is pulmonary dysfunction. With aneurysms adjacent to the left subclavian artery, the vagus and left recurrent laryngeal nerves are often adherent to the aortic wall and thus are susceptible to injury. Vocal cord paralysis should be suspected in patients who have postoperative hoarseness, and the presence of nerve damage should be confirmed by endoscopic examination. Vocal cord paralysis can be treated effectively by direct cord medialization (type 1 thyroplasty).\(^{122}\) Injury to the esophagus during

**Figure 22-14.** Illustration of the reversed elephant trunk technique using a traditional “island” approach to total aortic arch replacement. A. Stage 1: The distal aorta is repaired through a left thoracoabdominal approach. The aneurysm is opened after the aorta is clamped between the left common carotid artery and the left subclavian artery, which is also clamped. Before the proximal anastomosis is performed, the end of the graft is partly invaginated to leave a “trunk” for the subsequent repair. Proximal intercostal arteries are oversewn. B. After the proximal suture line is completed, the clamps are repositioned to restore blood flow to the left subclavian artery. The repair is completed by reattaching patent intercostal arteries to an opening in the side of the graft and creating a beveled distal anastomosis at the level of the visceral branches. C. Stage 2: The proximal aorta is repaired through a median sternotomy. The aortic arch is opened under hypothermic circulatory arrest. The “trunk” is pulled out and used to replace the aortic arch and ascending aorta. This eliminates the need for a new distal anastomosis and simplifies the procedure. Circulatory arrest and operative time, along with their attendant risks, are reduced. D. The completed two-stage repair of the entire thoracic aorta. (Modified with permission from Coselli JS, LeMaire SA, Carter SA, et al: The reversed elephant trunk technique used for treatment of complex aneurysms of the entire thoracic aorta, Ann Thorac Surg. 2005 Dec;80(6):2166-2172.)
the proximal anastomosis can have catastrophic consequences. Carefully separating the proximal descending thoracic aorta from the underlying esophagus before performing the proximal anastomosis minimizes the risk of a secondary aortoesophageal fistula. In patients who have previously undergone coronary artery bypass with a left internal thoracic artery graft, clamping proximal to the left subclavian artery can precipitate severe myocardial ischemia and cardiac arrest. When the need to clamp at this location is anticipated in these patients, a left common carotid-to-subclavian bypass is performed to prevent cardiac complications (Fig. 22-15).123

Endovascular Repair

**Descending Thoracic Aortic Aneurysms** Stent graft repair has become the standard treatment for patients with descending thoracic aortic aneurysm.55,56,124 Although aortic repair with a self-fixing endoprosthesis was reported by Volodos103,104 in the mid 1980s, it was the report by Parodi and associates125 of using endovascular stent grafting to repair abdominal aortic aneurysm that launched widespread interest in developing this approach. Only 3 years after this seminal report was published, Dake and colleagues126 reported performing endovascular descending thoracic aortic repair with “homemade” stent grafts in 13 patients.

Guidelines for the use of endovascular repair in thoracic aortic disease have been published,44 and reporting standards to uniformly describe the endovascular repair process have been established.127 Although endografting was initially approved to treat degenerative descending thoracic aortic aneurysm, newer devices have been approved for use in treating various descending thoracic aortic pathologies, including blunt aortic injury, penetrating aortic ulcer (see following section), coarctation, and dissection. Although the use of stent grafts in cases of aortic infection is not ideal, patients with a fistula or mycotic aneurysm are sometimes treated with endovascular devices as a bridge to open repair.

In elderly patients with severe comorbidity and patients who have undergone previous complex thoracic aortic procedures, endovascular repair is a particularly attractive alternative to standard open surgical procedures.128 Patients who undergo endovascular repair tend to have a lower incidence of intraoperative complications, a shorter length of stay, and a higher likelihood of being discharged to home than those who undergo open repair.129 As mentioned previously, appropriate patient selection depends on specific measurements taken from preoperative CT angiograms.

To protect patients against spinal cord ischemia during endovascular repair of the descending thoracic aorta, the most important maneuver is to keep the mean arterial perfusion pressure between 90 and 110 mmHg after the endograft is deployed. In patients who have had previous open or endovascular abdominal aortic aneurysm repair, cerebrospinal fluid drainage is recommended.130 The first step in the repair procedure is to obtain appropriate vascular access for the insertion of the thoracic stent graft. If the femoral artery will not accommodate the necessary

---

**Figure 22-15.** Illustration of a thoracoabdominal aortic aneurysm repair in a patient with a patent left internal thoracic artery-to-left anterior descending coronary artery graft. The proximal anastomosis is being performed while the aorta is clamped between the left common carotid and subclavian arteries. Myocardial perfusion is maintained through the carotid-subclavian bypass graft. (Modified with permission from Jones MM, Akay M, Murariu D, et al: Safe aortic arch clamping in patients with patent internal thoracic artery grafts. Ann Thorac Surg. 2010 Apr;89(4):e31-e32.)
sheath, then an iliac artery is exposed. If necessary, a graft can be sewn to the iliac artery in an end-to-side fashion to facilitate the deployment of the endograft. After 5,000 to 10,000 units of heparin are administered, a guidewire and the delivery sheath are typically inserted into the access artery under fluoroscopic guidance; depending on which endovascular device is used, the stent graft can be advanced through a sheath or with no sheath. The endograft is then advanced into the aorta and suitably positioned. Note that the best view of the distal arch and descending thoracic aorta is usually in the left anterior oblique position at an angle of approximately 40° to 50°. The device is then deployed, and the proximal and distal ends can be ballooned for better apposition of the stent graft to the aortic wall. An aortogram is then performed to rule out any endoleak, and protamine is administered. As an alternative to aortography, intravascular ultrasonography (IVUS) can be used to identify the proximal and distal landing zones, and the entire procedure can be performed with minimal or no contrast.

Although it is not uncommon to cover the left subclavian artery with the endograft to lengthen the proximal landing zone, findings suggest that the risk of spinal cord complications is heightened when the subclavian artery is covered and not revascularized, presumably because of a loss of collateral circulation to the spinal cord. To prevent this complication, a carotid-to-subclavian bypass can be easily constructed to maintain vertebral artery blood flow and minimize neurologic injury (Fig. 22-16). In addition, recent studies suggest that revascularization of the left subclavian artery is associated with lower stroke risk in patients in whom an endograft was deployed in Zone 2 and covered the left subclavian artery. In addition, new generations of stent grafts are being designed with side branches that can be placed within the left subclavian artery. This feature is particularly attractive if the proximal neck is short or if the patient has a patent left internal thoracic artery-to-left anterior descending coronary artery bypass. Indications for left subclavian artery revascularization include previous coronary artery bypass with patent internal thoracic artery, dominant left vertebral artery, aneurysm arising from the left subclavian artery, left arm arterio-venous fistula, and coverage of a long segment of the descending thoracic aorta.

**Elephant Trunk Completion** In select patients, elephant trunk completion repairs can be done with an endovascular approach (see Fig. 22-8C), rather than by the traditional open operation through a thoracotomy. Recall that an elephant trunk is used when an aortic aneurysm extends from the distal arch to the descending thoracic aorta. An endograft can be deployed at the time of elephant trunk construction or during a separate, subsequent procedure. When the stent is deployed in a retrograde manner during a second-stage procedure, the procedure is facilitated by placing radiopaque markers at the end of the elephant trunk during the first-stage procedure. This allows the distal end of the trunk to be identified via fluoroscopy. A guidewire can then be manipulated into the trunk and advanced into the ascending aorta to stabilize it during stent deployment. Note that advancing a wire in retrograde fashion from the femoral artery into the elephant trunk can be challenging. Occasionally, the wire must be advanced in an antegrade fashion from a brachial artery. The frozen elephant trunk technique—in which a short stent graft is delivered antegrade inside the trunk—can be used to perform the entire repair in one stage or to facilitate the second stage.

**Thoracoabdominal Aortic Aneurysms** Although endovascular thoracoabdominal aortic aneurysm repair remains experimental, it has been shown to be feasible in a handful of specialized centers. Endovascular thoracoabdominal aortic aneurysm repairs are quite complex, because at least one of the visceral arteries is incorporated into the repair. The number of visceral branches that need to be addressed varies with the extent of aortic coverage. The types of stent grafts used include fenestrated grafts, reinforced fenestrated grafts, branched or cuffed grafts, modular combinations of grafts, and multilayer stents. Graft fenestrations and branch vessels are typically aligned by using inflatable angioplasty balloons. Procedure time is not insignificant, nor is the amount of contrast medium required to obtain the highly detailed images needed to plan these procedures. In addition, some of the stent grafts used in endovascular thoracoabdominal aortic aneurysm repair are custom-made in advance and thus may take several weeks to obtain; therefore, their use is limited to cases of elective repair. In efforts to hasten repair and utilize off-the-shelf devices, parallel graft approaches, which use a combination of large- and small-diameter stents, have been reported. And, although some centers now propose distal coverage of the celiac axis for extent I thoracoabdominal aortic aneurysms, this potentially risky approach is not widely used.

It should be noted that, like open thoracoabdominal aortic aneurysm repair, endovascular repair carries risks of paraplegia, renal failure, stroke, and death, despite the apparent benefits of its being a less invasive procedure. Notably, reports from centers experienced in endovascular thoracoabdominal aortic repair primarily describe limited extent IV repairs. Although the technology is progressing rapidly, at present endovascular thoracoabdominal aortic aneurysm repair should be considered investigational.

**Hybrid Repair** Extensive hybrid thoracoabdominal aortic aneurysm repair can be a life-saving option in patients at high surgical risk, such as those who have limited physiologic reserve, are of advanced age, or have significant comorbidities. Hybrid procedures use open surgical techniques to reroute blood supply to the visceral arteries so that their aortic origins can be covered by stent grafts without causing visceral ischemia (Fig. 22-17). Endovascular methods are then used (either as part of the same procedure or at a later stage) to repair the aortic aneurysm, often with simple tube stent grafts; such devices are more readily available than the customized, modular stent grafts deployed in strictly endovascular repairs. Overall, results for hybrid thoracoabdominal aortic aneurysm repair have been somewhat disappointing. However, a handful of centers report acceptable outcomes in high-risk patients, particularly when a staged hybrid approach is used.

**Postoperative Considerations**

**Open Procedures** Aortic anastomoses are often extremely fragile during the early postoperative period. Even brief episodes of postoperative hypertension can disrupt suture lines and precipitate severe bleeding or pseudoaneurysm formation. Therefore, during the initial 24 to 48 hours, meticulous blood pressure control is maintained to protect the integrity of the anastomoses. Generally, we liberally use IV vasoactive agents to keep the mean arterial blood pressure between 80 and 90 mmHg. In patients with extremely friable aortic tissue, such as those with Marfan syndrome, we lower the target range to 70 to 80 mmHg. It is a delicate balancing act because one must be
Figure 22-16. Illustration of a “Zone 2” hybrid repair of the proximal descending thoracic aorta. A. The preoperative representation of the aneurysm shows that establishing a 2-cm proximal landing zone for a stent graft will require covering the origin of the left subclavian artery. B. Through a supraclavicular approach, a bypass from the left common carotid artery to the left subclavian artery is performed to reroute circulation and create a landing zone for the stent graft. After the bypass is completed, the left subclavian artery is ligated proximal to the graft. C. In the completed hybrid repair, the aneurysm has been excluded successfully by a stent graft that covers the origin of the left subclavian artery, and the proximal landing zone of the endograft is within zone 2. Importantly, blood flow to the left vertebral artery and arm is preserved by the bypass graft. (Reproduced with permission from Bozinovski J, LeMaire SA, Weldon SA: Hybrid Repairs of the Distal Aortic Arch and Proximal Descending Thoracic Aorta, Oper Tech Thorac Cardiovasc Surg 2007;12(3):167-177.)
mindful of spinal cord perfusion and avoid periods of relative hypotension while maintaining these low pressures.

Endovascular Procedures Many of the complications are directly related to manipulation of the delivery system within the iliac arteries and aorta. Patients with small, calcified, tortuous iliofemoral arteries are at particularly high risk for life-threatening iliac artery rupture. Although relatively uncommon, acute iatrogenic retrograde dissection into the aortic arch and ascending aorta is a life-threatening complication that necessitates emergency repair of the ascending aorta and aortic arch via sternotomy and cardiopulmonary bypass. The most important risk factors for this complication include incautious wire and catheter manipulation, aggressive proximal ballooning (especially in cases of acute descending thoracic aortic dissection), and hybrid arch repair in which the native ascending aorta is dilated (more than 4 cm). Retrograde proximal dissection converts a localized descending thoracic aortic aneurysm into an acute problem involving the entire thoracic aorta. Of note, retrograde aortic dissection may also occur several months after initial repair.

Another significant complication of descending thoracic aortic stent grafting is endoleak. An endoleak occurs when there is a persistent flow of blood (visible on radiologic imaging) into the aneurysm sac, and it may occur during the initial procedure or develop over time. Although endoleaks are a relatively common complication, they are not benign because they lead to continual pressurization of the sac, which can cause expansion or even rupture. These complications are categorized (Table 22-4) according to the site of the leak. Although all endoleaks may progress such that they can be considered life-threatening, type I and type III endoleaks generally necessitate early and aggressive intervention. Recently published reporting guidelines aid standardized reporting.

Other complications include stent graft misdeployment, device migration, endograft kinking or infolding, and stent graft infection, including fistula. Although not all complications related to stent grafts are fatal, endovascular repairs should be performed by expert teams qualified to address the variety of problems that may arise; some patients may need to have these devices removed and replaced with polyester grafts. Complications of endovascular repair are relatively common, so regularly scheduled radiologic imaging surveillance is of the utmost importance.

Aortic Dissection

Pathology and Classification

Aortic dissection, the most common catastrophic event involving the aorta, is a progressive separation of the aortic wall layers that usually occurs after a tear forms in the intima and inner media. As the separation of the layers of the media propagates, two channels are typically formed (Fig. 22-18): the original lumen, which remains lined by the intima and which is called the true lumen, and the newly formed channel within the layers of the media, which is called the false lumen. The dissecting membrane separates the true and false lumens. Additional tears in the dissecting membrane that allow communication between the two channels are called reentry sites. Although the separation of layers primarily progresses distally along the length of the aorta, it can also proceed in a proximal direction; this process often is referred to as proximal extension or retrograde dissection.

The extensive disruption of the aortic wall has severe anatomic consequences (Fig. 22-19). First, the outer wall of the false lumen is extremely thin, inflamed, and fragile, which makes it prone to expansion or rupture in the face of ongoing hemodynamic stress. Second, the expanding false lumen can compress the true lumen and cause malperfusion syndrome by interfering with blood flow in the aorta or any of its branch vessels, including the coronary, carotid, intercostal, visceral, renal, and iliac arteries. Finally, when the separation of layers occurs within the aortic root, the aortic valve commissures can become unhinged, which results in acute valvular regurgitation. The clinical consequences of each of these sequelae are addressed in detail in the section on clinical manifestations.

Dissection vs. Aneurysm. The relationship between dissection and aneurysmal disease requires clarification. Dissection and aneurysm are separate entities, although they often coexist and are mutual risk factors. In some cases, dissection occurs in patients without aneurysms, and the subsequent progressive dilatation of the weakened outer aortic wall ultimately results in an aneurysm. On the other hand, in patients with degenerative aneurysms, the ongoing deterioration of the aortic wall can lead to a superimposed dissection. The overused term dissecting aneurysm should be reserved for this specific situation.

Classification. For management purposes, aortic dissections are classified according to their location and chronicity. Improvements in imaging have increasingly revealed variants of aortic dissection that probably represent different forms along the spectrum of this condition.

Location To guide treatment, dissections are categorized according to their anatomic location and extent. The two traditional classification schemes that remain in common use are the DeBakey and the Stanford classification systems (Fig. 22-20). In their current forms, both of these schemes describe the segments of aorta that are involved in the dissection, rather than the site of the initial intimal tear. The main drawback of the Stanford classification system is that it does not distinguish between patients with isolated ascending aortic dissection and patients with dissection involving the entire aorta. Both types of patients would be classified as having type A dissections, despite the fact that their treatment, follow-up, and prognosis are substantially different.

Additional classification schemas include that by Borst and associates, in which the ascending and descending aorta are considered independently; the recent modification of the DeBakey classification by Tsagakis et al, which extends type II dissection into the aortic arch; and the Penn modification of the Stanford classification, which expands the classification to include the presence of tissue and global malperfusion. These modifications may help to better streamline the primary surgical intervention.

Figure 22-18. Illustration of longitudinal sections of the aortic wall and lumen. Blood flows freely downstream in normal aortic tissue. In classic aortic dissection, blood entering the media through a tear creates a false channel in the wall. Intramural hematomas arise when hemorrhage from the vasa vasorum causes blood to collect within the media; the intima is intact. Penetrating aortic ulcers are deep atherosclerotic lesions that burrow into the aortic wall and allow blood to enter the media. In each of these conditions, the outer aortic wall is severely weakened and prone to rupture.

Figure 22-20. Illustration of the classification schemes for aortic dissection based on which portions of the aorta are involved. Dissection can be confined to the ascending aorta (left) or the descending aorta (middle), or it can involve the entire aorta (right). (Used with permission from Baylor College of Medicine.)
Regardless of which system is used, patients with isolated ascending aortic dissection usually undergo emergent operation, as do patients with dissection involving both the ascending and descending thoracic segments. Patients with isolated descending thoracic and abdominal aortic dissection are typically treated medically, unless complications requiring surgery develop. Understanding the precise extent of dissection has become increasingly important as some aortic centers consider augmenting traditional ascending aortic repairs with endovascular techniques to treat dissected distal aortic segments.

**Chronicity** Aortic dissection also is categorized according to the time elapsed since the initial tear. Dissection is considered acute within the first 14 days after the initial tear; after 14 days, the dissection is considered chronic. Although arbitrary, the distinction between acute and chronic dissections has important implications, not only for decision making about perioperative management strategies and operative techniques, but also for evaluating surgical results. Figure 22-21 provides an algorithm for the management of acute aortic dissection. In light of the importance of acuity, Borst and associates\(^{154}\) have proposed a third phase—termed *subacute*—to describe the transition between the acute and chronic phases. The subacute period encompasses days 15 through 60 after the initial tear. Although this is past the traditional 14-day acute phase, patients with subacute dissection continue to have extremely fragile aortic

---

**Figure 22-21.** Algorithm used to facilitate decisions regarding treatment of acute aortic dissection. CT = computed tomography; MRA = magnetic resonance angiography; TEE = transesophageal echocardiography.
tissue, which may complicate operative treatment and increase the risks associated with surgery. Recently, the International Registry of Acute Aortic Dissections (IRAD) investigators proposed a new classification system for characterizing the phases of aortic dissection: The period within 24 hours from the onset of symptoms was defined as hyperacute, the period between 2 and 7 days was defined as acute, the period between 8 and 30 days was defined as subacute, and the period beyond 30 days was defined as chronic.159

**Variants** As noted earlier, advancements in noninvasive imaging of the aorta have revealed variants of aortic dissection (see Fig. 22-18). The recently introduced term acute aortic syndrome encompasses classic aortic dissection and its variants. Other aortic syndromes, which were once thought to be rare, include intramural hematoma (IMH) and penetrating aortic ulcer (PAU). Although the issue is somewhat controversial, the current consensus is that, in most cases, these variants of dissection should be treated identically to classic dissection.

An IMH is a collection of blood within the aortic wall, without an intimal tear, that is believed to be due to rupture of the vasa vasorum within the media. The accumulation of blood can result in a secondary intimal tear that ultimately leads to a dissection.160 Because IMH and aortic dissection represent a continuum, it is possible that IMH is seen less frequently than aortic dissection because IMH rapidly progresses to true dissection. The prevalence of IMH among patients with acute aortic syndromes is approximately 6%, and 16% progress to full dissection.161 An IMH can be classified according to its location (i.e., ascending or descending) and should be treated analogously to classic dissection.162

A PAU is essentially a disrupted atherosclerotic plaque that projects into the aortic wall and is associated with surrounding hematoma. Eventually, the ulcer can penetrate the aortic wall, which leads to dissection or rupture. The rate of disease progression is higher than that of IMH alone.163

**Causes and Clinical History**

Aortic dissection is a lethal condition with a reported incidence of 3.5 per 100,000 in the United States.164 Without appropriate modern medical or surgical treatment, most patients (approximately 90%) die within 3 months of dissection, mostly from rupture.165,166

Although several risk factors for aortic dissection have been identified, the specific causes remain unknown. Ultimately, any condition that weakens the aortic wall increases the risk of aortic dissection. Common general cardiovascular risk factors, such as smoking, hypertension, atherosclerosis, and hypercholesterolemia, are associated with aortic dissection. Patients with heritable forms of aortopathy, aortitis, bicuspid aortic valve, or preexisting medial degenerative disease are at increased risk for dissection, especially if they already have a thoracic aortic aneurysm.24 Aortic injury during cardiac catheterization, surgery, or endovascular aortic repair is a common cause of iatrogenic dissection. Other conditions that are associated with aortic dissection include cocaine and amphetamine abuse,167 as well as severe emotional stress or extreme physical exertion such as during weightlifting.168 Advances in the understanding of the molecular mechanisms behind abdominal aortic aneurysms have prompted similar investigations of thoracic aortic dissection.169-171

**Clinical Manifestations**

The onset of dissection often is associated with severe chest or back pain, classically described as “tearing,” that migrates distally as the dissection progresses along the length of the aorta. The location of the pain often indicates which aortic segments are involved. Pain in the anterior chest suggests involvement of the ascending aorta, whereas pain in the back and abdomen generally indicates involvement of the descending and thoracoabdominal aorta. Additional clinical sequelae of acute aortic dissection vary substantially and are best considered in terms of the dissection’s potential anatomic manifestations at each level of the aorta (see Fig. 22-19 and Table 22-5). Thus, potential complications of dissection of the aorta (and involved secondary arteries) may include cardiac ischemia (coronary artery) or tamponade, stroke (brachiocephalic arteries), paraplegia or paraparesis (intercostal arteries), mesenteric ischemia (superior mesenteric artery), kidney failure (renal arteries), and limb ischemia or loss of motor function (brachial or femoral arteries).

Ascending aortic dissection can directly injure the aortic valve, causing regurgitation. The severity of the regurgitation varies with the degree of commissural disruption, which ranges from partial separation of only one commissure, producing mild

SPECIFIC CONSIDERATIONS

PART II
valvular regurgitation, to full separation of all three commissures and complete prolapse of the valve into the left ventricle, producing severe acute heart failure. Patients with acute aortic valve regurgitation may report rapidly worsening dyspnea.

Ascending dissections also can extend into the coronary arteries or shear the coronary ostia off of the true lumen, causing acute coronary occlusion; when this occurs, it most often involves the right coronary artery. The sudden disruption of coronary blood flow can cause a myocardial infarction. This presentation of acute myocardial ischemia can mask the presence of aortic dissection, which results in delayed diagnosis and treatment.172

The thin and inflamed outer wall of a dissected ascending aorta often produces a serosanguineous pericardial effusion that can accumulate and cause tamponade. Suggestive signs include jugular venous distention, muffled heart tones, pulsus paradoxus, and low-voltage electrocardiogram (ECG) tracings. Free rupture into the pericardial space produces rapid tamponade and is generally fatal.

As the dissection progresses, any branch vessel from the aorta can become involved, which results in compromised blood flow and ischemic complications (i.e., malperfusion). Therefore, depending on which arteries are involved, the dissection can produce acute stroke, paraplegia, hepatic failure, bowel infarction, renal failure, or a threatened ischemic limb.

Diagnostic Evaluation
Because of the variations in severity and the wide variety of potential clinical manifestations, the diagnosis of acute aortic dissection can be challenging.173-175 Only 3 out of every 100,000 patients who present to an emergency department with acute chest, back, or abdominal pain are eventually diagnosed with aortic dissection. Not surprisingly, diagnostic delays are common; delays beyond 24 hours after hospitalization occur in up to 39% of cases. Unfortunately, delays in diagnosis lead to delays in treatment, which can have disastrous consequences. The European Society of Cardiology Task Force on Aortic Dissection stated, “The main challenge in managing acute aortic dissection is to suspect and thus diagnose the disease as early as possible.”173 A recent study by the IRAD investigators examined the reasons for delayed diagnosis and found that diagnosis lagged in women, as well as in patients with atypical symptoms, such as fever or mild pain (rather than severe pain).172 A high index of suspicion is critical, particularly in younger, atypical patients, who may have heritable disorders or other, less common risk factors.

Most patients with acute aortic dissection (80% to 90%) experience severe pain in the chest, back, or abdomen.173-175 The pain usually occurs suddenly, has a sharp or tearing quality, and often migrates distally as the dissection progresses along the aorta. For classification purposes (acute vs. subacute vs. chronic), the onset of pain is generally considered to represent the beginning of the dissection process. Most of the other common symptoms either are nonspecific or are caused by the secondary manifestations of dissection.

A discrepancy between the extremities in pulse, blood pressure, or both is the classic physical finding in patients with aortic dissection. It often occurs because of changes in flow in the true and false lumens, and it does not necessarily indicate extension into an extremity branch vessel. Involvement of the aortic arch often creates differences between the right and left arms, whereas descending aortic dissection often causes differences between the upper and lower extremities. Like symptoms, most of the physical signs after dissection are related to the secondary manifestations and therefore vary considerably (see Table 22-5). For example, signs of stroke or a threatened ischemic limb may dominate the physical findings in patients with carotid or iliac malperfusion, respectively.

Unfortunately, laboratory studies are of little help in diagnosing acute aortic dissection. There has been continued interest in using D-dimer level to aid in making this diagnosis.176 Several reports indicate that D-dimer is an extremely sensitive indicator of acute aortic dissection; elevated levels are found in approximately 97% of affected patients.177 Tests that are commonly used to detect acute coronary events—including ECG and tests for serum markers of myocardial injury—deserve special consideration and need to be interpreted carefully. Normal ECGs and serum marker levels in patients with acute chest pain should raise suspicion about the possibility of aortic dissection. It is important to remember that ECG changes and elevated serum marker levels associated with myocardial infarction do not exclude the diagnosis of aortic dissection because dissection can cause coronary malperfusion. Of note, abnormal ECGs have recently been shown to delay the diagnosis of aortic dissection, and the possibility of aortic dissection should not be prematurely ruled out.172,178 Similarly, although CXRs may show a widened mediastinum or abnormal aortic contour, up to 16% of patients with dissection have a normal-appearing CXR.174 The value of the CXR for detecting aortic dissection is limited, with a sensitivity of 67% and a specificity of 86%.179

Once the diagnosis of dissection is considered, the thoracic aorta should be imaged with CT, MRA, or echocardiography. The accuracy of these noninvasive imaging tests has all but eliminated the need for diagnostic aortography in most patients with suspected aortic dissection. Currently, the diagnosis of aortic dissection is usually established with contrast-enhanced CT, which has a sensitivity of 98% and a specificity of 87%, and, most importantly, acquires images swiftly.180 The classic diagnostic feature is a double-lumen aorta (Fig. 22-22). In addition, CT scans provide essential information about the segments of the aorta involved; the acuity of the dissection; aortic dilatation, including the presence of preexisting degenerative aneurysms; and the development of threatening sequelae, including pericardial effusion, early aortic rupture, and branch-vessel compromise. Although MRA also provides excellent imaging (with both a sensitivity and specificity of 98%), the MR suite is not well suited for critically ill patients. In patients who cannot undergo contrast-enhanced CT or MRA, transesophageal echocardiography can be used to establish the diagnosis.

Transesophageal echocardiography (TEE) is excellent for detecting dissection, aneurysm, and IMH in the ascending aorta. In appropriate hands, TEE has a demonstrated sensitivity and specificity as high as 98% and 95%, respectively.181 Furthermore, TEE offers important information about ventricular function and aortic valve competency. Finally, TEE is the diagnostic modality of choice for hemodynamically unstable patients in whom the diagnosis of ascending dissection is suspected; ideally, these patients should be taken to the operating room, where the TEE can be performed and, if the TEE is confirmatory, surgery can be started immediately.

In selected patients with ascending aortic dissection (i.e., those who have evidence of preexisting coronary artery disease), coronary angiography can be considered before surgery. Specific relative indications in these patients include a history
of angina or myocardial infarction, a recent myocardial perfusion study with abnormal results, previous coronary artery bypass or angioplasty, and acute ischemic changes on ECG. Contraindications include hemodynamic instability, aortic rupture, and pericardial effusion. In our practice, patients with acute aortic dissections rarely undergo coronary angiography. However, all patients presenting for elective repair of chronic ascending dissections have diagnostic coronary angiograms taken.

Of note, when malperfusion of the renal, visceral, or lower extremity arteries develops, the patient is usually treated in an angiography suite or hybrid operating room. Although the dissection usually is diagnosed on CT scan, these patients also undergo aortography, during which the mechanism of the malperfusion is ascertained and, if possible, corrected. Hence, catheter-based aortography may be obsolete as a diagnostic test for dissection, but it remains beneficial for patients with malperfusion.

**Treatment**

**Initial Assessment and Management.** Regardless of the location of the dissection, the initial treatment is the same for all patients with suspected or confirmed acute aortic dissection (see Fig. 22-21). Furthermore, because of the potential for rupture before the diagnosis is confirmed, aggressive pharmacologic management is started once there is clinical suspicion of dissection, and this treatment is continued during the diagnostic evaluation. The goals of pharmacologic treatment are to stabilize the dissection and prevent rupture.

Patients are monitored closely in an intensive care unit. Indwelling radial arterial catheters are used to monitor blood pressure and optimize titration of antihypertensive agents. Blood pressures in a malperfused limb can underrepresent the central aortic pressure; therefore, blood pressure is measured in the arm with the better pulse. Central venous catheters assure reliable IV access for delivering vasoactive medications. Pulmonary artery catheters are reserved for patients with severe cardiopulmonary dysfunction.

In addition to confirming the diagnosis of dissection and defining its acuity and extent, the initial evaluation focuses on determining whether any of several life-threatening complications are present. Particular attention is paid to changes in neurologic status, peripheral pulses, and urine output. Serial laboratory studies—including arterial blood gas concentrations, complete blood cell count, prothrombin and partial thromboplastin times, and serum levels of electrolytes, creatinine, blood urea nitrogen, and liver enzymes—are useful for detecting organ ischemia and optimizing management.

The initial management strategy, commonly described as *anti-impulse therapy* or *blood pressure control*, focuses on reducing aortic wall stress, the force of left ventricular ejection, chronotropy, and the rate of change in blood pressure (dP/dT). Reductions in dP/dT are achieved by lowering both cardiac contractility and blood pressure. The drugs initially used to accomplish these goals include IV β-adrenergic blockers, direct vasodilators, calcium channel blockers, and angiotensin-converting enzyme inhibitors. These agents are used to achieve a heart rate between 60 and 80 bpm, a systolic blood pressure between 100 and 110 mmHg, and a mean arterial blood pressure between 60 and 75 mmHg. These hemodynamic targets are maintained as long as urine output remains adequate and neurologic function is not impaired. Achieving adequate pain control with IV opiates, such as morphine and fentanyl, is important for maintaining acceptable blood pressure control.

β-Antagonists are administered to all patients with acute aortic dissections unless there are strong contraindications, such as severe heart failure, bradyarrhythmia, high-grade atrioventricular conduction block, or bronchospastic disease. Esmolol

---

**Figure 22-22.** Computed tomographic scans showing that the aorta has been separated into two channels—the true (T) and false (F) lumens—in two patients with different phases of aortic dissection. A. An acute DeBakey type I aortic dissection. The dissecting membrane appears wavy (arrows) in the early phase of dissection. Here, the true lumen of the proximal aorta can be seen to be extensively compressed. This may lead to malperfusion of the heart. B. A chronic DeBakey type III aortic dissection. In the chronic phase, the membrane appears straighter and less mobile (arrow) because it has stabilized over time. (Used with permission of Baylor College of Medicine.)
can be useful in patients with bronchospastic disease because it is a cardioselective, ultra-fast-acting agent with a short half-life. Labetalol, which causes both nonselective β-blockade and postsynaptic α1-blockade, reduces systemic vascular resistance without impairing cardiac output. Doses of β-agonists are titrated to achieve a heart rate of 60 to 80 bpm. In patients who cannot receive β-agonists, calcium channel blockers such as diltiazem are an effective alternative. Nitroprusside, a direct vasodilator, can be administered once β-blockade is adequate. When used alone, however, nitroprusside can cause reflex increases in heart rate and contractility, elevated dP/dT, and progression of aortic dissection. Enalapril and other angiotensin-converting enzyme inhibitors are useful in patients with renal malperfusion. These drugs inhibit renin release, which may improve renal blood flow.

**Treatment of Ascending Aortic Dissection**

**Acute Dissection** Because of the risk of aortic rupture, acute ascending aortic dissection is usually considered an absolute indication for emergency surgical repair. However, specific patient groups may benefit from nonoperative management or delayed operation.8183 Delayed repair may be considered for patients who (a) present with severe acute stroke or mesenteric ischemia, (b) are elderly and have substantial comorbidity, (c) are in stable condition and may benefit from transfer to specialized centers, or (d) have undergone a cardiac operation in the remote past. Regarding the last group, it is important that the previous operation not be too recent; dissections that occur during the first 3 weeks after cardiac surgery pose a high risk of rupture and tamponade, and such dissections warrant early operation.8184

In the absence of the aforementioned circumstances, most patients with acute ascending aortic dissection undergo emergent graft replacement of the ascending aorta. Operative repair is similar to that for aneurysm of the transverse aortic arch (previously described) because hypothermic circulatory arrest is commonly used regardless of the extent of repair. Immediately before the operation begins, intraoperative TEE is commonly performed to further assess baseline myocardial and valvular function and, if necessary, to confirm the diagnosis. The operation is performed via a median sternotomy with cardiopulmonary bypass and hypothermic circulatory arrest (Fig. 22-23). In preparation for circulatory arrest, cannulas are placed in the right axillary artery (to provide arterial inflow) and in the right atrium (to provide venous drainage).94 The innominate artery is sometimes used for arterial inflow if it is not dissected.985 After an appropriate level of cooling has been achieved (approximately 24°C), cardiopulmonary bypass is stopped, and the ascending aorta is opened. The innominate artery is then occluded with a clamp or snare, and flow from the axillary artery cannula is used to provide ACP.966 Currently as a default, we use bilateral ACP with a separate perfusion catheter in the left common carotid artery to ensure perfusion of the left side of the brain. This strategy of performing the distal anastomosis during a brief period of circulatory arrest, often termed open distal anastomosis, obviates the need to place a clamp across the fragile aorta, avoiding further aortic damage. Also, it allows the surgeon to carefully inspect the aortic arch for intimal tears. Traditionally, the entire arch is replaced only if a primary intimal tear is located in the arch or if the arch is aneurysmal; most commonly, repair is limited to replacement of the entire ascending aorta or to a beveled “hemiarch” repair.187 Conservative repair has been shown to increase the likelihood of early survival.188 The distal aortic cuff is prepared by tacking the inner and outer walls together and occasionally using a small amount of surgical adhesive to obliterate the false lumen and strengthen the tissue. A polyester tube graft is sutured to the distal aortic cuff. The anastomosis between the graft and the aorta is fashioned so that blood flow will be directed into the true lumen; this often alleviates distal malperfusion problems that were present preoperatively. After the distal anastomosis has been completed and adequately reinforced, the graft is deaired and clamped, full cardiopulmonary bypass is resumed, rewarming is initiated, and the proximal portion of the repair is started. In the absence of conditions that generally necessitate aortic root replacement (i.e., anuloaortic ectasia or heritable disorders, particularly Marfan and Loey-Dietz syndromes), aortic valve regurgitation can be corrected by resuspending the commissures onto the outer aortic wall.180 The proximal aortic cuff is prepared with tacking sutures and occasionally a small amount of surgical adhesive before the proximal aortic anastomosis is performed.

In the majority of patients who undergo surgical repair of acute ascending dissection, the dissection persists distal to the site of the operative repair; the residually dissected aorta, which generally includes at least a portion of the transverse aortic arch as well as a large portion of the distal aorta, is susceptible to dilatation over time. Extensive dilatation of the arch or distal aorta develops in 25% to 40% of survivors,190,191 and often necessitates further aortic repair. Additionally, long-term survival after acute proximal aortic dissection is generally poor, and rupture of the dilated distal aorta is a common cause of late death in these patients.188,190-192

The challenges that survivors of acute proximal aortic dissection commonly face over time have led to the development of alternative acute dissection strategies such as total arch replacement193 and hybrid arch strategies to extend proximal aortic repair into the distal aorta. The goal of hybrid arch approaches in acute dissection is to thrombose the residual false lumen by compressing it with the radial force that is exerted by a stent graft placed in the true lumen, thereby facilitating remodeling and preventing late aneurysm formation.194,195 However, in such repairs, the compressed false lumen may continue to be perfused in a retrograde fashion.

In Europe, Japan, and elsewhere, one-piece hybrid prostheses are now available that incorporate a polyester graft for the proximal repair and a stent graft component for the descending aorta. The device enables single-stage “frozen elephant trunk” repair of the ascending aorta, entire aortic arch, and proximal descending thoracic aorta.196 In the United States, such devices are not currently available, so this repair is commonly done by concomitantly deploying a commercially available stent graft in an antegrade fashion after fully replacing the ascending aorta and aortic arch. In some variations of this off-label approach, the stent graft is directly sutured to the distal aspect of the proximal open repair, whereas in others, there may be a gap of native tissue between the open and endovascular repair. Although this technique appears to be extensively used outside the United States, and with early and mid-term success,194,197-199 only a few U.S. reports describe its use.200-202 Emerging reports describe an enhanced risk of spinal cord ischemia, a risk that is not usually associated with open arch repair. This is probably due to the extensive coverage of the intercostal vessels by the stent graft. Uncertainties in the frozen elephant trunk procedure need to be addressed before it becomes a standard
Figure 22-23. Illustration of proximal aortic repair for acute ascending aortic dissection. A. This repair requires a median sternotomy and cardiopulmonary bypass. The ascending aorta is opened during hypothermic circulatory arrest, while antegrade cerebral perfusion is delivered via an axillary artery graft (shown) or via an innominate artery graft, provided that the innominate artery is not dissected (see Fig. 22-10). B. The dissecting membrane is removed to expose the true lumen. C. An open distal anastomosis prevents clamp injury of the friable arch tissue and allows inspection of the arch lumen. A balloon perfusion catheter in the left common carotid artery ensures bilateral antegrade cerebral perfusion. If the origin of the dissection (i.e., intimal tear or disruption) does not extensively involve the greater curvature of the aortic arch, and if there is no evidence of a preexisting arch aneurysm, a beveled, hemiarch repair is carried out, preserving most of the greater curvature of the arch. The aorta is transected, beginning at the greater curvature immediately proximal to the origin of the innominate artery and extending distally toward the lesser curvature to the level of the left subclavian artery. Consequently, most of the transverse aortic arch, except for the dorsal segment containing the brachiocephalic arteries, is removed. An appropriately sized, sealed (with collagen or gelatin) polyester tube graft is selected, and the beveled distal anastomosis is made with continuous 3-0 or 4-0 monofilament suture; the potential space between the true and false lumen can be obliterated with a small amount of surgical adhesive or by using a strip of Teflon felt. To improve hemostasis, the distal anastomosis can be reinforced by placing interrupted mattress sutures with felt pledgets. D. After cardiopulmonary bypass is resumed and a cross-clamp is applied to the hemiarch replacement graft, the aortic valve is assessed. Disrupted commissures are resuspended with pledgeted mattress sutures to restore valvular competence. E. The aorta is generally transected at the sinotubular junction, and a very small amount of surgical adhesive can be applied between the true and false lumens, or more commonly, the false lumen within the proximal aortic stump is obliterated by inserting a semicircle of felt within the false lumen of the noncoronary sinus. The trimmed edges are brought together by using 6-0 polypropylene sutures. F. The proximal anastomosis is carried out at the sinotubular junction, incorporating the distal margin of the commissures. G. In patients with residual distal aortic dissection (such as in DeBakey type I aortic dissection), hemiarch repair can be extended with antegrade stent delivery to the descending thoracic aorta. (Used with permission of Baylor College of Medicine.)
recommendation for this subset of patients. Another alternative employs separate grafts: a standard polyester graft to replace the ascending aorta and proximal hemiarch, and a stent graft delivered antegrade into the descending thoracic aorta (Fig. 22-23G). Although this procedure differs from a formal “frozen elephant trunk” repair in that it does not replace the entire arch, it is meant to achieve the same goal: promoting remodeling of the dissected descending aortic segment.

**Chronic Dissection** Occasionally, patients with ascending aortic dissection present for repair in the chronic phase. In most respects, the operation is similar to that for acute dissection repair. One notable difference is that the tissue is stronger in chronic dissection than in acute dissection, which makes suturing safer. In addition, the false lumen is not obliterated at the distal anastomosis; instead, the dissecting membrane is fenestrated into the arch to assure perfusion of both lumens and to prevent postoperative malperfusion complications. Unlike operations for acute dissection, operations for chronic dissection are often aggressive repairs that extend into the arch and root because the tissues are much less fragile.

**Treatment of Descending Aortic Dissection**

**Nonoperative Management** Nonoperative, pharmacologic management of acute descending aortic dissection results in lower morbidity and mortality rates than traditional open surgical treatment does. The most common causes of death during nonoperative treatment are aortic rupture and end-organ malperfusion. Therefore, patients are continually reassessed for new complications. Serial CT scans are generally obtained during the index hospitalization—usually on day 2 or 3 and on day 8 or 9 of treatment—and compared with the initial scan to rule out significant aortic expansion.

Once the patient’s condition has been stabilized, pharmacologic management is gradually shifted from IV to oral medications. Oral therapy, usually including a β-antagonist, is initiated when systolic pressure is consistently between 100 and 110 mmHg and the neurologic, renal, and cardiovascular systems are stable. Many patients can be discharged after their blood pressure is well controlled with oral agents and after serial CT scans confirm the absence of aortic expansion.

Long-term pharmacologic therapy is important for patients with chronic aortic dissection. β-Blockers remain the drugs of choice. In a 20-year follow-up study, DeBakey and colleagues found that inadequate blood pressure control was associated with late aneurysm formation. Aneurysms developed in only 17% of patients with “good” blood pressure control, compared with 45% of patients with “poor” control.

Aggressive imaging follow-up is recommended for all patients with chronic aortic dissection. Both contrast-enhanced CT and MRA scans provide excellent aortic imaging and facilitate serial comparisons to detect progressive aortic expansion. The first surveillance scan is obtained approximately 6 weeks after the onset of dissection. Subsequent scans are obtained at 3 to 6 months and then at 1 year after onset. If the aorta appears to be stable, imaging is obtained annually thereafter. Scans are obtained more frequently in high-risk patients, such as those with Marfan or Loeys-Dietz syndrome, and in those in whom significant aortic expansion is detected. For patients who have undergone graft repair of descending aortic dissection, annual CT or MRA scans are also obtained to detect false aneurysm formation or dilatation of unrepaird segments of aorta. Early detection of worrisome changes allows timely, elective intervention before rupture or other complications develop; rupture of the distal aorta is relatively common in patients with chronic aortic dissection and often results in death.

**Indications for Open Surgery** In the acute phase of descending aortic dissection, open surgery has been traditionally reserved for patients who experience complications. Complicated acute distal aortic dissections are those with aortic rupture, increasing periaortic or pleural fluid volume, rapidly expanding aortic diameter, uncontrolled hypertension, and persistent pain despite adequate medical therapy and malperfusion. In general terms, emergency open operations were originally intended to prevent or repair rupture and relieve life-threatening ischemic manifestations. However, open operation is associated with high morbidity in such cases; now that stent graft technology is available, endovascular surgical intervention is recommended for patients with complicated acute distal aortic dissection.

Acute dissection superimposed on a preexisting aneurysm is considered a life-threatening condition and is therefore another indication for operation. Finally, patients who have a history of noncompliance with medical therapy may ultimately benefit more from surgical intervention if they are otherwise reasonable operative candidates.

In the chronic phase, the indications for open surgical intervention for aortic dissection are similar to those for degenerative thoracic aortic aneurysm, although a slightly lower threshold of repair is now recommended. Guidelines for thoracic aortic disease recommend elective operation in otherwise healthy patients when the affected segment has reached a diameter of 5.5 cm, especially in patients with heritable disorders. Rapid aortic enlargement and other factors that increase the likelihood of aortic rupture may also be considered.

**Endovascular Treatment**

**Malperfusion Syndrome** Endovascular therapy is routinely used in patients with descending aortic dissection complicated by visceral malperfusion. Abdominal malperfusion syndrome often is fatal; prompt identification of visceral ischemia and expedited treatment to restore hepatic, gastrointestinal, and renal perfusion are imperative for a positive outcome. As described in a later section, several open surgical techniques can be used to reestablish blood flow to compromised organs. However, in acute cases, open surgery is associated with poor outcomes. Therefore, endovascular intervention is the preferred initial approach in such cases. In one endovascular technique known as endovascular fenestration, a balloon is used to create a tear in the dissection flap, which allows blood to flow in both the true and false lumens. Although endovascular fenestration was commonly used in the past, its use has declined in recent years as direct aortic and branch-vessel stenting techniques have evolved and gained favor. Placing a stent graft in the true lumen of the aorta can resolve a “dynamic” malperfusion. Occasionally, a small stent must be placed directly in the lumen of a visceral or renal artery because the dissection has propagated into the branch, resulting in “static” malperfusion at the origin.

Iliofemoral malperfusion causing limb-threatening leg ischemia also can be treated via an endovascular approach. Limb malperfusion usually resolves after the endovascular repair of acute descending thoracic aortic dissection. If the malperfusion does not resolve, then a femoral-to-femoral arterial bypass graft is an effective option.
Acute Dissection Although surgery has been traditionally recommended for patients with complicated acute descending aortic dissection, many centers have shifted toward using endovascular stent grafts as the preferred approach in these cases because of the high morbidity associated with the open operation. Evidence suggests that emergent endovascular repair in patients with true lumen collapse and complications such as rupture or dynamic malperfusion may be lifesaving in these difficult-to-treat patients. However, these patients remain at risk of further complication or future reintervention. Although endovascular repair in patients with heritable aortic disorders is generally not recommended, this technique can be used as a bridge to later, definitive repair in such life-threatening circumstances.66

Controversy exists regarding the use of endovascular stent grafts to treat uncomplicated acute descending dissection; some encouraging data have been published in the last couple of years.210 The goal of this treatment strategy is to use the stent graft to cover the intimal tear, seal the entry site of the dissection, and eventually cause thrombosis of the false lumen to aid in aortic remodeling and reduce late aortic expansion. Such procedures take place in a hybrid operating room. After the true lumen is accessed through the femoral arteries, an aortogram is taken, and the intimal tear is identified. Note that the diameter of the true lumen is measured on the preoperative contrast-enhanced CT scan. The use of IVUS is encouraged to help access the true lumen, verify navigation of the wire inside the true lumen, and confirm measurements. For these cases, a stent graft is selected with a diameter no more than 10% greater than that of the true lumen. Unlike stents deployed to treat most descending thoracic aortic aneurysms, stents deployed to treat descending thoracic aortic dissections must not be ballooned, because ballooning can cause a new intimal tear, retrograde dissection into the ascending aorta, or even aortic rupture. The ideal length of the descending thoracic aorta that should be covered in patients with acute distal descending dissection remains unclear. Close monitoring with serial imaging is necessary after endovascular repair because the false lumen remains at risk for retrograde perfusion or pressurization.

Chronic Dissection Endovascular treatment of chronic descending aortic dissection is supported by the 5-year data of the INSTEAD-XL trial, which showed that endovascular repair combined with optimal medical treatment was associated with slower disease progression and greater aorta-specific survival than optimal medical treatment alone.211 Importantly, patients in the trial had dissections in the early chronic phase, many within 10 to 12 weeks of onset and all within 1 year of onset. Endovascular repair of chronic dissection is particularly challenging because the relative rigidity of the dissecting membrane—which increases over time during the chronic phase—and the presence of multiple reentry sites make it difficult to exclude the false lumen.

Penetrating Aortic Ulcer Patients with PAUs appear to be good candidates for endovascular intervention. Covering the focal ulceration with a stent graft has been shown to be an effective treatment.212 In a recent study by Patel and colleagues,213 endovascular repair of PAU was associated with better early outcomes than open repair. However, when PAU was associated with adjacent hematoma within the aortic wall, rates of subsequent reintervention were increased.

Open Repair

Acute Dissection In patients with acute aortic dissection, open surgical repair of the descending thoracic or thoracoabdominal aorta has been traditionally associated with high morbidity and mortality.174 Therefore, surgery was generally only performed to prevent fatal rupture or to restore branch-vessel perfusion in patients with complicated dissection.208 With the evolution of endovascular technology, open repair has fallen out of favor in recent years.

Malperfusion Syndrome In patients with malperfusion, when an endovascular approach is unavailable or unsuccessful, open surgery is necessary. Lower-extremity ischemia can be readily addressed with surgical extra-anatomic revascularization techniques, such as femoral-to-femoral bypass grafting. In patients with abdominal organ ischemia, flow to the compromised bed must be reestablished swiftly. Although they are considered second-line therapies, multiple techniques are available, including graft replacement of the aorta (with flow redirected into the true lumen), open aortic fenestration, and visceral or renal artery bypass.

Chronic Dissection A more aggressive replacement usually is performed during elective aortic repairs in patients with chronic dissection. In many regards, the operative approach used in these patients is identical to that used for descending thoracic and thoracoabdominal aortic aneurysms, as described in the first half of this chapter (Fig. 22-24). One key difference is the need to excise as much dissecting membrane as possible to clearly identify the true and false lumens and to locate all important branch vessels. When the dissection extends into the visceral or renal arteries, the membrane can be fenestrated, or the false lumen can be obliterated with sutures or intraluminal stents. Asymmetric expansion of the false lumen can create wide separation of the renal arteries. This problem is addressed by reattaching the mobilized left renal artery to a separate opening in the graft or by performing a left renal artery bypass with a side graft. Wedges of dissecting membrane also are excised from the aorta adjacent to the proximal and distal anastomoses, which allows blood to flow through both true and false lumens. When placing the proximal clamp is not technically feasible, hypothermic circulatory arrest can be used to facilitate the proximal portion of the repair.

OUTCOMES

Improvements in anesthesia, surgical techniques, and perioperative care have led to substantial improvements in outcome after thoracic aortic aneurysm repair. When performed in specialized centers, these operations are associated with excellent survival rates and acceptable morbidity rates. The interpretation of outcomes data is complicated by site-specific variables, such as the number of years reported and whether data are taken from single-practice centers or from pooled, multicenter, or national registries, and by patient-specific variables, such as type of enrollment, urgency and extent of repair, concomitant procedures performed, and the presence of preexisting risk factors such as advanced age, previous cardiovascular repair, disease of any system or organ, or heritable conditions.

Repair of Proximal Aortic Aneurysms

Risks associated with the open repair of the proximal aorta vary by extent of repair and are greatest for repairs involving total arch replacement.71,214 All varieties of aortic root replacement have shown acceptable early mortality rates and few complications. Two groups with 20 and 27 years’ experience with composite valve graft replacement reported early mortality rates of 5.6% and 1.9%, respectively; the more recent repairs had better outcomes.215,216 Early mortality rates for stentless porcine
tissue root replacements are also low, ranging from 3.6% to 6.0%. Early mortality rates for contemporary valve-sparing approaches to aortic root replacement are quite low (1%–2%) in experienced centers. Late survival rates after valve-sparing root procedures range from 97% to 99% at 5 years and approach 94% at 10 years.

Repairs incorporating the ascending aorta and aortic arch have acceptable outcomes; risk increases with patient-specific factors such as severe atherosclerosis or as larger sections of the aortic arch are incorporated into the repair. A revised surgical strategy—such as the use of hypothermic circulatory arrest—is often needed to avoid clamping atherosclerotic sections in the “porcelain” aorta. In Zingone and colleagues’ series of 64 patients who underwent replacement of atherosclerotic ascending aorta, hypothermic circulatory arrest was used in 61 patients (95%). Even though these patients had substantial comorbidity and 83% underwent concomitant cardiac repairs, acceptable rates of early mortality (11%) and stroke (6%) were obtained. Other

---

**Figure 22-24.** Illustration of distal aortic repair of a chronic dissection. A. Thoracoabdominal incision. B. Extent II thoracoabdominal aortic aneurysm resulting from chronic aortic dissection. The patient has previously undergone composite valve graft replacement of the aortic root and ascending aorta. After left heart bypass is initiated, the proximal portion of the aneurysm is isolated by placing clamps on the left subclavian artery, between the left common carotid and left subclavian arteries, and across the middle descending thoracic aorta. C. The isolated segment of aorta is opened by using electrocautery. D. The dissecting membrane is excised, and bleeding intercostal arteries are oversewn. The aorta is prepared for proximal anastomosis by transecting it distal to the proximal clamp and separating this portion from the esophagus (not shown). E. The proximal anastomosis between the aorta and an appropriately sized polyester graft is completed with continuous polypropylene suture. F. After left heart bypass has been stopped and the distal aortic cannula has been removed, the proximal clamp is repositioned onto the graft, the other two clamps are removed, and the remainder of the aneurysm is opened. G. The rest of the dissecting membrane is excised, and the openings to the celiac, superior mesenteric, and renal arteries are identified. H. Selective visceral perfusion with oxygenated blood from the bypass circuit is delivered through balloon perfusion catheters placed in the celiac and superior mesenteric arterial ostia. Cold crystalloid is delivered to the renal arteries. The critical intercostal arteries are reattached to an opening cut in the graft. I. To minimize spinal cord ischemia, the proximal clamp is repositioned distal to the intercostal reattachment site. A second oval opening is fashioned in the graft adjacent to the visceral vessels. Selective perfusion of the visceral arteries continues during their reattachment to the graft. A separate anastomosis is often required to reattach the left renal artery. J. After the balloon perfusion catheters are removed and the visceral anastomosis is completed, the clamp is again moved distally, restoring blood flow to the celiac, renal, and superior mesenteric arteries. The final anastomosis is created between the graft and the distal aorta. (Reproduced with permission from Creager MA, Dzau VS, Loscalzo J: Vascular Medicine, 7th ed. Philadelphia, PA: Elsevier/Saunders; 2006.)
studies indicate that the enhanced risk of neurocognitive disturbances in ascending repairs using circulatory arrest are not offset by lower rates of early mortality. Regarding extended proximal repair, reported early mortality rates after traditional stage 1 elephant trunk repairs (primarily using island reattachment strategies) range from 2.3 to 13.9%.229-233

Contemporary mortality rates for extensive proximal aortic repair have improved as new strategies and modified adjuncts have been adopted. For example, by adopting contemporary approaches, we have reduced early mortality for stage 1 elephant trunk repairs from 12% to 2% in our patients.86,230 Similarly, in a report by Kazui and colleagues234 covering 20 years of experience and 472 consecutive patients who underwent aortic arch repair with selective ACP, operative mortality was 16.0% for early repairs and 4.1% for more recent repairs. Other contemporary reports of the use of techniques such as moderate hypothermia and Y-graft approaches235-238 indicate similarly improved outcomes; early mortality ranges from 1% to 7%, stroke rates range from 1% to 6%, and no cases of paraplegia are reported. Although paraplegia has traditionally been an unusual and infrequent complication of aortic arch repair, it has been reported as a complication of “long” elephant trunk approaches and frozen elephant trunk approaches.239

Because of the heterogeneity of hybrid arch approaches and the tendency to use these approaches in high-risk patients, results of hybrid arch repair are difficult to interpret. In a recent report from our group,49 among 319 consecutive patients who underwent total arch replacement in the last 8.5 years, 274 patients had traditional open repair and 45 patients had hybrid zone 0 exclusion repairs. The rate of permanent adverse outcome (death, persistent neurologic deficit at discharge, or persistent hemodialysis at discharge) was not significantly different between the two groups. A higher overall stroke rate was noticed in the hybrid group, reinforcing the importance of catheter skills and careful wire manipulation. A meta-analysis conducted by Koulliias and Wheatley241 of data from 15 studies with 463 patients found an average 30-day mortality rate of 8.3%; stroke, 4.4%; paraplegia, 3.9%; and endoleak, 9.2%. Of note, relatively few repairs (30%) were performed “off-pump,” and the majority of repairs used cardiopulmonary bypass or hypothermic circulatory arrest. Additionally, several reports of small series have documented increased risk of acute retrograde aortic dissection during hybrid arch repairs; rates range from 0% to 7.5%, and these patients face significant mortality risk (ranging from 33% to 100%) should this occur.
Treatment of Acute Ascending Aortic Dissection
The International Registry of Acute Aortic Dissection (IRAD) provides the most comprehensive data on contemporary outcomes in patients with acute aortic dissection. This registry was established in 1996 and has accumulated data from >7000 patients treated for acute aortic dissection at 51 centers in 12 countries. An IRAD analysis of data from 776 patients who underwent surgical repair of acute ascending aortic dissection revealed an in-hospital mortality rate of 23.8%. The investigators identified several preoperative predictors of early mortality, including age >70 years, previous cardiac surgery, hypotension or shock at presentation, abrupt onset of symptoms, migrating pain, cardiac tamponade, preoperative renal failure, pulse deficit, and evidence of myocardial ischemia or infarction on ECG. In a report from IRAD, in-hospital mortality after surgical treatment had decreased from 25% in 1995 to 18% in 2013. The German Registry for Acute Aortic Dissection (GERAADA) has collected data on more than 3300 patients from 56 centers since 2006. In a report of 1436 patients with acute proximal dissection that was surgically repaired using hypothermic circulatory arrest with or without unilateral and bilateral ACP, the early mortality rates ranged from 13.9% to 19.4%; the 628 patients with unilateral ACP had the lowest rate of early death. Operative mortality reported by North American centers varies from 5% to 17%; improvements in outcomes may be related to the implementation of protocol-based management and the assembly of thoracic aortic teams.

Repair of Distal Aortic Aneurysms
Endovascular Repair of Descending Thoracic Aortic Aneurysms. In the earliest series of endovascular repairs of descending thoracic aortic aneurysms, mortality and morbidity were difficult to assess. Most of the reported series were small and included a large proportion of high-risk patients with substantial comorbidity. Subsequent evidence from pivotal, nonrandomized trials that compared patients who underwent endograft exclusion with historical or concurrent patients who underwent open repair showed that the stent graft groups had significantly less morbidity and early mortality than the open repair groups, although in two of the trials, a nonsignificant between-group difference was observed in the rate of stroke. Five-year comparative data show that the two groups differed significantly in their aneurysm-related mortality rates (2.8% for endovascular patients and 11.7% for open repair patients) but not in their rates of all-cause mortality (which were 32% and 31%, respectively). Additional pivotal trial 5-year outcomes indicate the growing disparity between aneurysm-related (96.1%) and all-cause survival (58.5%) in patients with endovascular repair, leading some to comment on the possible futility of repair in many patients. Among 8967 patients identified in the National Inpatient Sample database (8255 with open repair and 712 with endovascular repair), the odds of death were 46% lower among patients who underwent endovascular repair rather than open repair. The endovascular repair group also had lower odds of postoperative neurologic, cardiac, and respiratory complications.

Open Repair of Descending Thoracic and Thoracoabdominal Aortic Aneurysms. Contemporary results of open repairs of descending thoracic aortic aneurysms, including those performed in select patients with chronic dissection, indicate that early mortality rates range from 4.1% to 8.0%, renal failure rates range from 4.2% to 7.5%, and paraplegia rates range from 2.3% to 5.7%; stroke rates are generally lower, ranging from 1.8% to 2.1%. In our series, although the risk of paraplegia increased with the extent of repair, the risk of mortality was greatest for those undergoing repair of the proximal two thirds of the descending aorta. As expected, stroke rates after distal aortic repairs were highest when the clamp site was near the left subclavian artery.

Contemporary series of open thoracoabdominal aortic repairs show acceptable survival. Reported outcome rates range from 5% to 12% for early mortality, 3.8% to 9.5% for paraplegia, 1.7% to 5.2% for stroke, and 6% to 12% for renal complications. Many of these series summarize 10 to 20 years of surgical experience, although some present a shorter but more contemporary experience. Even for complex thoracoabdominal aortic aneurysms, mortality and morbidity after thoracoabdominal aortic aneurysm repair, reported that patients treated at low-volume centers fared less well. Replacing the entire thoracoabdominal aorta (i.e., performing an extent II repair) carries the highest risk of death, bleeding, renal failure, and paraplegia. Early survival has been estimated at 79% at 2 years, and mid-term survival has been estimated at 63% at 5 years. In our recent report of 3309 repairs, the overall mortality rate was 7.5%, and the rate of operative death was higher in extent II and III repairs than in extent I and IV. Permanent paraplegia and paraparesis occurred in 2.9% and 2.4% of patients, respectively, and the incidence of paraplegia in patients 50 years of age or younger was only 1.1%. Estimated survival after repair was 84% ± 1% at 1 year, 64% ± 1% at 5 years, 37% ± 1% at 10 years, and 18% ± 1% at 15 years.

Treatment of Descending Thoracic Aortic Dissection
Nonoperative Management. The in-hospital mortality rate is 8.7% for patients with acute descending aortic dissection who receive nonoperative treatment; however, when IRAD stratified patients according to clinical presentation, the mortality rate for patients with uncomplicated dissection was less than 4%, whereas the mortality rate for patients with complicated dissection was more than 20%. The primary causes of death during nonoperative management are rupture, malperfusion, and cardiac failure. Risk factors associated with treatment failure—defined as death or need for surgery—include an enlarged aorta, persistent hypertension despite maximal treatment, oliguria, and peripheral ischemia. Among patients who receive nonoperative treatment for descending aortic dissection and who survive the acute period, approximately 90% remain alive 1 year later, and approximately 76% are alive 3 years later.

Endovascular Treatment. For patients with complicated acute descending thoracic aortic dissection, including rupture and malperfusion of the visceral or renal arteries, an endovascular approach is ideal. The Stanford group reported a 93% technical success rate for endovascular reperfusion of an ischemic bed. Their experience with the use of first-generation stent grafts to treat acute complicated descending dissections...
was also encouraging: Complete thrombosis of the false lumen occurred in 79% of patients. The early mortality rate was 16%, comparable to that associated with open techniques.\textsuperscript{273} A meta-analysis of observational studies of endovascular repair, which included 248 patients with acute descending thoracic aortic dissection, found a 30-day mortality rate of 9.8%.\textsuperscript{274} When compared with early mortality rates obtained from IRAD data,\textsuperscript{174} this rate is substantially lower than the rate associated with open surgical treatment and is similar to the rate achieved with nonoperative management. However, patients with complicated acute descending dissection remain susceptible to late events; at 1 year, survival is approximately 70%, and reintervention is needed in about 10% of survivors.\textsuperscript{275}

The ADSORB trial\textsuperscript{276} focused on patients with uncomplicated acute descending thoracic aortic dissection. Patients were randomly assigned to optimal medical therapy alone (n = 31) or endovascular repair plus optimal medical therapy (n = 30).\textsuperscript{277} The 1-year results showed aortic remodeling with false lumen thrombosis and reduced diameter in the group treated with endovascular repair.

The INSTED-XL trial involved 140 patients with stable, early-chronic descending thoracic aortic dissection who were randomly assigned to either endovascular repair plus optimal medical treatment or optimal medical therapy alone.\textsuperscript{211} The eagerly anticipated 5-year data showed that endovascular repair was associated with greater survival and slower disease progression.

**CONCLUSIONS**

Aortic aneurysm may present as localized or extensive disease. The availability and development of adjuncts and endovascular techniques have supported the constant evolution of surgical strategies to tackle these complex problems. Repair strategies range from isolated, totally endovascular aortic repair for descending thoracic aneurysms to extensive total aortic and staged replacements with a combination of both open and endovascular techniques. Regardless of the difficulty of accurately assessing the risks associated with aortic repair, surgical repair of the thoracoabdominal aorta clearly remains the most challenging aortic repair in terms of mortality and morbidity. Accordingly, replacing the entire thoracoabdominal aorta (i.e., performing an extent II repair) carries the highest risk of death, renal failure, and paraplegia.\textsuperscript{69,70,261,263,269}

Key Points

1. Carotid intervention as a preventive strategy should be performed in patients with 60% or greater symptomatic internal carotid artery stenosis and those with 80% or greater asymptomatic internal carotid artery stenosis. Carotid intervention for asymptomatic stenosis between 60% and 79% remains controversial. The modality of carotid intervention—carotid endarterectomy versus carotid stenting—remains controversial; currently, carotid endarterectomy appears to be associated with lower stroke rate with long term durability, whereas carotid stenting is more suitable under certain challenging anatomic or physiologic conditions.

2. Abdominal aortic aneurysms should be repaired when the risk of rupture, determined mainly by aneurysm size, exceeds the risk of death due to perioperative complications or concurrent illness. Endovascular repair with less perioperative morbidity and mortality compared with open reconstruction is preferred in patients with suitable anatomic morphology for stent-graft placement.

3. Treatment objectives for symptomatic mesenteric ischemia are to improve quality of life and prevent bowel infarction. Endovascular intervention with stenting has similar treatment efficacy comparative with less perioperative morbidity compared to open mesenteric bypass. Surgical reconstruction has a proven durability and patency rate compared with endovascular intervention.

4. Aortoiliac occlusive disease can be treated with either endovascular means or open reconstruction, depending on patient risk stratification, occlusion characteristics, and symptomatology.

5. Claudication is a marker of extensive atherosclerosis and is mainly managed with risk factor modification and pharmacotherapy. Only 5% of patients with claudication will need intervention because of disabling extremity pain. The 5-year mortality of a patient with claudication approaches 30%. Patients with rest pain or tissue loss need expedient evaluation and vascular reconstruction to ameliorate the severe extremity pain and prevent limb loss. Endovascular intervention is preferred as the first line of therapy for lower extremity occlusive disease, whereas bypass reconstruction should be considered in failed endovascular therapy or long segment femoropopliteal occlusive disease.

GENERAL APPROACH TO THE VASCULAR PATIENT

Since the vascular system involves every organ system in our body, the symptoms of vascular disease are as varied as those encountered in any medical specialty. Lack of adequate blood supply to target organs typically presents with pain, for example, calf pain with lower extremity claudication, postprandial abdominal pain from mesenteric ischemia, and arm pain with axillo-subclavian arterial occlusion. In contrast, stroke and transient ischemic attack (TIA) are the presenting symptoms from middle cerebral embolization as a consequence of a stenosed internal carotid artery. The pain syndrome of arterial disease is usually divided clinically into acute and chronic types, with all shades of severity between the two extremes. Sudden onset of pain can indicate complete occlusion of a critical vessel, leading to more severe pain and critical ischemia in the target organ, resulting in lower limb gangrene or intestinal infarction. Chronic pain results from a slower, more progressive atherosclerotic occlusion, which can be totally or partially compensated by developing collateral vessels. Acute on chronic is another pain pattern in which a patient most likely has an underlying arterial stenosis that suddenly occludes, for example, the patient with a history of calf claudication who now presents with sudden, severe acute limb-threatening ischemia. The clinician should always try to understand and relate the clinical manifestations to the underlying pathologic process.

The Vascular History

Appropriate history should be focused based on the presenting symptoms related to the vascular system (Table 23-1). Of particular importance in the previous medical history is noting prior vascular interventions (endovascular or open surgical), and all vascular patients should have inquiry made about their prior cardiac history and current cardiac symptoms. Approximately 30% of vascular patients will be diabetic. A history of prior and current smoking status should be noted.

The patient with carotid disease in most cases is completely asymptomatic, having been referred based on the finding of a cervical bruit or duplex finding of stenosis. Symptoms of carotid territory TIs include transient monocular blindness (amaurosis), contralateral weakness or numbness, and dysphasia. Symptoms persisting longer than 24 hours constitute a stroke. In contrast, the patient with chronic mesenteric ischemia is likely to present with postprandial abdominal pain and weight loss. The patient fears eating because of the pain, avoids food, and loses weight. It is very unlikely that a patient with abdominal pain who has not lost weight has chronic mesenteric ischemia.

The patient with lower extremity pain on ambulation has intermittent claudication that occurs in certain muscle groups; for example, calf pain upon exercise usually reflects superficial femoral artery disease, while pain in the buttocks reflects iliac disease. In most cases, the pain manifests in one muscle group below the level of the affected artery, occurs only with exercise, and is relieved with rest only to recur at the same location, hence the term “window gazer’s disease.” Rest pain (a manifestation of severe underlying occlusive disease) is constant and occurs in the foot (not the muscle groups), typically at the metatarsophalangeal junction, and is relieved by dependency. Often the

The Vascular Physical Examination

Specific vascular examination should include abdominal aortic palpation, carotid artery examination, and pulse examination of the lower extremity (femoral, popliteal, posterior tibial, and dorsalis pedis arteries). The abdomen should be palpated for an abdominal aortic aneurysm, detected as an expansile pulse above the level of the umbilicus. It should also be examined for the presence of bruits. Because the aorta typically divides at the level of the umbilicus, an aortic aneurysm is most frequently palpable in the epigastrium. In thin individuals, a normal aortic pulsation is palpable, while in obese patients, even large aortic aneurysms may not be detectable. Suspicion of a clinically enlarged aorta should lead to the performance of an ultrasound scan for a more accurate definition of aortic diameter.

The carotids should be auscultated for the presence of bruits, although there is a higher correlation with coronary artery disease than underlying carotid stenosis. A bruit at the angle of the mandible is a significant finding, leading to follow-up duplex scanning. The differential diagnosis is a transmitted murmur from a sclerotic or stenotic aortic valve. The carotid is palpable deep to the sternocleidomastoid muscle in the neck. Palpation, however, should be gentle and rarely yields clinically useful information.

Upper extremity examination is necessary when an arteriovenous graft is to be inserted in patients who have symptoms of arm pain with exercise. Thoracic outlet syndrome (TOS) can result in occlusion or aneurysm formation of the subclavian artery. Distal embolization is a manifestation of TOS; consequently, the fingers should be examined for signs of ischemia and ulceration. The axillary artery enters the limb below the middle of the clavicle, where it can be palpated in thin patients. It is usually easily palpable in the axilla and medial upper arm. The brachial artery is most easily located at the antecubital fossa immediately medial to the biceps tendon. The radial artery is palpable at the wrist anterior to the radius.

For lower extremity vascular examination, the femoral pulse is usually palpable midway between the anterior superior iliac spine and the pubic tubercle. The popliteal artery is palpated in the popliteal fossa with the knee flexed to 45° and the foot supported on the examination table to relax the calf muscles. Palpation of the popliteal artery is a bimanual technique. Both thumbs are placed on the tibial tuberosity anteriorly, and the fingers are placed into the popliteal fossa between the two heads of the gastrocnemius muscle. The popliteal artery is palpated by compressing it against the posterior aspect of the tibia just below the knee. The posterior tibial pulse is detected by palpation 2 cm posterior to the medial malleolus. The dorsalis pedis is detected 1 cm lateral to the hallucis longus extensor tendon, which dorsiflexes the great toe and is clearly visible on the dorsum of the foot. Pulses can be graded using either the traditional four-point scale or the basic two-point scale system (Table 23-2). The foot should also be carefully examined for pallor on elevation and rubor on dependency, as these findings are indicative of chronic ischemia. Note should also be made of nail changes and loss of hair. Ulceration and other findings specific to disease states are described in relevant sections later in this chapter.

After reconstructive vascular surgery, the graft may be available for examination, depending on its type and course.

The in situ lower extremity graft runs in the subcutaneous fat and can be palpated along most of its length. A change in pulse quality, aneurysmal enlargement, or a new bruit should be carefully noted. Axillofemoral grafts, femoral-to-femoral grafts, and arteriovenous access grafts can usually be easily palpated as well.

Noninvasive Diagnostic Evaluation of the Vascular Patient

Ankle-Brachial Index. There is increasing interest in the use of the ankle-brachial index (ABI) to evaluate patients at risk for cardiovascular events. An ABI less than 0.9 correlates with increased risk of myocardial infarction and indicates significant, although perhaps asymptomatic, underlying peripheral vascular disease. The ABI is determined in the following ways. Blood pressure is measured in both upper extremities using the highest systolic blood pressure as the denominator for the ABI. The ankle pressure is determined by placing a blood pressure cuff above the ankle and measuring the return to flow of the posterior tibial and dorsalis pedis arteries using a pencil Doppler probe over each artery. The ratio of the systolic pressure in each vessel divided by the highest arm systolic pressure can be used to express the ABI in both the posterior tibial and dorsalis pedis arteries (Fig. 23-1). Normal is more than 1. Patients with claudication typically have an ABI in the 0.5 to 0.7 range, and those with rest pain are in the 0.3 to 0.5 range. Those with gangrene have an ABI of less than 0.3. These ranges can vary depending on the degree of compressibility of the vessel. The test is less reliable in patients with heavily calcified vessels. Due to noncompressibility, some patients, such as diabetics and those with end-stage renal disease, may have ABI ≥1.40 and require additional noninvasive diagnostic testing to evaluate for peripheral artery disease. Alternative tests include toe-brachial pressures, pulse volume recordings, transcutaneous oxygen measurements, or vascular imaging (duplex ultrasound).

Segmental Limb Pressures. By placing serial blood pressure cuffs down the lower extremity and then measuring the pressure with a Doppler probe as flow returns to the artery below the cuff, it is possible to determine segmental pressures down the leg. This data can then be used to infer the level of the occlusion. The systolic pressure at each level is expressed as a ratio, with the highest systolic pressure in the upper extremities as the denominator. Normal segmental pressures commonly show high thigh pressures 20 mmHg or greater in comparison to the brachial artery pressures. The low thigh pressure should be equivalent to brachial pressures. Subsequent pressures should fall by no more than 10 mmHg at each level. A pressure gradient of 20 mmHg between two subsequent levels is usually indicative of occlusive disease at that level. The most frequently used index is the ratio of the ankle pressure to the brachial pressure,
Underlying arterial occlusive disease. Cuffs placed at different levels on the leg detect changes in blood volume and produce a pulse volume recording (PVR) when connected to a plethysmograph (Fig. 23-2). To obtain accurate PVR waveforms, the cuff is inflated to 60 to 65 mmHg, so as to detect volume changes without causing arterial occlusion. Pulse volume tracings are suggestive of proximal disease if the upstroke of the pulse is not brisk, the peak of the wave tracing is rounded, and there is disappearance of the dicrotic notch.

Although isolated segmental limb pressures and PVR measurements are 85% accurate when compared with angiography in detecting and localizing significant atherosclerotic lesions, when used in combination, accuracy approaches 95%. For this reason, it is suggested that these two diagnostic modalities be used in combination when evaluating peripheral artery disease.

Radiologic Evaluation of the Vascular Patient

Ultrasound. Ultrasound examinations are relatively time consuming, require experienced technicians, and may not visualize all arterial segments. Doppler waveform analysis can suggest atherosclerotic occlusive disease if the waveforms in the insonated arteries are biphasic, monophasic, or asymmetrical. B-mode ultrasonography provides black and white, real-time images. B-mode ultrasonography does not evaluate blood flow; thus, it cannot differentiate between fresh thrombus and flowing blood, which have the same echogenicity. Calcification in atherosclerotic plaques will cause acoustic shadowing. B-mode ultrasound probes cannot be sterilized. Use of the B-mode probe intraoperatively requires a sterile covering and gel to maintain an acoustic interface. Experience is needed to obtain and interpret images accurately. Duplex ultrasonography entails performance of B-mode imaging, spectral Doppler scanning, and color-flow duplex scanning. The caveat to performance of duplex ultrasonography is meticulous technique by a certified vascular ultrasound technician, so that the appropriate 60° Doppler angle is maintained during insonation with the ultrasound probe. Alteration of this angle can markedly alter waveform appearance and subsequent interpretation of velocity measurements. Direct imaging of intra-abdominal vessels with duplex ultrasound is less reliable because of the difficulty in visualizing the vessels through overlying bowel. These disadvantages currently limit the applicability of duplex scanning in the evaluation of aortoiliac and infrapopliteal disease. A clinical study has shown that duplex ultrasonography had lower sensitivity in the calculation of infrapopliteal vessel stenosis in comparison to conventional digital subtraction or computed tomography angiography. Few surgeons rely solely on duplex ultrasonography for preoperative planning in lower extremity revascularizations; but with experience, lower extremity arteries can be insonated to determine anatomy, and the functional significance of lesions can be determined by calculation of degree of stenosis from velocity ratios. Duplex scanning is unable to evaluate recently implanted polytetrafluoroethylene (PTFE) and polyester (Dacron) grafts because they contain air, which prevents ultrasound penetration.

Computed Tomography Angiography. Computed tomography angiography (CTA) is a noninvasive, contrast-dependent method for imaging the arterial system. It depends on intravenous infusion of iodine-based contrast agents. The patient is advanced through a rotating gantry, which images serial transverse slices. The contrast-filled vessels can be extracted from the slices and rendered in three-dimensional format (Fig. 23-3).
Figure 23-2. Typical report of peripheral vascular study with arterial segmental pressure measurement plus Doppler evaluation of the lower extremity.

The extracted images can also be rotated and viewed from several different directions during postacquisition image processing. This technology has been advanced as a consequence of aortic endografting. CTA provides images for postprocessing that can be used to display the aneurysm in a format that demonstrates thrombus, calcium, lumen, and the outer wall, and allows “fitting” of a proposed endograft into the aneurysm (Fig. 23-4). CTA is increasingly being used to image the carotid bifurcation, and as computing power increases, the speed of image acquisition and resolution will continue to increase. The major limitations of multidetector CTA are use of contrast and presence of artifacts caused by calcification and stents. CTA can

Figure 23-3. A multidetector computed tomography angiography with three-dimensional reconstruction of the iliofemoral arterial circulation in two patients with lower leg claudication. A. Arterial calcifications (single short arrows) are present in the bilateral distal superficial femoral arteries. B. A 53-year-old man with occluded right common iliac artery (double arrows).
overestimate the degree of in-stent stenosis, while heavy calcification can limit the diagnostic accuracy of the method by causing a “blooming artifact.” The artifacts can be overcome with alteration in image acquisition technique. There are no randomized trials to document the superiority of multidetector CTA over traditional angiography, but there is emerging evidence to support the claim that multidetector CTA has sensitivity, specificity, and accuracy that rival invasive angiography.

**Magnetic Resonance Angiography.** Magnetic resonance angiography (MRA) has the advantage of not requiring iodinated contrast agents to provide vessel opacification (Fig. 23-5). Gadolinium is used as a contrast agent for MRA studies, and because it is generally not nephrotoxic, it can be used in patients with elevated creatinine. MRA is contraindicated in patients with pacemakers, defibrillators, spinal cord stimulators, intracerebral shunts, cochlear implants, and cranial clips. Patients with claustrophobia may require sedation to be able to complete the test. The presence of metallic stents causes artifacts and signal drop-out; however, these can be dealt with using alternations in image acquisition and processing. Nitinol stents produce minimal artifact. Compared to other modalities, MRA is relatively slow and expensive. However, due to its noninvasive nature and decreased nephrotoxicity, MRA is being used more frequently for imaging vasculature in various anatomic distributions.

**Diagnostic Angiography.** Diagnostic angiography is considered the gold standard in vascular imaging. In many centers, its use is rapidly decreasing due to the development of noninvasive imaging modalities such as duplex arterial mapping, CTA, and MRA. Nevertheless, contrast angiography still remains in widespread use. The essential aspects of angiography are vascular access and catheter placement in the vascular bed that requires examination. The imaging system and the contrast agent are used to opacify the target vessel. Although in the past this function has largely been delegated to the interventional radiology service, an increasing number of surgeons are performing this procedure and following the diagnostic imaging with immediate surgical or endovascular intervention. There are several considerations when relying on angiography for imaging.

Approximately 70% of atherosclerotic plaques occur in an eccentric location within the blood vessel; therefore, images can be misleading when trying to evaluate stenoses because angiography is limited to a uniplanar “lumenogram.” With increased use of intravascular stent deployment, it has also been noted that assessment of stent apposition and stent position in relation to surrounding branches may be inaccurate. Furthermore, angiography exposes the patient to the risks of both ionizing radiation and intravascular contrast. Nevertheless, contrast angiography remains the most common invasive method of vascular investigation for both diagnostic and therapeutic intervention. The angiogram usually provides the final information needed to decide whether or not to proceed with operation or endovascular interventions.

Digital subtraction angiography (DSA) offers some advantages over conventional cut-film angiography such as excellent visualization despite use of lower volumes of contrast media. In particular, when multilevel occlusive lesions limit the amount of contrast reaching distal vessels, supplemental use of digital subtraction angiographic techniques may enhance visualization and definition of anatomy. Intra-arterial DSA uses a portable, axially
rotatable imaging device that can obtain views from different angles. DSA also allows for real-time video replay (Fig. 23-6). An entire extremity can be filmed with DSA using repeated injections of small amounts of contrast agent to obtain sequential angiographic images, the so-called pulse-chase technique.

**Preoperative Cardiac Evaluation**

The most important and most controversial aspect of preoperative evaluation in patients with atherosclerotic disease requiring surgical intervention is the detection and subsequent management of associated coronary artery disease. Several studies have documented the existence of significant coronary artery disease in 40% to 50% or more of patients requiring peripheral vascular reconstructive procedures, 10% to 20% of whom may be relatively asymptomatic largely because of their inability to exercise. Myocardial infarction is responsible for the majority of both early and late postoperative deaths. Most available screening methods lack sensitivity and specificity to predict postoperative cardiac complications. There have been conflicting reports regarding the utility of preoperative dipyridamole-thallium nuclear imaging or dobutamine-echocardiography to stratify vascular patients in terms of perioperative cardiac morbidity and mortality. In nearly half of patients, thallium imaging proves to be unnecessary because cardiac risk can be predicted by clinical information alone. Even with coronary angiography, it is difficult to relate anatomic findings to functional significance and, hence, surgical risk. There are no data confirming that percutaneous coronary interventions or surgical revascularization prior to vascular surgical procedures impact mortality or incidence of myocardial infarctions. In fact, coronary angiography is associated with its own inherent risks, and patients undergoing coronary artery bypass grafting or coronary percutaneous transluminal angioplasty (PTA) before needed aortoiliac reconstructions are subjected to the risks and complications of both procedures.

The Coronary Artery Revascularization Prophylaxis (CARP) trial showed that coronary revascularization in patients with peripheral vascular disease and significant coronary artery disease, who are considered high risk for perioperative complications, did not reduce overall mortality or perioperative myocardial infarction. Additionally, patients who underwent prophylactic coronary revascularization had significant delays prior to undergoing their vascular procedure and increased limb morbidity compared to patients who did not. Studies do support improvement in cardiovascular and overall prognosis with medical optimization of patients. Therefore, use of perioperative β-blockade, as well as use of antiplatelet medication, statins, and angiotensin-converting enzyme inhibitors, is encouraged in vascular patients.

![Figure 23-6. Digital subtraction angiography (DSA) provides excellent visualization of intravascular circulation with intra-arterial contrast administration. As depicted in this DSA study, multilevel lesions are demonstrated, which include a focal left iliac artery stenosis (large arrow), right superficial femoral occlusion (curved arrows), left superficial femoral stenosis (small arrow), and multiple tibial artery stenoses (arrowheads).](image-url)
in a manner that would enable an accurate comparison with the more traditional methods of open surgical intervention. Long-term follow-up for these procedures is frequently lacking; however, because of the potential to treat patients with decreased mortality and morbidity, endovascular skills and techniques are being adopted into mainstream vascular surgery.

**Needles and Access**

Needles are used to achieve percutaneous vascular access. The size of the needle will be dictated by the diameter of the guidewire used. Most often, an 18-gauge needle is used, as it will accept a 0.035-inch guidewire. A 21-gauge micropuncture needle will accept a 0.018-inch guidewire. The most popular access needle is the Seldinger needle, which can be used for single- and double-wall puncture techniques.

Femoral arterial puncture is the most common site for access. The common femoral artery (CFA) is punctured over the medial third of the femoral head, which is landmarked using fluoroscopy. The single-wall puncture technique requires a sharp, beveled needle tip and no central stylet. The anterior wall of the vessel is punctured with the bevel of the needle pointing up, and pulsatile back-bleeding indicates an intraluminal position. This method is most useful for graft punctures, patients with abnormal clotting profiles, or if thrombolytic therapy is anticipated. Once the needle assumes an intraluminal position, verified by pulsatile back-bleeding, the guidewire may be advanced. This is always passed gently and under fluoroscopic guidance to avoid subintimal dissection or plaque disruption. Double-wall puncture techniques are performed with a blunt needle that has a removable inner cannula. The introducer needle punctures both walls of the artery and is withdrawn until bleeding is obtained to confirm intraluminal position prior to advancing a guidewire. There can be troublesome bleeding from the posterior arterial wall puncture; therefore, single puncture techniques are preferred.

Retrograde femoral access is the most common arterial access technique (Fig. 23-7). The advantages of this technique include the size and fixed position of the CFA, as well as the relative ease of compression against the femoral head at the end of the procedure. Care should be taken to avoid puncturing the external iliac artery above the inguinal ligament because this can result in retroperitoneal hemorrhage secondary to ineffective compression of the puncture site. Likewise, puncturing too low, at or below the CFA bifurcation, can result in thrombosis or pseudoaneurysm formation of the superficial femoral artery (SFA) or profunda femoris artery (PFA). Antegrade femoral access is more difficult than retrograde femoral access, and there is a greater tendency to puncture the SFA, but it is invaluable when the aortic bifurcation cannot be traversed or when devices are not long enough to reach a lesion from a contralateral femoral access approach. Occasionally, when the distal aorta or bilateral iliac arteries are inaccessible because of the extent of atherosclerotic lesions, scarring, or presence of bypass conduits, the brachial artery must be used to obtain access for diagnostic and therapeutic interventions. The left brachial artery is punctured because this avoids the origin of the carotid artery and thus decreases the risk of catheter-related emboli to the brain. The artery is accessed with a micropuncture needle just proximal to the antecubital crease. The use of brachial access is associated with a higher risk of thrombosis and nerve injuries than femoral access.

**Guidewires**

Guidewires are used to introduce, position, and exchange catheters. A guidewire generally has a flexible and stiff end. In general, only the flexible end of the guidewire is placed in the vessel. All guidewires are composed of a stiff inner core and an outer tightly coiled spring that allows a catheter to track over the guidewire. There are five essential characteristics of guidewires: size, length, stiffness, coating, and tip configuration.

Guidewires come in different maximum transverse diameters, ranging from 0.011 to 0.038 inches. For most aortoiliac procedures, a 0.035-inch wire is most commonly used, whereas the smaller diameter 0.018-inch guidewires are reserved for selective small vessel angiography such as infrageniculate or carotid lesions. In addition to diameter size, guidewires come in varying lengths, usually ranging from 180 to 260 cm in length. Increasing the length of the wire always makes it more difficult to handle and increases the risk of contamination. While performing a procedure, it is important to maintain the guidewire across the lesion until the completion arteriogram has been satisfactorily completed.

The stiffness of the guidewire is also an important characteristic. Stiff wires allow for passage of large aortic stent graft devices without kinking. They are also useful when trying to perform sheath or catheter exchanges around a tortuous artery. An example of a stiff guidewire is the Amplatz wire. Hydrophilic coated guidewires, such as the Glidewire, have become invaluable tools for assisting in difficult catheterizations. The coating is primed by bathing the guidewire in saline solution. The slippery nature of this guidewire along with its torque capability significantly facilitate in difficult catheterizations. Guidewires also come in various tip configurations. Angled tip wires like the angled Glidewire can be steered to manipulate a catheter across a tight stenosis or to select a specific branch of a vessel. The Rosen wire has a soft curved end, which makes it ideal for renal artery stenting. The soft curl of this wire prevents it from perforating small renal branch vessels.
Hemostatic Sheaths
The hemostatic sheath is a device through which endovascular procedures are performed. The sheath acts to protect the vessel from injury as wires and catheters are introduced (Fig. 23-8). A one-way valve prevents bleeding through the sheath, and a side-port allows contrast or heparin flushes to be administered during the procedure. Sheaths are sized by their inner diameter. The most commonly used sheaths for percutaneous access have a 5- to 9-French inner diameter, but with open surgical exposure of the CFA, sheaths as large as 26 French can be introduced. Sheaths also vary in length, and long sheaths are available so that interventions remote from the site of arterial access can be performed.

Catheters
A wide variety of catheters exist that differ primarily in the configuration of the tip. The multiple shapes permit access to vessels of varying dimensions and angulations. Catheters are used to perform angiography and protect the passage of balloons and stents, and they can be used to direct the guidewire through tight stenoses or tortuous vessels.

Angioplasty Balloons
Angioplasty balloons differ primarily in their length and diameter, as well as the length of the catheter shaft. As balloon technology has advanced, lower profiles have been manufactured (i.e., the size that the balloon assumes upon deflation). Balloons are used to perform angioplasty on vascular stenoses, to deploy stents, and to assist with additional expansion after insertion of self-expanding stents (Fig. 23-9). Besides length and diameter, operators need to be familiar with several other balloon characteristics. Noncompliant and low-compliance balloons tend to be inflated to their preset diameter and offer greater dilating force at the site of stenosis. Low-compliance balloons are the mainstay for peripheral intervention. Lower profile balloons are less likely to get caught during passage through stents and are easier to pull out of sheaths. Under fluoroscopic guidance, balloon inflation is performed until the waist of the atherosclerotic lesion disappears and the balloon is at the full profile. The duration of balloon inflation and pressures used for the angioplasty depend on the indication for the intervention and the location and characteristics of the lesion being treated. Frequently, several inflations are required to achieve a full profile of the balloon. Occasionally, a lower profile balloon is needed to predilate the tight stenosis so that the selected balloon catheter can cross the lesion. After inflation, most balloons do not regain their preinflation diameter and assume a larger profile. Trackability, pushability, and cross-ability of the balloon should all be considered when choosing a particular balloon. Lastly, shoulder length is an important characteristic to consider when selecting a balloon because of the potential to cause injury during performance of PTA in adjacent arterial segments. There is always risk of causing dissection or rupture during PTA; thus, a completion angiogram is performed while the wire is still in place. Leaving the wire in place provides access for repeating the procedure, placing a stent or stent graft if warranted.

Stents
Vascular stents are commonly used after an inadequate angioplasty with dissection or elastic recoil of an arterial stenosis. They serve to buttress collapsible vessels and help prevent atherosclerotic restenosis. Appropriate indications for primary stenting of a lesion without an initial trial of angioplasty alone are evolving in manners that are dependent on the extent and site of the lesion. Stents are manufactured from a variety of metals including stainless steel, tantalum, cobalt-based alloy,

Figure 23-8. All percutaneous endovascular procedures are performed through an introducer sheath (large arrow), which provides an access conduit from skin to intravascular compartment. The sheath also acts to protect the vessel from injury as guidewires (small arrows) and catheters are introduced.

Figure 23-9. A. An artery with luminal narrowing caused by plaque. B. A balloon angioplasty catheter is positioned within the diseased artery, which is inflated to enlarge the intravascular channel. C. The plaque is compressed with widened flow lumen as the result of balloon angioplasty.
and nitinol. Vascular stents are classified into two basic categories: balloon-expandable stents and self-expanding stents.

Self-expanding stents (Fig. 23-10) are deployed by retracting a restraining sheath and usually consist of Elgiloy (a cobalt, chromium, nickel alloy) or nitinol (a shape memory alloy composed of nickel and titanium), the latter of which will contract and assume a heat-treated shape above a transition temperature that depends on the composition of the alloy. Self-expanding stents will expand to a final diameter that is determined by stent geometry, hoop strength, and vessel size. The self-expanding stent is mounted on a central shaft and is placed inside an outer sheath. It relies on a mechanical spring-like action to achieve expansion. With deployment of these stents, there is some degree of foreshortening that has to be taken into account when choosing the area of deployment. In this way, self-expanding stents are more difficult to place with absolute precision. There are several advantages related to self-expanding stents. Self-expanding stents generally come in longer lengths than balloon-expandable stents and are therefore used to treat long and tortuous lesions. Their ability to continually expand after delivery allows them to accommodate adjacent vessels of different size. This makes these stents ideal for placement in the internal carotid artery. These stents are always oversized by 1 to 2 mm relative to the largest diameter of normal vessel adjacent to the lesion in order to prevent immediate migration.

Balloon-expandable stents are usually composed of stainless steel, mounted on an angioplasty balloon, and deployed by balloon inflation (Fig. 23-11). They can be manually placed on a chosen balloon catheter or obtained premounted on a balloon catheter. The capacity of a balloon-expandable stent to shorten in length during deployment depends on both stent geometry and the final diameter to which the balloon is expanded. These stents are more rigid and are associated with a shorter time to complete endothelialization. They are often of limited flexibility and have a higher degree of crush resistance when compared to self-expanding stents. This makes them ideal for short-segment lesions, especially those that involve the ostia such as proximal common iliac or renal artery stenosis.

An important area of evolution in endovascular therapy in recent years is the development of drug-eluting stents (DES). These stents are usually composed of nitinol and have various anti-inflammatory drugs bonded to them. Over time, the stents release the drug into the surrounding arterial wall and help prevent restenosis. Numerous randomized controlled trials have proven their benefit in coronary arteries. Clinical studies have similarly proved early efficacy of DES in the treatment of peripheral arterial disease.

**Stent Grafts**

The combination of a metal stent covered with fabric gave birth to the first stent grafts. Covered stents have been designed with either a surrounding PTFE or polyester fabric and have been used predominantly for treatment of traumatic vascular lesions, including arterial disruption and arteriovenous fistulas (Fig. 23-12). However, these devices may well find a growing role in treatment of iliac or femoral arterial occlusive disease as well as popliteal aneurysms.

Endovascular aneurysm repair using the concept of stent grafts was initiated by Parodi in 1991. Since that time, a large number of endografts have been inserted under the auspice of clinical trials initially and now as Food and Drug Administration (FDA)-approved devices. Currently there are more than

![Figure 23-10](image1.png) **Figure 23-10.** Self-expanding stents are made of tempered stainless steel or nitinol, an alloy of nickel and titanium, and are restrained when folded inside a delivery catheter. After being released from the restraining catheter, the self-expanding stents will expand to a final diameter that is determined by stent geometry, hoop strength, and vessel size.

![Figure 23-11](image2.png) **Figure 23-11.** In a balloon-expandable stent, the stent is pre-mounted on a balloon catheter. The balloon stretches the stent members beyond their elastic limit. The stent is deployed by full balloon expansion. This type of stent has a higher degree of crush resistance when compared to self-expanding stents, which is ideal for short-segment calcified ostial lesions.
eighth FDA-approved endovascular devices for abdominal aortic aneurysm repair. In general, majority of these devices require that patients have an infrarenal aneurysm with at least a 15-mm proximal aortic neck below the renal arteries and not greater than 60° of angulation. For those patients with associated common iliac artery aneurysmal disease, endovascular treatment can be achieved by initial coil embolization of the ipsilateral hypogastric artery with extension of the endovascular device into the external iliac artery. Newer generation devices with branched endograft can be deployed in the internal iliac artery while maintain in-line flow from the common iliac to external iliac artery to exclude the common iliac artery aneurysm. Recent clinical trials have demonstrated clinical efficacy of fenestrated aortic endograft in treating aneurysm involving the visceral segment of the abdominal aorta. The FDA has similarly approved several thoracic endograft devices for the treatment of descending thoracic aortic aneurysm. Clinical studies have similarly demonstrated durability and efficacy of thoracic aortic devices in patients with traumatic aortic transections and aortic dissections.

CAROTID ARTERY DISEASE

Atherosclerotic occlusive plaque is by far the most common pathology seen in the carotid artery bifurcation. Thirty percent to 60% of all ischemic strokes are related to atherosclerotic carotid bifurcation occlusive disease. In the following section, we first focus our discussion on the clinical presentation, diagnosis, and management—including medical therapy, surgical carotid endarterectomy, and stenting—of atherosclerotic carotid occlusive disease. In the second part of the section, we provide a review on other less common nonatherosclerotic diseases involving the extracranial carotid artery, including kink and coil, fibromuscular dysplasia, arterial dissection, aneurysm, radiation arteritis, Takayasu’s arteritis, and carotid body tumor.

Epidemiology and Etiology of Carotid Occlusive Disease

Approximately 700,000 Americans suffer a new or recurrent stroke each year. Eighty-five percent of all strokes are ischemic, and 15% are hemorrhagic. Hemorrhagic strokes are caused by head trauma or spontaneous disruption of intracerebral blood vessels. Ischemic strokes are due to hypoperfusion from arterial occlusion or, less commonly, to decreased flow resulting from proximal arterial stenosis and poor collateral network. Common causes of ischemic strokes are cardiogenic emboli in 35%, carotid artery disease in 30%, lacunar in 10%, miscellaneous in 10%, and idiopathic in 15%. The term cerebrovascular accident is often used interchangeably to refer to an ischemic stroke. A transient ischemic attack (TIA) is defined as a temporary focal cerebral or retinal hypoperfusion state that resolves spontaneously within 24 hours after its onset. However, the majority of TIs resolve within minutes, and longer-lasting neurologic deficits more likely represent a stroke. Recently, the term brain attack has been coined to refer to an acute stroke or TIA, denoting the condition as a medical emergency requiring immediate attention, similar to a heart attack.

Stroke due to carotid bifurcation occlusive disease is usually caused by atheroemboli (Fig. 23-13). The carotid bifurcation is an area of low flow velocity and low shear stress. As the blood circulates through the carotid bifurcation, there is separation of flow into the low-resistance internal carotid artery and the high-resistance external carotid artery. Characteristically, atherosclerotic plaque forms in the outer wall opposite to the flow divider (Fig. 23-14). Atherosclerotic plaque formation is complex, beginning with intimal injury, platelet deposition, smooth muscle cell proliferation, and fibroplasia, and leading to subsequent luminal narrowing. With increasing degree of stenosis in the internal carotid artery, flow becomes more turbulent, and the risk of atheroembolization escalates. The severity of stenosis is commonly divided into three categories according to the luminal diameter reduction: mild (<50%), moderate (50–69%), and severe (70–99%). Severe carotid stenosis is a strong predictor for stroke. In turn, a prior history of neurologic symptoms (TIA or stroke) is an important determinant for recurrent ipsilateral stroke. The risk factors for the development of carotid artery bifurcation disease are similar to those causing atherosclerotic occlusive disease in other vascular beds. Increasing age, male gender, hypertension, tobacco smoking, diabetes mellitus, homocysteinemia, and hyperlipidemia are well-known predisposing factors for the development of atherosclerotic occlusive disease.

Clinical Manifestations of Cerebral Ischemia

TIA is a focal loss of neurologic function, lasting for less than 24 hours. Crescendo TIAs refer to a syndrome comprising repeated TIAs within a short period of time that is characterized by complete neurologic recovery in between. At a minimum, the term should probably be reserved for those with either daily events or multiple resolving attacks within 24 hours.
extracranial disease and poor intracranial collateral recruitment. Reversible ischemic neurologic deficits refer to ischemic focal neurologic symptoms lasting longer than 24 hours but resolving within 3 weeks. When a neurologic deficit lasts longer than 3 weeks, it is considered a completed stroke. Stroke in evolution refers to progressive worsening of the neurologic deficit, either linearly over a 24-hour period or interspersed with transient periods of stabilization and/or partial clinical improvement.

Patients who suffer cerebrovascular accidents typically present with three categories of symptoms including ocular symptoms, sensory/motor deficit, and/or higher cortical dysfunction. The common ocular symptoms associated with extracranial carotid artery occlusive disease include amaurosis fugax and presence of Hollenhorst plaques. Amaurosis fugax, commonly referred to as transient monocular blindness, is a temporary loss of vision in one eye that patients typically describe as a window shutter coming down or grey shedding of the vision. This partial blindness usually lasts for a few minutes and then resolves. Most of these phenomena (>90%) are due to embolic occlusion of the main artery or the upper or lower divisions. Monocular blindness progressing over a 20-minute period suggests a migrainous etiology. Occasionally, the patient will recall no visual symptoms while the optician notes a yellowish plaque within the retinal vessels, which is also known as Hollenhorst plaque. These plaques are frequently derived from cholesterol embolization from the carotid bifurcation and warrant further investigation. Additionally, several ocular symptoms may be caused by microembolization from extracranial carotid diseases including monocular visual loss due to retinal artery or optic nerve ischemia, the ocular ischemia syndrome, and visual field deficits secondary to cortical infarction and ischemia of the optic tracts. Typical motor and/or sensory symptoms associated with cerebrovascular accidents are lateralized or focal neurologic deficits. Ischemic events tend to have an abrupt onset, with the severity of the insult being apparent from the onset and not usually associated with seizures or paresthesia. In contrast, they represent loss or diminution of neurologic function. Furthermore, motor or sensory deficits can be unilateral or

Hemodynamic TIAs represent focal cerebral events that are aggravated by exercise or hemodynamic stress and typically occur after short bursts of physical activity, postprandially, or after getting out of a hot bath. It is implied that these are due to severe

Figure 23-13. Stroke due to carotid bifurcation occlusive disease is usually caused by atheroemboli arising from the internal carotid artery, which provides the majority of blood flow to the cerebral hemisphere. With increasing degree of stenosis in the carotid artery, flow becomes more turbulent, and the risk of atheroembolization escalates.

Figure 23-14. A. The carotid bifurcation is an area of low flow velocity and low shear stress. As the blood circulates through the carotid bifurcation, there is separation of flow into the low-resistance internal carotid artery and the high-resistance external carotid artery. B. The carotid atherosclerotic plaque typically forms in the outer wall opposite to the flow divider due in part to the effect of the low shear stress region, which also creates a transient reversal of flow during the cardiac cycle.
bilateral, with the upper and lower limbs being variably affected depending on the site of the cerebral lesion. The combination of a motor and sensory deficit in the same body territory is suggestive of a cortical thromboembolic event as opposed to lacunar lesions secondary to small vessel disease of the penetrating arterioles. However, a small proportion of the latter may present with a sensorimotor stroke secondary to small vessel occlusion within the posterior limb of the internal capsule. Pure sensory and pure motor strokes and those strokes where the weakness affects one limb only or does not involve the face are more typically seen with lacunar as opposed to cortical infarction. A number of higher cortical functions, including speech and language disturbances, can be affected by thromboembolic phenomena from the carotid artery, with the most important clinical example for the dominant hemisphere being dysphasia or aphasia and visuospatial neglect being an example of nondominant hemisphere injury.

**Diagnostic Evaluation**

Duplex ultrasonography is the most widely used screening tool to evaluate for atherosclerotic plaque and stenosis of the extracranial carotid artery. It is also commonly used to monitor patients serially for progression of disease or after intervention (carotid endarterectomy or angioplasty). Duplex ultrasound of the carotid artery combines B-mode gray-scale imaging and Doppler waveform analysis. Characterization of the carotid plaque on gray-scale imaging provides useful information about its composition. However, there are currently no universal recommendations that can be made based solely on the sonographic appearance of the plaque. On the other hand, criteria have been developed and well refined for grading the degree of carotid stenosis based primarily on Doppler-derived velocity waveforms.

The external carotid artery has a high-resistance flow pattern with a sharp systolic peak and a small amount of flow in diastole. In contrast, a normal internal carotid artery will have a low-resistance flow pattern with a broad systolic peak and a large amount of flow during diastole. The flow pattern in the common carotid artery resembles that in the internal carotid artery, as 80% of the flow is directed to the internal carotid artery, with waveforms that have broad systolic peaks and moderate amount of flow during diastole. Conventionally, velocity measurements are recorded in the common, external, carotid bulb, and the proximal, mid, and distal portions of the internal carotid artery. Characteristically, the peak systolic velocity is increased at the site of the vessel stenosis. The end-diastolic velocity is increased with greater degree of stenosis. In addition, stenosis of the internal carotid artery can lead to color shifts with color mosaics indicating a poststenotic turbulence. DAMPENING of the Doppler velocity waveforms is typically seen in areas distal to severe carotid stenosis where blood flow is reduced. It is well known that occlusion of the ipsilateral internal carotid artery can lead to a “falsely” elevated velocity on the contralateral side due to an increase in compensatory blood flow. In the presence of a high-grade stenosis or occlusion of the internal carotid artery, the ipsilateral common carotid artery displays high flow resistance waveforms, similar to those seen in the external carotid artery. If there is a significant stenosis in the proximal common carotid artery, its waveforms may be damped with low velocities.

The Doppler grading systems of carotid stenosis were initially established by comparison to angiographic findings of disease. Studies have shown variability in the measurements of the duplex properties by different laboratories, as well as heterogeneity in the patient population, study design, and techniques. One of the most commonly used classifications was established at the University of Washington School of Medicine in Seattle, Washington. Diameter reduction of 50% to 79% is defined by peak systolic velocity greater than 125 cm/s with extensive spectral broadening. For stenosis in the range of 80% to 99%, the peak systolic velocity is greater than 125 cm/s, and peak diastolic velocity is greater than 140 cm/s. The ratio of internal carotid to common carotid artery peak systolic velocity has also been part of various ultrasound diagnostic classifications. A ratio greater than 4 is a great predictor of angiographic stenosis of 70% to 99%. A multispecialty consensus panel has developed a set of criteria for grading carotid stenosis by duplex examination (Table 23-3).

MRA is increasingly being used to evaluate for atherosclerotic carotid occlusive disease and intracranial circulation. MRA is noninvasive and does not require iodinated contrast agents. MRA uses phase contrast or time-of-flight, with either two-dimensional or three-dimensional data sets for greater accuracy. Three-dimensional contrast-enhanced MRA allows data to be obtained in coronal and sagittal planes with improved image qualities due to shorter study time. In addition, the new MRA techniques allow for better reformation of images in various planes to allow better grading of stenosis. There have been numerous studies comparing the sensitivity and specificity of

MRA imaging for carotid disease to duplex and selective contrast angiography. Magnetic resonance imaging (MRI) of the brain is essential in the assessment of acute stroke patients. MRI with diffusion-weighted imaging can differentiate areas of acute ischemia, areas still at risk for ischemia (penumbra), and chronic cerebral ischemic changes. However, computed tomography (CT) imaging remains the most expeditious test in the evaluation of acute stroke patients to rule out intracerebral hemorrhage. Recently, multidetector CTA has gained increasing popularity in the evaluation of carotid disease. This imaging modality can provide volume rendering, which allows rotation of the object with accurate anatomic structures from all angles (Fig. 23-15). The advantages of CTA over MRA include faster data acquisition time and better spatial resolution. However, grading of carotid stenosis by CTA requires further validation at the time of this writing before it can be widely applied.

Historically, DSA has been the gold standard test to evaluate the extra- and intracranial circulation (Fig. 23-16). This is an invasive procedure, typically performed via a transfemoral puncture, and involves selective imaging of the carotid and vertebral arteries using iodinated contrast. The risk of stroke during cerebral angiography is generally reported at approximately 1% and is typically due to atheroembolization related to wire and catheter manipulation in the arch aorta or proximal branch vessels. Over the last few decades, however, the incidence of neurologic complications following angiography has been reduced, due to the use of improved guidewires and catheters, better resolution digital imaging, and increased experience. Local access complications of angiography are infrequent and include development of hematoma, pseudoaneurysm, distal embolization, and acute vessel thrombosis. Currently, selective angiography is particularly used for patients with suspected intracranial disease and for patients in whom percutaneous revascularization is considered. The techniques of carotid angioplasty and stenting for carotid bifurcation occlusive disease are described in detail later in this chapter. We generally use CTA or MRA to get information about the aortic arch anatomy and presence of concomitant intracranial disease and collateral pathway in planning our strategy for carotid stenting or endarterectomy.

Treatment of Carotid Occlusive Disease
Conventionally, patients with carotid bifurcation occlusive disease are divided into two broad categories: patients without prior history of ipsilateral stroke or TIA (asymptomatic) and those with prior or current ipsilateral neurologic symptoms (symptomatic). It is estimated that 15% of all strokes are preceded by a TIA. The 90-day risk of a stroke in a patient presenting with a TIA is 3% to 17%. According to the Cardiovascular Health Study, a longitudinal population-based study of coronary artery disease and stroke in men and women, the prevalence of TIA in men was 2.7% for ages of 65 and 69 and 3.6% for ages 75 to 79; the prevalence in women was 1.4% and 4.1%, respectively. There have been several studies reporting on the effectiveness of stroke prevention with medical treatment and carotid endarterectomy for symptomatic patients with moderate to severe carotid stenosis. Early and chronic aspirin therapy has been shown to reduce stroke recurrence rate in several large clinical trials.

Symptomatic Carotid Stenosis
Currently, most stroke neurologists prescribe both aspirin and clopidogrel for secondary

Figure 23-15. A. Carotid computed tomography angiography is a valuable imaging modality that can provide a three-dimensional image reconstruction with high image resolution. A carotid artery occlusion is noted in the internal carotid artery B. The entire segment of extracranial carotid artery is visualized from the thoracic compartment to the base of skull.

Figure 23-16. A carotid angiogram reveals an ulcerated carotid plaque (arrow) in the proximal internal carotid artery, which also resulted in a high-grade internal carotid artery stenosis.
stroke prevention in patients who have experienced a TIA or stroke. In patients with symptomatic carotid stenosis, the degree of stenosis appears to be the most important predictor in determining risk for an ipsilateral stroke. The risk of a recurrent ipsilateral stroke in patients with severe carotid stenosis approaches 40%. Two large multicenter randomized clinical trials, the European Carotid Surgery Trial (ECST) and the North American Symptomatic Carotid Endarterectomy Trial (NASCET), have both shown a significant risk reduction in stroke for patients with symptomatic high-grade stenosis (70–99%) undergoing carotid endarterectomy when compared to medical therapy alone.20,21 Although there has been much discussion regarding the different methodologies used in the measurement of carotid stenosis and calculation of the lifetable data between the two studies, both of these studies had similar clinical results. The findings of these two landmark trials have also been reanalyzed in many subsequent publications. The main conclusions of the trials remain validated and widely acknowledged. Briefly, the NASCET study showed that for high-grade carotid stenosis, the cumulative risk of ipsilateral stroke was 26% in the medically treated group and 9% in the surgically treated group at 2 years. For patients with moderate carotid artery stenosis (50–69%), the benefit of carotid endarterectomy is less but still favorable when compared to medical treatment alone; the 5-year fatal or nonfatal ipsilateral stroke rate was 16% in the surgically treated group versus 22% in the medically treated group.22 The risk of stroke was similar for the remaining group of symptomatic patients with less than 50% carotid stenosis, whether they had endarterectomy or medical treatment alone. The ECST reported similar stroke risk reduction for patients with severe symptomatic carotid stenosis and no benefit in patients with mild stenosis when carotid endarterectomy was performed versus medical therapy.21

The optimal timing of carotid intervention after acute stroke, however, remains debatable. Earlier studies showed an increased rate of postoperative stroke exacerbation and conversion of a bland to hemorrhagic infarction when carotid endarterectomy was carried out within 5 to 6 weeks after acute stroke. The dismal outcome reported in the early experience was likely related to poor patient selection. The rate of stroke recurrence is not insignificant during the interval period and may be reduced with early intervention for symptomatic carotid stenosis. Contemporary series have demonstrated acceptable low rates of perioperative complications in patients undergoing carotid endarterectomy within 4 weeks after acute stroke.22 In a recent retrospective series, carotid artery stenting when performed early (<2 weeks) after the acute stroke was associated with higher mortality than when delayed (>2 weeks).23

Asymptomatic Carotid Stenosis. Whereas there is universal agreement that carotid revascularization (endarterectomy or stenting) is effective in secondary stroke prevention for patients with symptomatic moderate and severe carotid stenosis, the management of asymptomatic patients remains an important controversy to be resolved. Generally, the detection of carotid stenosis in asymptomatic patients is related to the presence of a cervical bruit or based on screening duplex ultrasound findings. In one of the earlier observational studies, the authors showed that the annual occurrence rate of neurologic symptoms was 4% in a cohort of 167 patients with asymptomatic cervical bruits followed prospectively by serial carotid duplex scan.24 The mean annual rate of carotid stenosis progression to a greater than 50% stenosis was 8%. The presence of or progression to a greater than 80% stenosis correlated highly with either the development of a total occlusion of the internal carotid artery or new symptoms. The major risk factors associated with disease progression were cigarette smoking, diabetes mellitus, and age. This study supported the contention that it is prudent to follow a conservative course in the management of asymptomatic patients presenting with a cervical bruit.

One of the first randomized clinical trials on the treatment of asymptomatic carotid artery stenosis was the Asymptomatic Carotid Atherosclerosis Study (ACAS), which evaluated the benefits of medical management with antiplatelet therapy versus carotid endarterectomy.25 Over a 5-year period, the risk of ipsilateral stroke in individuals with a carotid artery stenosis greater than 60% was 5.1% in the surgical arm. On the other hand, the risk of ipsilateral stroke in patients treated with medical management was 11%. Carotid endarterectomy produced a relative risk reduction of 53% over medical management alone. The results of a larger randomized trial from Europe, the Asymptomatic Carotid Surgery Trial (ACST), recently confirmed similar beneficial stroke risk reduction for patients with asymptomatic, greater than 70% carotid stenosis undergoing endarterectomy versus medical therapy.26 An important point derived from this latter trial was that even with improved medical therapy, including the addition of statin drugs and clopidogrel, medical therapy was still inferior to endarterectomy in the primary stroke prevention for patients with high-grade carotid artery stenosis. It is generally agreed that asymptomatic patients with severe carotid stenosis (80–99%) are at significantly increased risk for stroke and stand to benefit from either surgical or endovascular revascularization. However, revascularization for asymptomatic patients with a less severe degree of stenosis (60–79%) remains controversial.

**Carotid Endarterectomy Versus Angioplasty and Stenting**

Currently, the argument is no longer whether medical therapy alone is inferior to surgical endarterectomy in stroke prevention for severe carotid stenosis. Rather, the debate now revolves around whether carotid angioplasty and stenting produce the same benefits demonstrated by carotid endarterectomy. Since carotid artery stenting was approved by the FDA for clinical application in 2004, this percutaneous procedure has become a treatment alternative in patients who are deemed “high risk” for endarterectomy (Table 23-4). In contrast to many endovascular peripheral arterial interventions, percutaneous carotid stenting represents a much more challenging procedure, because it requires complex catheter-based skills using the 0.014-inch guidewire system and distal protection device. Moreover, current carotid stent devices predominantly use the monorail guidewire system, which requires more technical agility compared with the over-the-wire catheter system that is routinely used in peripheral interventions. This percutaneous intervention often requires balloon angioplasty and stent placement through a long carotid guiding sheath via a groin approach. Poor technical skills can result in devastating treatment complications such as stroke, which can occur in part due to plaque embolization during the balloon angioplasty and stenting of the carotid artery. Because of these various procedural components that require high technical proficiency, many early clinical investigations of carotid artery stenting, which included physicians with little or no carotid stenting experience, resulted in alarmingly poor

Clinical outcomes. A Cochrane review noted that, before 2006, a total of 1269 patients had been studied in five randomized controlled trials comparing percutaneous carotid intervention and surgical carotid reconstruction.27 Taken together, these trials revealed that carotid artery stenting had a greater procedural risk of stroke and death when compared to carotid endarterectomy (odds ratio, 1.33; 95% confidence interval, 0.86–2.04). Additionally, a greater incidence of carotid restenosis was noted in the stenting group than the endarterectomy cohorts.

However, the constant improvement of endovascular devices, procedural techniques, and adjunctive pharmacologic therapy will likely improve the treatment success of percutaneous carotid intervention. Critical appraisals of several prospective randomized trials comparing the efficacy of carotid stenting versus endarterectomy are available for review.28 Two recently published randomized controlled trial, the Carotid Revascularization Endarterectomy Versus Stent Trial (CREST) and the International Carotid Stenting Study (ICSS) have reported somewhat differing results.29 CREST compared the efficacy of carotid endarterectomy and carotid stenting in both symptomatic and asymptomatic patients.30 Primary end points included 30-day periprocedural composite death, stroke, myocardial infarction, or any ipsilateral stroke up to 4 years. CREST investigators reported no difference between stenting (5.2%) and endarterectomy (4.5%) in terms of primary end point. When each variable was independently analyzed, there was a higher rate of stroke in the stenting group at 30 days (4.1% vs. 2.3%) and a higher rate of myocardial infarction in the endarterectomy group (2.3% vs. 1.1%). The ICSS was a multicenter, international, randomized controlled trial comparing carotid stenting versus endarterectomy in patients with symptomatic carotid stenosis.31 The risk of stroke, death, and myocardial infarction in the stenting group (8.5%) was significantly higher than in the surgical arm (5.2%). The finding that carotid endarterectomy is safer than carotid stenting is also supported by the results of an MRI substudy, which showed significantly more new lesions by diffusion-weighted imaging in the carotid stenting than the carotid endarterectomy patients.

All available randomized studies have provided some answers and raised some questions. Some ongoing clinical trials will undoubtedly provide more insights on the efficacy of carotid stenting in the near future. Currently, the Society for Vascular Surgeons recommends carotid endarterectomy as first-line treatment for most symptomatic patients with stenosis of 50% to 99% and asymptomatic patients with stenosis of 60% to 99%.32 The perioperative risk of stroke and death in asymptomatic patients must be below 3% to ensure benefit for the patient. Carotid artery stenting should be reserved for symptomatic patients with stenosis of 50% to 99% at high risk for carotid endarterectomy for anatomic or medical reasons. Carotid artery stenting is not recommended for asymptomatic patients at this time. Asymptomatic patients at high risk for intervention or with a life expectancy of less than 3 years should be considered for medical management as the first-line therapy.

Surgical Techniques of Carotid Endarterectomy

Although carotid endarterectomy is one of the earliest vascular operations ever described and its techniques have been perfected in the last two decades, surgeons continue to debate many aspects of this procedure. For instance, there is no universal agreement with regard to the best anesthetic of choice, the best intraoperative cerebral monitoring, whether to “routinely” shunt, open versus eversion endarterectomy, and patch versus primary closure. Various anesthetic options are available for patient undergoing carotid endarterectomy including general, local, and regional anesthesia. Typically, the anesthesia of choice depends on the preference of the surgeon, anesthesiologist, and patient. However, depending on the anesthetic given, the surgeon must decide whether intraoperative cerebral monitoring is necessary or intra-arterial carotid shunting will be used. In general, if the patient is awake, then his or her abilities to respond to commands during carotid clamp period determine the adequacy of collateral flow to the ipsilateral hemisphere. On the other hand, intraoperative eneroencephalogram (EEG) or transcranial power Doppler (TCD) has been used to monitor for adequacy of cerebral perfusion during the clamp period for patients undergoing surgery under general anesthesia. Focal ipsilateral decreases in amplitudes and slowing of EEG waves are indicative of cerebral ischemia. Similarly, a decrease to less than 50% of baseline velocity in the ipsilateral middle cerebral artery is a sign of cerebral ischemia. For patients with poor collateral flow exhibiting signs of cerebral ischemia, intra-arterial carotid shunting with removal of the clamp will restore cerebral flow for the remaining part of the surgery. Stump pressures have been used to determine the need for intra-arterial carotid shunting. Some surgeons prefer to shunt all patients on a routine basis and do not use intraoperative cerebral monitoring.
The patient’s neck is slightly hyperextended and turned to the contralateral side, with a roll placed between the shoulder blades. An oblique incision is made along the anterior border of the sternocleidomastoid muscle centered on top of the carotid bifurcation (Fig. 23-17). The platysma is divided completely. Typically, tributaries of the anterior jugular vein are ligated and divided. The dissection is carried medial to the sternocleidomastoid. The superior belly of the omohyoid muscle is usually encountered just anterior to the common carotid artery. This muscle can be divided. The carotid fascia is incised, and the common carotid artery is exposed. The common carotid artery is mobilized cephalad toward the bifurcation. The dissection of the carotid bifurcation can cause reactive bradycardia related to stimulation of the carotid body. This reflex can be blunted with injection of lidocaine 1% into the carotid body or reversed with administration of intravenous atropine. A useful landmark in the dissection of the carotid bifurcation is the common facial vein. This vein can be ligated and divided. Frequently, the 12th cranial nerve (hypoglossal nerve) traverses the carotid bifurcation just behind the common facial vein. The external carotid artery is mobilized just enough to get a clamp across. Often, a branch of the external carotid artery crossing to the sternocleidomastoid can be divided to allow further cephalad mobilization of the internal carotid artery. For high bifurcation, division of the posterior belly of the digastric muscle is helpful in establishing distal exposure of the internal carotid artery.

Intravenous heparin sulfate (1 mg/kg) is routinely administered just prior to carotid clamping. The internal carotid artery is clamped first using a soft noncrushing vascular clamp to prevent distal embolization. The external and common carotid arteries are clamped subsequently. A longitudinal arteriotomy is made in the distal common carotid artery and extended into the bulb and past the occlusive plaque into the normal part of the internal carotid artery. Endarterectomy is carried out to remove the occlusive plaque (Fig. 23-18). If necessary, a temporary shunt can be inserted from the common carotid artery to the internal carotid artery to maintain continuous antegrade cerebral blood flow (Fig. 23-19). Typically, a plane is teased out from the vessel wall, and the entire plaque is elevated and removed. The distal transition line in the internal carotid artery where the plaque had been removed must be examined carefully and should be smooth. Tacking sutures are placed when an intimal flap remains in this transition to ensure no obstruction to flow (Fig. 23-20). The occlusive plaque is usually removed from the origin of the external carotid artery using the eversion technique. The endarterectomized surface is then irrigated and any debris removed. A patch (autogenous saphenous vein, synthetic such as polyester, PTFE, or biologic material) is sewn to close the arteriotomy (Fig. 23-21). Whether patch closure is necessary in all patients and which patch is the best remain controversial. However, most surgeons agree that patch closure is
SPECIFIC CONSIDERATIONS

B. Indications for Endarterectomy

The distal transition line (left side of the picture) in the internal carotid artery where the plaque had been removed must be examined carefully and should be smooth. Tacking sutures (arrows) are placed when an intimal flap remains in this transition to ensure no obstruction to flow.

Figure 23-20. The distal transition line (left side of the picture) in the internal carotid artery where the plaque had been removed must be examined carefully and should be smooth. Tacking sutures (arrows) are placed when an intimal flap remains in this transition to ensure no obstruction to flow.

Indicated particularly for the small vessel (<7 mm). The eversion technique has also been advocated for removing the plaque from the internal carotid artery. In the eversion technique, the internal carotid artery is transected at the bulb, the edges of the divided vessel are everted, and the occluding plaque is “peeled” off the vessel wall. The purported advantages of the eversion technique are no need for patch closure and a clear visualization of the distal transition area. Reported series have not shown a clear superiority of one technique over the others. Surgeons will likely continue to use the technique of their choice. Just prior to completion of the anastomosis to close the arteriotomy, we thoroughly flush the vessels of any potential debris. When the arteriotomy is closed, flow is restored to the external carotid artery first and to the internal carotid artery second. Intravenous protamine sulfate can be given to reverse the effect of heparin anticoagulation following carotid endarterectomy. The wound is closed in layers. After surgery, the patient’s neurologic condition is asserted in the operating room prior to transfer to the recovery area.

Complications of Carotid Endarterectomy. Most patients tolerate carotid endarterectomy very well and typically are discharged home within 24 hours after surgery. Complications after endarterectomy are infrequent but can be potentially life-threatening or disabling. Acute ipsilateral stroke is a dreaded complication following carotid endarterectomy.

Cerebral ischemia can be due to either intraoperative or postoperative events. Embolizations from the occlusive plaque or prolonged cerebral ischemia are potential causes of intraoperative stroke. The most common cause of postoperative stroke is due to embolization. Less frequently, acute carotid artery occlusion can cause acute postoperative stroke. This is usually due to carotid artery thrombosis related to closure of the arteriotomy, an occluding intimal flap, or distal carotid dissection. When patients experience acute symptoms of neurologic ischemia after endarterectomy, immediate intervention may be indicated. Carotid duplex scan can be done expeditiously to assess patency of the extracranial internal carotid artery. Reexploration is mandated for acute carotid artery occlusion. Cerebral angiography can be useful if intracranial revascularization is considered.

Local complications related to surgery include excessive bleeding and cranial nerve palsies. Postoperative hematoma in the neck after carotid endarterectomy can lead to devastating airway compromise. Any expanding hematoma should be evacuated and active bleeding stopped. Securing an airway is critical and can be extremely difficult in patients with large postoperative neck hematoma. The reported incidence of postoperative cranial nerve palsies after carotid endarterectomy varies from 1% to 30%. Well-recognized injuries involve the marginal mandibular, vagus, hypoglossal, superior laryngeal, and recurrent laryngeal nerves. Often these are traction injuries but can also be due to severance of the respective nerves.

Techniques of Carotid Angioplasty and Stenting

Percutaneous carotid artery stenting has become an accepted alternative treatment in the management of patients with carotid bifurcation disease (Fig. 23-22). The perceived advantages of percutaneous carotid revascularization are related to the minimal invasiveness of the procedure compared to surgery. There are anatomic conditions based on angiographic evaluation in which carotid artery stenting should be avoided due to increased procedure-related risks (Table 23-5). In preparation for carotid stenting, the patient should be given oral clopidogrel 3 days prior to the intervention if the patient was not already taking the drug. The procedure is done in either the operating room with angiographic capabilities or in a dedicated angiography room. The patient is placed in the supine position. The patient’s blood pressure and cardiac rhythm are closely monitored.

To gain access to the carotid artery, a retrograde transfemoral approach is most commonly used as the access site for carotid intervention. Using the Seldinger technique, we insert a diagnostic 5- or 6-French sheath in the CFA. A diagnostic arch

Figure 23-21. A. An autologous or synthetic patch can be used to close the carotid arteriotomy incision, which maintains the luminal patency. B. A completion closure of carotid endarterectomy incision using a synthetic patch.
aortogram is obtained. The carotid artery to be treated is then selected using a 5-French diagnostic catheter, and contrast is injected to show the carotid anatomy. It is important to assess the contralateral carotid artery, vertebrobasilar, and intracranial circulation if these are not known based on the preoperative noninvasive studies. Once the decision is made to proceed with carotid artery stenting, with the tip of the diagnostic catheter still in the common carotid artery, a 0.035-inch, 260-cm long stiff guidewire is placed in the ipsilateral external carotid artery. Anticoagulation with intravenous bivalirudin bolus (0.75 mg/kg) followed by an infusion rate of 2.5 mg/kg per hour for the remainder of the procedure is routinely administered. Next the diagnostic catheter is withdrawn and a 90-cm, 6-French guiding sheath is advanced into the common carotid artery over the stiff guide wire. It is critical not to advance the sheath beyond the occlusive plaque in the carotid bulb. The stiff wire is then removed, and preparation is made to deploy the distal embolic protection device (EPD). Several distal EPDs are available (Table 23-6). The EPD device is carefully deployed beyond the target lesion. With regard to the carotid stents, there are several stents that have received approval from the FDA and are commercially available for carotid revascularization (Table 23-7). All current carotid stents use the rapid-exchange monorail 0.014-inch platform. The size selection is typically based on the size of common carotid artery. Predilatation using a 4-mm balloon may be necessary to allow passage of the stent delivery catheter. Once the stent is deployed across the occlusive plaque, postdilatation is usually performed using a ≤5.5-mm balloon. It is noteworthy that balloon dilation of the carotid bulb may lead to immediate bradycardia due to stimulation of the glossopharyngeal nerve. The EPD is then retrieved and the procedure is completed with removal of the sheath from the femoral artery. The puncture site is closed using available closure device or with manual compression. Throughout the procedure, the patient’s neurologic function is closely monitored. The bivalirudin infusion is

Table 23-5

Unfavorable carotid angiographic appearance in which carotid stenting should be avoided

- Extensive carotid calcification
- Polypoid or globular carotid lesions
- Severe tortuosity of the common carotid artery
- Long-segment stenoses (>2 cm in length)
- Carotid artery occlusion
- Severe intraluminal thrombus (angiographic defects)
- Extensive middle cerebral artery atherosclerosis

stopped and the patient is kept on clopidogrel (75 mg daily) for at least 1 month and aspirin indefinitely.

**Complications of Carotid Stenting.** Although there have been no randomized trials comparing carotid stenting with and without EPD, the availability of EPDs appears to have reduced the risk of distal embolization and stroke. The results of the various clinical trials and registries of carotid stenting have been reported and compared. It is well known that distal embolization as detected by TCD is much more frequent with carotid stenting even with EPD, when compared with carotid endarterectomy. However, the clinical significance of the distal embolization detected by TCD is not clear because most are asymptomatic. Acute carotid stent thrombosis is rare. The incidence of in-stent carotid restenosis is not well known but is estimated at 10% to 30%. Duplex surveillance shows elevated peak systolic velocities within the stent after carotid stenting not infrequently. However, velocity criteria are being formulated to determine the severity of in-stent restenosis after carotid stenting by ultrasound duplex. It appears that systolic velocities exceeding 300 to 400 cm/s would represent >70% to 80% restenosis. Bradycardia and hypotension occur in up to 20% of patients undergoing carotid stenting. Systemic administration of atropine is usually effective in reversing the bradycardia. Other technical complications of carotid stenting are infrequent and include carotid artery dissection and access site complications, such as groin hematoma, femoral artery pseudoaneurysm, distal embolization, and acute femoral artery thrombosis.

**Nonatherosclerotic Disease of the Carotid Artery**

**Carotid Coil and Kink.** A carotid coil consists of an excessive elongation of the internal carotid artery producing tortuosity of the vessel (Fig. 23-23). Embryologically, the carotid artery is derived from the third aortic arch and dorsal aortic root and is uncoiled as the heart and great vessels descend into the mediastinum. In children, carotid coils appear to be congenital in origin. In contrast, elongation and kinking of the carotid artery in adults are associated with the loss of elasticity and an abrupt angulation of the vessel. Kinking is more common in women than men. Cerebral ischemic symptoms caused by kinks of the carotid artery are similar to those from atherosclerotic carotid lesions but are more likely due to cerebral hypoperfusion than embolic episodes. Classically, sudden head rotation, flexion, or extension can accentuate the kink and provoke ischemic symptoms. Most carotid kinks and coils are found incidentally on carotid duplex scan. However, interpretation of the Doppler frequency shifts and spectral analysis in tortuous carotid arteries can be difficult because of the uncertain angle of insonation. Cerebral angiography, with multiple views taken in neck flexion, extension, and rotation, is useful in the determination of the clinical significance of kinks and coils.

**Fibromuscular Dysplasia.** Fibromuscular dysplasia (FMD) usually involves medium-sized arteries that are long and have few branches (Fig. 23-24). Women in the fourth or fifth decade of life are more commonly affected than men. Hormonal effects on the vessel wall are thought to play a role in the pathogenesis of FMD. FMD of the carotid artery is commonly bilateral, and in about 20% of patients, the vertebral artery is also involved.37

**Figure 23-23.** Excessive elongation of the carotid artery can result in carotid kinking (arrow), which can compromise cerebral blood flow and lead to cerebral ischemia.
An intracranial saccular aneurysm of the carotid siphon or middle cerebral artery can be identified in up to 50% of the patients with FMD. Four histologic types of FMD have been described in the literature. The most common type is medial fibroplasia, which may present as a focal stenosis or multiple lesions with intervening aneurysmal outpouchings. The disease involves the media with the smooth muscle being replaced by fibrous connective tissue. Commonly, mural dilations and microaneurysms can be seen with this type of FMD. Medial hyperplasia is a rare type of FMD, with the media demonstrating excessive amounts of smooth muscle. Intimal fibroplasia accounts for 5% of all cases and occurs equally in both sexes. The media and adventitia remain normal, and there is accumulation of subendothelial mesenchymal cells with a loose matrix of connective tissue causing a focal stenosis in adults. Finally, premedial dysplasia represents a type of FMD with elastic tissue accumulating between the media and adventitia. FMD can also involve the renal and external iliac arteries. It is estimated that approximately 40% of patients with FMD present with a TIA due to embolization of platelet aggregates. DSA demonstrates the characteristic “string of beads” pattern, which represents alternating segments of stenosis and dilatation. The string of beads can also be shown noninvasively by CTA or MRA. FMD should be suspected when an increased velocity is detected across a stenotic segment without associated atherosclerotic changes on carotid duplex ultrasound. Antiplatelet medication is the generally accepted therapy for asymptomatic lesions. Endovascular treatment is recommended for patients with documented lateralizing symptoms. Surgical correction is rarely indicated.

**Carotid Artery Dissection.** Dissection of the carotid artery accounts for approximately 20% of strokes in patients younger than 45 years of age. The etiology and pathogenesis of spontaneous carotid artery dissection remain incompletely understood. Arterial dissection involves hemorrhage within the media, which can extend into the subadventitial and subintimal layers. When the dissection extends into the subadventitial space, there is an increased risk of aneurysm formation. Subintimal dissections can lead to intramural clot or thrombosis. Traumatic dissection is typically a result of hyperextension of the neck during blunt trauma, neck manipulation, strangulation, or penetrating injuries to the neck. Even in supposedly spontaneous cases, a history of preceding unrecognized minor neck trauma is not uncommon. Connective disorders, such as Ehlers-Danlos syndrome, Marfan’s syndrome, α₁-antitrypsin deficiency, or FMD, may predispose to carotid artery dissection. Iatrogenic dissections can also occur due to catheter manipulation or balloon angioplasty.

Typical clinical features of carotid artery dissection include unilateral neck pain, headache, and ipsilateral Horner’s syndrome in up to 50% of patients, followed by manifestations of the cerebral or ocular ischemia and cranial nerve palsies. Neurologic deficits can result either because of hemodynamic failure (caused by luminal stenosis) or by an artery-to-artery thromboembolism. The ischemia may cause TIAs or infarctions, or both. Catheter angiography has been the method of choice to diagnose arterial dissections, but with the advent of duplex ultrasonography, MRI/MRA, and CTA, most dissections can now be diagnosed using noninvasive imaging modalities (Fig. 23-25).

The dissection typically starts in the internal carotid artery distal to the bulb. Uncommonly, the dissection can start in the common carotid artery or is an extension of a more proximal aortic dissection. Medical therapy has been the accepted primary treatment of symptomatic carotid artery dissection. Anticoagulation (heparin and warfarin) and antiplatelet therapy have been commonly used, although there have not been any randomized studies to evaluate their effectiveness. The prognosis depends on the severity of neurologic deficit but is generally good in extracranial dissections. The recurrence rate is low. Therapeutic interventions have been reserved for recurrent TIAs or strokes or failure of medical treatment. Endovascular options include intra-arterial stenting, coiling of associated pseudoaneurysms, or, more recently, deployment of covered stents.

**Figure 23-24.** A carotid fibromuscular dysplasia with typical characteristics of multiple stenoses with intervening aneurysmal outpouching dilations. The disease involves the media with the smooth muscle being replaced by fibrous connective tissue.

**Figure 23-25.** Carotid ultrasound reveals a patient with a carotid artery dissection in which carotid flow is separated in the true flow lumen (long arrow) from the false lumen (short arrow).
Carotid Artery Aneurysms. Carotid artery aneurysms are rare, encountered in less than 1% of all carotid operations (Fig. 23-26). The true carotid artery aneurysm is generally due to atherosclerosis or medial degeneration. The carotid bulb is involved in most carotid aneurysms, and bilateralism is present in 12% of the patients. Patients typically present with a pulsatile neck mass. The available data suggest that, untreated, these aneurysms lead to neurologic symptoms from embolization. Thrombosis and rupture of the carotid aneurysm are rare. Pseudoaneurysms of the carotid artery can result from injury or infection. Mycotic aneurysms often involved syphilis in the past, but they are now more commonly associated with peritonsillar abscesses caused by *Staphylococcus aureus* infection. FMD and spontaneous dissection of the carotid artery can lead to the formation of true aneurysms or pseudoaneurysms. Whereas conventional surgery has been the primary mode of treatment in the past, carotid aneurysms are currently being treated more commonly using endovascular approaches.38

Carotid Body Tumor. The carotid body originates from the third branchial arch and from neuroectodermal-derived neural crest lineage. The normal carotid body is located in the adventitia or periadventitial tissue at the bifurcation of the common carotid artery (Fig. 23-27). The gland is innervated by the glossopharyngeal nerve. Its blood supply is derived predominantly from the external carotid artery but can also come from the vertebral artery. Carotid body tumor is a rare lesion of the neuroendocrine system. Other glands of neural crest origin are seen in

Figure 23-27. **A.** A carotid body tumor (*arrow*) located adjacent to the carotid bulb. **B.** Following periadventitial dissection, the carotid body tumor is removed.
the neck, parapharyngeal spaces, mediastinum, retroperitoneum, and adrenal medulla. Tumors involving these structures have been referred to as paraganglioma, glomus tumor, or chemodectoma. Approximately 5% to 7% of carotid body tumors are malignant. Although chronic hypoxemia has been invoked as a stimulus for hyperplasia of carotid body, approximately 35% of carotid body tumors are hereditary. The risk of malignancy is greatest in young patients with familial tumors.

Symptoms related to the endocrine products of the carotid body tumor are rare. Patients usually present between the fifth and seventh decades of life with an asymptomatic lateral neck mass. The diagnosis of carotid body tumor requires confirmation on imaging studies. Carotid duplex scan can localize the tumor to the carotid bifurcation, but CT or MRI is usually required to further delineate the relationship of the tumor to the adjacent structures. Classically, a carotid body tumor will widen the carotid bifurcation. The Shamban classification describes the tumor extent: I, tumor is less than 5 cm and relatively free of vessel involvement; II, tumor is intimately involved but does not encase the vessel wall; and III, tumor is intramural and encases the carotid vessels and adjacent nerves. With good-resolution CT and MRI, arteriography is usually not required. However, arteriography can provide an assessment of the vessel invasion and intracranial circulation and allows for preoperative embolization of the feeder vessels, which has been reported to reduce intraoperative blood loss. Surgical resection is the recommended treatment for suspected carotid body tumor.

Carotid Trauma. Blunt or penetrating trauma to the neck can cause injury to the carotid artery. Notwithstanding the massive bleeding from carotid artery transection, injury to the carotid artery can result in carotid dissection, thrombosis, or pseudoaneurysm formation. Carotid duplex ultrasound can be useful to locate the site of injury in the cervical segment of the carotid artery. Spiral CTA has become the modality of choice to detect extracranial carotid artery injury. Confirmation of carotid injury by contrast cerebral angiography remains the gold standard diagnostic test. Injuries to the cervical segment of the common and internal carotid arteries can be repaired surgically. Acute carotid artery thrombosis is usually treated medically with anticoagulation if the patient is asymptomatic. Revascularization should be considered for patients presenting with ongoing cerebral ischemia related to carotid artery thrombosis. Traumatic carotid artery dissection can cause cerebral ischemia due to thromboembolization, decreased flow, or thrombosis. Commonly, the dissection involves the distal portion of the cervical and petrous segment of the internal carotid artery. Medical management with antiplatelet or anticoagulation therapy is usually adequate for uncomplicated traumatic carotid dissection. In patients with pseudoaneurysms of the carotid artery that are located in a segment that is out of surgical reach, the use of selective coil embolization of the pseudoaneurysm or exclusion of the pseudoaneurysm by a covered stent graft has been reported. Bare metal stent has been used with success in the treatment of traumatic carotid artery dissection.

ABDOMINAL AORTIC ANEURYSM

Despite more than 50,000 patients undergoing elective repair of abdominal aortic aneurysm (AAA) each year in the United States, approximately 15,000 patients die annually as a result of ruptured aneurysm, making it the 10th leading cause of death in men in this country. The incidence appears to be increasing, and this is due in part to improvements in diagnostic imaging and, more importantly, a growing elderly population. With early diagnosis and timely intervention, aneurysm rupture-related death is largely preventable. Conventional treatment of an AAA involves replacing the aneurysmal segment of the aorta with a prosthetic graft, with the operation performed through a large abdominal incision. Techniques for this open abdominal surgery have been refined, adapted, and extensively studied by vascular surgeons over the past four decades. Despite a well-documented low perioperative mortality rate of 2% to 3% in large academic institutions, the thought of undergoing an open abdominal aortic operation often provokes a sense of anxiety in many patients due in part to the postoperative pain associated with the large abdominal incision as well as the long recovery time needed before the patient can return to normal physical activity.

The most common location of aortic aneurysms is the infrarenal aorta. Endovascular stent graft placement represents a revolutionary and minimally invasive treatment for infrarenal AAAs that only requires 1 to 2 days of hospitalization, and the patient can return to normal physical activity within 1 week. The concept of using an endoluminal device in the management of vascular disease was first proposed by Dotter and colleagues, who successfully treated a patient with iliac occlusion using transluminal angioplasty in 1964. Nearly two decades later, Parodi and colleagues reported the first successful endovascular repair of AAA using a stent graft device. Since then, a variety of stent graft technologies have been developed to treat AAA. The rapid innovation of this new treatment modality has undoubtedly captured the attention of patients with aortic aneurysms as well as physicians who practice endovascular therapy. Physicians in general should be knowledgeable regarding available treatment options of AAA in order to provide adequate evaluation and education to patients and their families. The purpose of this section is to outline the treatment options for AAAs, including conventional repair and endovascular approach. Advantages and potential complications of these treatments will also be addressed.

Causes and Risk Factors

The pathogenesis of aneurysmal disease of the aorta is complex and multifactorial. A degenerative process in the aortic wall is the most common cause of AAA development. Matrix metalloproteinases (MMP), proteolytic enzymes, are found abundantly in the wall of AAA. Atherosclerotic disease, age, male sex, smoking history, family history, hypertension, coronary artery disease, and chronic obstructive pulmonary disease are associated with the development of AAA. Diabetes and black race have negative association with AAA. Other less common causes include inflammation, infection, and connective tissue disease. Inflammatory AAA accounts for 5% to 10% of all AAAs. In contrast to atherosclerotic AAA, the inflammatory variant is characterized pathologically by marked thickening of the aneurysm wall, fibrosis of the adjacent retroperitoneum, and rigid adherence of the adjacent structures to the anterior aneurysm wall. Male sex and smoking are even stronger risk factors in inflammatory AAA. Smoking cessation is the first step of medical therapy, followed by surgical repair. Infectious or mycotic AAA is rare but is associated with high mortality. Patients with connective tissue disorders such as Marfan’s syndrome and Ehlers-Danlos syndrome tend to have more extensive and larger aneurysms at a younger age.
Natural History of Aortic Aneurysm

The natural history of an AAA is to expand and rupture. AAA exhibits a “staccato” pattern of growth, where periods of relative quiescence may alternate with expansion. Therefore, although an individual pattern of growth cannot be predicted, average aggregate growth is approximately 3 to 4 mm/year. There is some evidence to suggest that larger aneurysms may expand faster than smaller aneurysms, but there is significant overlap between the ranges of growth rates at each strata of size.

Rupture risk appears to be directly related to aneurysm size as predicted by Laplace's Law. Although more sophisticated methods of assessing rupture risk based on finite element analysis of wall stress are under active investigation, maximum transverse diameter remains the standard method of risk assessment for aneurysm rupture. In the past, AAA rupture risk has been overestimated. More recently, two landmark studies have served to better define the natural history of AAA. Based on best available evidence, the annualized risk of rupture is given in Table 23-8. The rupture risk is quite low below 5.5 cm and begins to rise exponentially thereafter. This size can serve as an appropriate threshold for recommending elective repair provided one’s surgical mortality is below 5%. For each size strata, however, women appear to be at higher risk for rupture than men, and a lower threshold of 4.5 to 5.0 cm may be reasonable in good-risk patients. Although data are less compelling, a pattern of rapid expansion of >0.5 cm within 6 months can be considered a relative indication for elective repair. Aneurysms that fall below these indications may safely be followed with CT or ultrasound at 6-month intervals, with long-term outcomes equivalent to earlier surgical repair. Interestingly, in the Aneurysm Detection and Management (ADAM) study, 80% of all AAAs that were followed in this manner eventually came to repair within 5 years.

Unless symptomatic or ruptured, AAA repair is a prophylactic repair. The rationale for recommending repair is predicated on the assumption that the risk of aneurysm rupture exceeds the combined risk of death from all other causes such as cardiopulmonary disease and cancer. On the other hand, our limitation in predicting timing and cause of death is underscored by the observation that over 25% of patients who were deemed unfit for surgical repair because of their comorbidities died from rupture of their aneurysms within 5 years.

Clinical Manifestations

Most AAAs are asymptomatic and are usually found incidentally during workup for chronic back pain or kidney stones. Physical examination is neither sensitive nor specific except in thin patients. Large aneurysms may be missed in the obese, while normal aortic pulsations may be mistaken for an aneurysm in thin individuals. Rarely patients present with back pain and/or abdominal pain with a tender pulsatile mass. Patients with these symptoms must be treated as a rupture until proven otherwise. If the patient is hemodynamically stable and the aneurysm is intact on a CT scan, the patient is admitted for blood pressure control with intravenous antihypertensive agents and undergoes repair usually within 12 to 24 hours or at least during the same hospitalization. In contrast, patients who are hemodynamically unstable with a history of acute back pain and/or syncopal and a known unrepaired AAA or a pulsatile abdominal mass should be immediately taken to the operating room with a presumed diagnosis of a ruptured AAA.

Overall mortality of AAA rupture is 71% to 77%, which includes all out-of-hospital and in-hospital deaths, as compared with 2% to 6% for elective open surgical repair. Nearly half of all patients with ruptured AAA will die before reaching the hospital. For the remainder, surgical mortality is 45% to 50% and has not substantially changed in the last 30 years.

Relevant Anatomy

An AAA is defined as a pathologic focal dilation of the aorta that is greater than 30 mm or 1.5 times the adjacent diameter of the normal aorta (Fig. 23-28). Male aortas tend to be larger than female aortas, and there is generalized growth of the aortic diameter with each decade of life. Ninety percent of AAAs are infrarenal in location and have a fusiform morphology. There is a higher predilection for juxtarenal and suprarenal AAAs in women compared with men. Concomitant common iliac and/or hypogastric artery aneurysms can be found in 20% to 25% of patients. Although the etiology of most aortic aneurysms is atherosclerotic, clinically significant peripheral occlusive disease is unusual and present in less than 10% of all cases.

Although extravascular anatomy is important for open surgical repair of AAA, intravascular anatomy and aortoiliac morphology are important for endovascular repair. Pertinent anatomic dimensions include the diameter of the proximal nondilated infrarenal aortic neck, which can range from 18 to 30 mm; common iliac artery, which can range from 8 to 16 mm; and external iliac arteries, which can range from 6 to 10 mm. Morphologically, the aortic neck can manifest complex angulation above and below the renal arteries due to combination of elongation and anterolateral displacement by the posterior bulge of the aneurysmal aorta. Furthermore, the shape of the proximal neck is rarely tubular, but often is conical, reverse conical, or barrel-shaped. Distally, the iliac arteries can have severe

tortuosity with multiple compound turns. Although significant from hemodynamic standpoint, severe iliac calcifications combined with extreme tortuosity can pose a formidable challenge during endovascular repair.

**Diagnostic Evaluation**
