Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.
Contents

Volume 1

Part I

Basic Considerations 1

1. Leadership in Surgery ........................................ 3
   Stephen Markowiak, Hollis Merrick, Shiela Beroukhim,
   Jeremy J. Laukka, Amy Lightner, Munier Nazzal,
   Lee Hammerling, James R. Macho, and F. Charles Brunicardi

2. Systemic Response to Injury and Metabolic Support ............. 27
   Siobhan A. Corbett

3. Fluid and Electrolyte Management of the Surgical Patient .......... 83
   Matthew D. Neal

4. Hemostasis, Surgical Bleeding, and Transfusion .................. 103
   Ronald Chang, John B. Holcomb, Evan Leibner,
   Matthew Pommery, and Rosemary A. Kozar

5. Shock ............................................................ 131
   Brian S. Zuckerbraun, Andrew B. Peitzman, and Timothy R. Billiar

6. Surgical Infections ............................................. 157
   Robert E. Bulander, David L. Dunn, and
   Greg J. Beilman

7. Trauma ........................................................... 183
   Clay Cothren Burlew and Ernest E. Moore

8. Burns .............................................................. 251
   Jeffrey H. Anderson, Samuel P. Mandell, and
   Nicole S. Gibran

9. Wound Healing .................................................. 271
   Munier Nazzal, Mohammad F. Osman,
   Heitham Albeshri, Darren B. Abbas, and Carol A. Angel

10. Oncology ......................................................... 305
    William E. Carson III, Funda Meric-Bernstam, and
    Raphael E. Pollock

11. Transplantation .................................................. 355
    David L. Dunn, Angelika C. Gruessner, and
    Rainer W.G. Gruessner

12. Quality, Patient Safety, Assessments of Care, and Complications .... 397
    Martin A. Makary, Peter B. Angood, and
    Mark L. Shapiro

Part II

Specific Considerations 511

13. Physiologic Monitoring of the Surgical Patient ..................... 433
    Anthony R. Cyr and Louis H. Alarcon

14. Minimally Invasive Surgery, Robotics, Natural Orifice Transluminal
    Endoscopic Surgery, and Single-Incision Laparoscopic Surgery ...... 453
    Donn H. Spight, Blair A. Jobe, and John G. Hunter

15. Molecular Biology, The Atomic Theory of Disease, and Precision Surgery ... 479
    Xin-Hua Feng, Xia Lin, Xinran Li, Juehua Yu,
    John Nemunaitis, and F. Charles Brunicardi

Specific Considerations

16. The Skin and Subcutaneous Tissue .................................. 513
    Patrick Harbour and David H. Song

17. The Breast .................................................................. 541
    Catherine C. Parker, Senthil Damodaran,
    Kirby J. Bland, and Kelly K. Hunt

18. Disorders of the Head and Neck ...................................... 613
    Antoine Eskander, Stephen Y. Kang,
    Michael S. Harris, Bradley A. Otto, Oliver Adunka,
    Randal S. Weber, and Theodoros N. Teknos

19. Chest Wall, Lung, Mediastinum, and Pleura ......................... 661
    Katie S. Nason, Rose B. Ganin, and James D. Luketich

20. Congenital Heart Disease ............................................ 751
    Ragav Murthy, Tbilitha G. Moe, Glen A. Van Arsdell,
    John J. Nigro, and Tara Karamlou

21. Acquired Heart Disease ............................................... 801
    Matthew R. Schill, Ali J. Khiabani, Puja Kachroo,
    and Ralph J. Damiano Jr

22. Thoracic Aneurysms and Aortic Dissection .......................... 853
    Scott A. Lefair, Ourania Preventza, and Joseph S. Coselli

23. Arterial Disease ....................................................... 897
    Peter H. Lin, Carlos F. Bechara, Changyi Chen,
    and Frank J. Veith

24. Venous and Lymphatic Disease ....................................... 981
    Atish Chopra, Timothy K. Lien,
    and Gregory L. Moneta

25. Esophagus and Diaphragmatic Hernia ................................ 1009
    Blair A. Jobe, John G. Hunter, and David I. Watson

26. Stomach ............................................................... 1099
    Robert E. Roses and Daniel T. Dempsey
Volume 2

27. The Surgical Management of Obesity ..........1167
   Anita P. Courcoulas and Philip R. Schauer

28. Small Intestine ........................................ 1219
   Ali Tavakkoli, Stanley W. Ashley, and Michael J. Zinner

29. Colon, Rectum, and Anus ............................ 1259
   Mary R. Kwaan, David B. Stewart Sr, and Kelli Bullard Dunn

30. The Appendix .......................................... 1331
   Fadi S. Dahdah, David Heidt, and Kiran K. Turaga

31. Liver .................................................... 1345
   David A. Geller, John A. Goss, Ronald W. Busuttil, and Allan Tsung

32. Gallbladder and the Extrahepatic Biliary System .................................................. 1393
   Kelly R. Haisley and John G. Hunter

33. Pancreas .................................................. 1429
   William E. Fisher, Dana K. Andersen, John A. Windsor, Vikas Dudeja, and F. Charles Brunicardi

34. The Spleen ................................................. 1517
   Adrian E. Park, Eduardo M. Targarona, Adam S. Welz, and Carlos Rodriguez-Otero Luppi

35. Abdominal Wall, Omentum, Mesentery, and Retropertioneum ...................................... 1549
   Scott Kizy and Sayeed Ikramuddin

36. Soft Tissue Sarcomas ................................. 1567
   Ricardo J. Gonzalez, Alessandro Gronchi, and Raphael E. Pollock

37. Inguinal Hernias ........................................ 1599
   Chandan Das, Tahir Jamil, Stephen Stanek, Ziya Baghmanli, James R. Macho, Joseph Sferra, and F. Charles Brunicardi

38. Thyroid, Parathyroid, and Adrenal .............. 1625
   Geeta Lal and Orlo H. Clark

39. Pediatric Surgery ....................................... 1705
   David J. Hackam, Jeffrey Upperman, Tracy Girkischelt, Kasper Wang, and Henri R. Ford

40. Urology .................................................... 1759
   Ahmad Shahsigh, Michael Sourial, Farah F. Bellow, Christopher McLung, Rama Jayanthi, Stephanie Kielb, Geoffrey N. Box, Bodo E. Knudsen, and Cheryl T. Lee

41. Gynecology ............................................... 1783
   Sarah M. Temkin, Thomas Gregory, Elise C. Kohn, and Linda Duska

42. Neurosurgery ............................................ 1827
   Ashwin G. Ramayya, Saurabh Sinha, and M. Sean Grady

43. Orthopedic Surgery .................................... 1879
   Nabil A. Ebraheim, Bert J. Thomas, Freddie H. Fu, Bart Muller, Dharmesh Vyas, Matt Niesen, Jonathan Pribaz, and Klaus Draenert

44. Surgery of the Hand and Wrist ..................... 1925
   Scott D. Lifchez and Brian H. Cho

45. Plastic and Reconstructive Surgery ............. 1967
   Rajiv Y. Chandawarkar, Michael J. Miller, Brian C. Kellogg, Steven A. Schulz, Ian L. Valerio, and Richard E. Kirschner

46. Anesthesia for Surgical Patients .................. 2027
   Junaid Nizamuddin and Michael O’Connor

47. Surgical Considerations in Older Adults ........ 2045
   Anne M. Suskind and Emily Finlayson

48. Ethics, Palliative Care, and Care at the End of Life .................................................. 2061
   Daniel E. Hall, Eliza W. Beal, Peter A. Angelos, Geoffrey P. Dunn, Daniel B. Hinshaw, and Timothy M. Pavlik

49. Global Surgery ........................................... 2077
   Katherine E. Smiley, Haile T. Debis, Catherine R. deVries, and Raymond R. Price

50. Optimizing Perioperative Care: Enhanced Recovery and Chinese Medicine ................... 2113
   Catherine R. deVries, and Raymond R. Price

51. Understanding, Evaluating, and Using Evidence for Surgical Practice ......................... 2137
   Andrew J. Benjamin, Andrew B. Schneider, Jeffrey B. Matthews, and Gary An

52. Ambulatory Surgery .................................... 2153
   Marcus Adair, Stephen Markowiak, Hollis Merrick, James R. Macho, Kara Richardson, Moriah Masculo, Munier Nazzal, and F. Charles Brunicardi

53. Skills and Simulation .................................. 2163
   Neal E. Seymour and Carla M. Pugh

54. Web-Based Education and Implications of Social Media ............................................ 2187
   Lillian S. Kao and Michael E. Zenilman

Index/2197
Contributors

Darren B. Abbas, MD
Clinical Instructor
Department of Surgery
University of Toledo College of Medicine and Life Sciences
Toledo, Ohio
Chapter 9, Wound Healing

Marcus Adair, MD
Clinical Instructor
Department of Surgery
University of Toledo College of Medicine and Life Sciences
Toledo, Ohio
Chapter 52, Ambulatory Surgery

Oliver Adunka, MD, FACS
Professor
Vice-Chair, Clinical Operations
Department of Otolaryngology-Head and Neck Surgery
Director, Division of Otology/Neurotology and Cranial Base Surgery
The Ohio State University-James Comprehensive Cancer Center
Columbus, Ohio
Chapter 18, Disorders of the Head and Neck

Louis H. Alarcon, MD, FACS, FCCM
Professor of Surgery and Critical Care Medicine
Medical Director, Division of Trauma Surgery
University of Pittsburgh
Pittsburgh, Pennsylvania
Chapter 13, Physiologic Monitoring of the Surgical Patient

Heitham Albeshri, MD
Clinical Instructor
Department of Surgery
University of Toledo College of Medicine and Life Sciences
Toledo, Ohio
Chapter 9, Wound Healing

Gary An, MD
Professor of Surgery
Department of Surgery
The University of Chicago Medicine
Chicago, Illinois
Chapter 51, Understanding, Evaluating, and Using Evidence for Surgical Practice

Dana K. Andersen, MD, FACS
Scientific Program Manager
Division of Digestive Diseases and Nutrition
National Institute of Diabetes and Digestive and Kidney Diseases
National Institutes of Health
Bethesda, Maryland
Chapter 33, Pancreas

Jeffrey H. Anderson, MD
Resident, Department of Surgery
Harborview Medical Center
Seattle, Washington
Chapter 8, Burns

Carol A. Angel, MD
Clinical Instructor
Department of Surgery
University of Toledo College of Medicine and Life Sciences
Toledo, Ohio
Chapter 9, Wound Healing

Peter A. Angelos, MD, PhD, FACS
Linda Kohler Anderson Professor of Surgery and Surgical Ethics
Chief, Endocrine Surgery
Associate Director
MacLean Center for Clinical Medical Ethics
The University of Chicago Medicine
Chicago, Illinois
Chapter 48, Ethics, Palliative Care, and Care at the End of Life

Peter B. Angood, MD, CPE, FRCS(C), FACS, MCCM
President and Chief Executive Officer
American Association for Physician Leadership
Tampa, Florida
Chapter 12, Quality, Patient Safety, Assessments of Care, and Complications

Glen S. Van Arsdell, MD
Chief, Pediatric Cardiac Surgery
Mattel Children’s Hospital
University of California
Los Angeles, California
Chapter 20, Congenital Heart Disease
Contributors

Stanley W. Ashley, MD
General & Gastrointestinal Surgery
Brigham and Women’s Hospital
Frank Sawyer Professor of Surgery
Harvard Medical School
Boston, Massachusetts
Chapter 28, Small Intestine

Ziya Baghmanli, MD
Clinical Instructor
Department of Surgery
University of Toledo Medical Center
Toledo, Ohio
Chapter 37, Inguinal Hernias

Eliza W. Beal
Clinical Instructor, Department of General Surgery
The Ohio State University
Columbus, Ohio
Chapter 48, Ethics, Palliative Care, and Care at the End of Life

Carlos F. Bechara, MD
Associate Professor of Surgery
Program Director, Vascular Surgery Fellowship
Department of Surgery
Loyola University Medical Center
Maywood, Illinois
Chapter 23, Arterial Disease

Greg J. Beilman, MD
Owen H and Sarah Davidson Wangensteen Chair of Experimental Surgery
University of Minnesota
Minneapolis, Minnesota
Chapter 6, Surgical Infections

Fara F. Bellows, MD
Clinical Assistant Professor
Department of Urology
The Ohio State University
Columbus, Ohio
Chapter 40, Urology

Andrew J. Benjamin, MD, MS
The University of Chicago Medicine
Chicago, Illinois
Chapter 51, Understanding, Evaluating, and Using Evidence for Surgical Practice

Shiela Beroukhim, MD
Clinical Instructor
Harbor-UCLA Medical Center
Torrance, California
Chapter 1, Leadership in Surgery

Timothy R. Billiar, MD, FACS
George Vance Foster Professor and Chair
Department of Surgery
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania
Chapter 5, Shock

Kirby I. Bland, MD
Fay Fletcher Kerner Professor
The University of Alabama at Birmingham
Department of Surgery
Birmingham, Alabama
Chapter 17, The Breast

Geoffrey N. Box, MD
Assistant Professor
Department of Urology
The Ohio State University
Columbus, Ohio
Chapter 40, Urology

F. Charles Brunicardi, MD, FACS
John Howard Endowed Professor of Pancreatic Surgery
Chair, Department of Surgery
Director, Cancer Program
University of Toledo College of Medicine and Life Sciences
Academic Chief of Surgery
ProMedica Health System
Toledo, Ohio
Chapter 1, Leadership in Surgery
Chapter 15, Molecular Biology, The Atomic Theory of Disease, and Precision Surgery
Chapter 33, Pancreas
Chapter 37, Inguinal Hernias
Chapter 52, Ambulatory Surgery

Robert E. Bulander, Jr., MD, PhD
Assistant Professor of Surgery
University of Minnesota
Minneapolis, Minnesota
Chapter 6, Surgical Infections

Clay Cothren Burlew, MD, FACS
Professor of Surgery
Director, Surgical Intensive Care Unit
Program Director, Surgical Critical Care Fellowship
Program Director, Trauma & Acute Care Surgery Fellowship
The Ernest E. Moore Shock Trauma Center
Denver Health Medical Center
University of Colorado School of Medicine
Denver, Colorado
Chapter 7, Trauma

Ronald W. Busuttil, MD, PhD
William P. Longmire, Jr., Chair in Surgery
Professor and Executive Chair
Department of Surgery
David Geffen School of Medicine at University of California-Los Angeles
Los Angeles, California
Chapter 31, Liver
William E. Carson III, MD, FACS
Professor of Surgery and Vice Chair for Promotion and Tenure
The John B. and Jane T. McCoy Chair in Cancer Research
Interim Chief, Division of Surgical Oncology
Associate Director for Clinical Research
OSU Comprehensive Cancer Center
The Ohio State University
Columbus, Ohio
Chapter 10, Oncology

Rajiv Y. Chandawarkar, MD, MBA
Acting Chair
Department of Plastic and Reconstructive Surgery
The Ohio State University Wexner Medical Center
Columbus Ohio
Chapter 45, Plastic and Reconstructive Surgery

Ronald Chang, MD
Department of Surgery
University of Texas Houston
Houston, Texas
Chapter 4, Hemostasis, Surgical Bleeding, and Transfusion

Changyi Chen, MD, PhD
Professor of Surgery
Michael E. DeBakey Department of Surgery
Baylor College of Medicine
Houston, Texas
Chapter 23, Arterial Disease

Brian H. Cho, MD
Resident in Plastic Surgery
Johns Hopkins Department of Plastic Surgery
Baltimore, Maryland
Chapter 44, Surgery of the Hand and Wrist

Atish Chopra, MD
Fellow, Division of Vascular Surgery
Department of Surgery
Oregon Health & Science University
Portland, Oregon
Chapter 24, Venous and Lymphatic Disease

Orlo H. Clark, MD, FACS
Professor Emeritus, Department of Surgery
UCSF Mt Zion Medical Center
San Francisco, California
Chapter 38, Thyroid, Parathyroid, and Adrenal

Siobhan A. Corbett, MD
Associate Professor of Surgery
Department of Surgery
Rutgers-Robert Wood Johnson Medical School
Rutgers Biomedical and Health Sciences
New Brunswick, New Jersey
Chapter 2, Systemic Response to Injury and Metabolic Support

Joseph S. Coselli, MD
Vice-Chair, Michael E. DeBakey Department of Surgery
Professor, Cullen Foundation Endowed Chair
Chief, Division of Cardiothoracic Surgery
Baylor College of Medicine
Chief, Adult Cardiac Surgery Texas Heart Institute
Chief, Adult Cardiac Surgery Section
Associate Chief, Cardiovascular Service
Baylor St. Luke’s Medical Center
Houston, Texas
Chapter 22, Thoracic Aneurysms and Aortic Dissection

Anita P. Courcoulas, MD, MPH, FACS
Professor of Surgery
Section Head, MIS Bariatric & General Surgery
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania
Chapter 27, The Surgical Management of Obesity

Zhigang Cui, MD
Associate Professor of Surgery
Department of Surgery
Tianjin Medical University
Nankai Hospital
Institute of Acute Abdomen of Tianjin, Tianjin, China
Chapter 50, Optimizing Perioperative Care: Enhanced Recovery and Chinese Medicine

Anthony R. Cyr, MD, PhD
Clinical Instructor
Department of Surgery
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania
Chapter 13, Physiologic Monitoring of the Surgical Patient

Fadi S. Dahdaleh, MD
Department of Surgery
University of Chicago
Chicago, Illinois
Chapter 30, The Appendix

Ralph J. Damiano, MD
Evarts A. Graham Professor of Surgery
Chief, Division of Cardiothoracic Surgery
Co-Chair, Heart & Vascular Center
Washington University School of Medicine
St Louis, Missouri
Chapter 21, Acquired Heart Disease

Senthil Damodaran, MD, PhD
Assistant Professor
Departments of Breast Medical Oncology and Investigational Cancer Therapeutics
The University of Texas MD Anderson Cancer Center
Houston, Texas
Chapter 17, The Breast
Contributors

Chandan Das, MD
Clinical Instructor
Department of Surgery
University of Toledo College of Medicine and Life Sciences
Toledo, Ohio
Chapter 37, Inguinal Hernias

Haile T. Debas, MD, FACS
Maurice Galante Distinguished Professor of Surgery, Emeritus
Founding Executive Director, Global Health Sciences
Director Emeritus, University of California Global Health Institute
Dean Emeritus, School of Medicine
Former Chancellor
University of California, San Francisco
San Francisco, California
Chapter 49, Global Surgery

Daniel T. Dempsey, MD, FACS
Professor of Surgery
Department of Surgery
Perelman School of Medicine
University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 26, Stomach

Catherine R. deVries, MD
Professor of Surgery
Adjunct Associate Professor of Family Medicine/Public Health
University of Utah
Salt Lake City, Utah
Chapter 49, Global Surgery

Vikas Dudeja, MD
Assistant Professor of Surgery
Division of Surgical Oncology
Department of Surgery
University of Miami
Miami, Florida
Chapter 33, Pancreas

David L. Dunn, MD, PhD
Prospect, Kentucky
Chapter 6, Surgical Infections
Chapter 11, Transplantation

Geoffrey P. Dunn, MD
Medical Director
Department of Surgery
Hamot Medical Center
Erie, Pennsylvania
Chapter 48, Ethics, Palliative Care, and Care at the End of Life

Kelli Bullard Dunn, MD, FACS, FASCRS
Vice Dean, Community Engagement and Diversity
Professor of Surgery
University of Louisville School of Medicine
Louisville, Kentucky
Chapter 29, Colon, Rectum, and Anus

Nabil A. Ebraheim, MD
Chairman and Professor
Department of Orthopaedic Surgery
The University of Toledo Medical Center
Toledo, Ohio
Chapter 43, Orthopedic Surgery

Antoine Eskander, MD, ScM, FRCSC
Assistant Professor, University of Toronto
Department of Otolaryngology—Head & Neck Surgery
Sunnybrook Health Sciences Centre, Surgical Oncologist
Michael Garron Hospital, Endocrine Surgery
Institute for Clinical Evaluative Sciences (ICES), Adjunct Scientist
Toronto, Ontario, Canada
Chapter 18, Disorders of the Head and Neck

Stephen A. Esper, MD, MBA
Assistant Professor
Department of Anesthesiology and Perioperative Medicine
Director, UPMC Centers for Perioperative Care
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania
Chapter 50, Optimizing Perioperative Care: Enhanced Recovery and Chinese Medicine

Xin-Hua Feng, PhD
Distinguished Investigator
Life Sciences Institute
Zhejiang University
Hangzhou, Zhejiang, China
Professor of Molecular Cell Biology
Michael E. DeBakey Department of Surgery and Department of Molecular & Cellular Biology
Baylor College of Medicine
Houston, Texas
Chapter 15, Molecular Biology, The Atomic Theory of Disease, and Precision Surgery

Emily Finlayson, MD, MS, FACS
Professor in Residence
Department of Surgery, Division of General Surgery
Department of Medicine, Division of Geriatrics
Phillip R. Lee Institute for Health Policy Studies
Director, Center for Surgery in Older Adults
Director, Department of Surgery Faculty Mentoring Program
Department of Surgery
University of California San Francisco
San Francisco, California
Chapter 47, Surgical Considerations in Older Adults
William E. Fisher, MD, FACS
Professor of Surgery, Clinical Vice Chair and
Chief, Division of General Surgery
George L. Jordan, MD Chair of General Surgery
Michael E. DeBakey Department of Surgery
Director, Elkins Pancreas Center
Baylor College of Medicine
Houston, Texas
*Chapter 33, Pancreas*

Henri R. Ford, MD, MHA
Dean and Chief Academic Officer
University of Miami Miller School of Medicine
Don Soffer Clinical Research Center
Miami, Florida
*Chapter 39 Pediatric Surgery*

Freddie H. Fu, MD, DSc (Hon.), DPs (Hon.)
Distinguished Service Professor
University of Pittsburgh
David Silver Professor and Chairman
Department of Orthopaedic Surgery
University of Pittsburgh School of Medicine
Head Team Physician
University of Pittsburgh Department of Athletics
Pittsburgh, Pennsylvania
*Chapter 43, Orthopedic Surgery*

David A. Geller, MD
Richard L. Simmons Professor of Surgery
Chief, Division of Hepatobiliary and Pancreatic Surgery
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania
*Chapter 31, Liver*

Nicole S. Gibran, MD, FACS
Professor, Department of Surgery
Associate Dean, Research and Graduate Education
Harborview Medical Center
University of Washington School of Medicine
Seattle, Washington
*Chapter 8, Burns*

Ricardo J. Gonzalez, MD, FACS
Chair, Sarcoma Department
Professor of Surgery
Chief of Surgery, Moffitt Cancer Center
Tampa, Florida
*Chapter 36, Soft Tissue Sarcoma*

John A. Goss, MD
Professor of Surgery
Michael E. DeBakey Department of Surgery
Division of Abdominal Transplantation and
Hepatobiliary Surgery
Baylor College of Medicine
Houston, Texas
*Chapter 31, Liver*

M. Sean Grady, MD
Charles Harrison Frazier Professor
Chairman
Department of Neurosurgery
Perelman School of Medicine at University of
Pennsylvania
Philadelphia, Pennsylvania
*Chapter 42, Neurosurgery*

Angelika Gruessner, PhD
Professor of Medicine
State University of New York (SUNY-Downstate)
New York, New York
*Chapter 11, Transplantation*

Rainer Gruessner, MD
Clarence & Mary Dennis Professor of Surgery
Chairman, Department of Surgery
State University of New York (SUNY-Downstate)
New York, New York
*Chapter 11, Transplantation*

David J. Hackam, MD, PhD, FACS
Garrett Professor and Chief of Pediatric Surgery
Professor of Surgery, Pediatrics and Cell Biology
Johns Hopkins University School of Medicine
Pediatric Surgeon-in-Chief and Co-Director
Johns Hopkins Children’s Center
The Charlotte R. Bloomberg Children’s Center
Baltimore, Maryland
*Chapter 39, Pediatric Surgery*

Kelly R. Haisley, MD
Clinical Instructor
Department of Surgery
Oregon Health and Science University
Portland, Oregon
*Chapter 32, Gallbladder and the Extrahepatic Biliary System*

Lee Hammerling, MD
Chief Academic Officer
President, New Ventures
ProMedica Health System
Toledo, Ohio
*Chapter 1, Leadership in Surgery*

Patrick Harbour, MD
Department of Plastic Surgery
MedStar Georgetown University Hospital
Washington, DC
*Chapter 16, The Skin and Subcutaneous Tissue*

Michael S. Harris, MD
Assistant Professor, Department of Otolaryngology
Assistant Professor, Medical College of Wisconsin
Department of Otolaryngology & Communication Sciences
Division of Neurotology & Skull Base Surgery
Milwaukee, Wisconsin
*Chapter 18, Disorders of the Head and Neck*
Contributors

David G. Heidt, MD, FACS
Clinical Associate Professor

Chapter 5, Shock
It was a singular privilege to serve as editor-in-chief of the first and subsequent six editions of *Principles of Surgery*. The invitation from the current editor-in-chief, Dr. F. Charles Brunicardi, who has discharged that responsibility for the ensuing four editions, to participate in the textbook’s 50th anniversary, is gratifying. The readers of the first seven editions often commented on the distinctive yellow cover. On this particular celebration of longevity, the color yellow connotes “gold.”

The past 50 years has witnessed an unimaginable growth in scientific knowledge available to students of surgery. The “science of surgery” has gained dominance over the “art of surgery.” Diverse technologies have been incorporated to expedite diagnosis and improve surgical excision or repair. The establishment of more precise criteria for categorization and analyzing data, coupled with advances in informatics, has allowed for the practice of “evidence-based medicine and surgery.” It is, as if, today’s surgeons have adopted a new language, new rules, new protocols—and anticipate new outcomes. The passage of time has been associated with transformative change, which has been beautifully captured in the 11th edition.

Among the “Basic Considerations” that transcend individual organ systems, change has occurred at an ever-accelerating pace, in multiple arenas, with variable consequences, since the first edition made its debut. Not all changes have been favorable. Increased effectiveness of antibiotics has improved the outcomes of the treatment of sepsis, but has been associated with the appearance of *clostridium difficile* colitis and lethal MRSA hospital outbreaks. HIV, AIDS, HPV (human papilloma virus), and hepatitis B and C had not entered the surgical lexicon prior to publication of *Principles of Surgery*.

Over the course of years, trauma has become an ever-increasing problem. Since publication of the first edition, improved diagnostic techniques have altered the approach to individuals who sustained major trauma. The concept of immediate “damage control to be followed by delayed definitive treatment,” the availability of angioembolization to control bleeding, and inert material to maintain protect the unclosed abdominal abdomen for protected state for a critical, at times prolonged, period of time, during which caloric requirements are satisfied parenterally.

In oncology, a more precise tumor classification based on size, nodal involvement, metastases, chemical and biologic characteristics has been accepted. This, in turn, has allowed for more meaningful assessment of a variety of therapeutic regimens. Chemotherapy has been joined by immunotherapy, and targeted, precision genomic therapy has recently been introduced.

At the time of publication of the first edition of *Principles of Surgery*, only the kidney was deemed clinically acceptable for homotransplantation and satisfactory immunosuppression had not been developed. Advances in immunosuppression have added the liver, pancreas, small bowel, heart, and lungs to the list of organs transplanted with anticipated success.

Among the 1805 pages of text in the first edition, “facts” and “declarations by experts” have failed to stand the test of time for a variety of reasons. Little effort is required to uncover statements that now would be judged “False!” For example: (1) Cancer of the hypopharynx is three to four times as common as cancer of the larynx (the reverse is true). (2) Effective treatment of a single ventricle in a neonate is not feasible. (3) The distal 1 to 2 cm of the esophageal lumen is normally lined by columnar rather than squamous epithelium (the description of a Barrett’s esophagus). (4) There is but one treatment for acute appendicitis…the only question to be resolved is the timing of surgical intervention. (5) The adenomatous (colon) polyp is a lesion of negligible malignant potential. (6) The only acceptable treatment for a splenic injury accompanied by any evidence of intraperitoneal bleeding in an adult is splenectomy. (7) Hundred percent of patients with primary hyponatremia have hypokalemia (most have no hypokalemia). More dramatic is the evidence that many of the prevalent surgical procedures that merited detailed illustration, consuming multiple pages in the first edition, are now, rarely if ever, performed.
It must be emphasized that a textbook chronicles a science during the contemporaneous time. The first edition, as is true for each of the 11 editions of *Principles of Surgery*, is a compendium that pertains, solely, up to the time of publication. Print does not imply permanence. Print often outlasts the fact it promulgates. I congratulate Dr. Brunicardi and the coeditors on a modern and beautifully written 11th edition that carries forward the tradition of the *Principles of Surgery* into the next 50 years.

Seymour I. Schwartz, MD, FACS
Distinguished Alumni Professor of Surgery
University of Rochester School of Medicine & Dentistry
It is both an honor and a privilege to be asked to become an associate editor for the 11th edition of *Schwartz’s Principles of Surgery*. Much has changed since the first edition was published in 1969, particularly in terms of how adult learners obtain knowledge. Today, approximately nine out of ten American adults use the internet and internet use by college graduates is nearly universal. Journal articles on any and all topics are available with a few keystrokes, with over 1,000 new articles being added daily to archives such as PubMed Central. Additionally, there are a multitude of online textbooks, videos of procedures, interactive surgical simulator applications, and other web-based resources that are widely available to medical students and professionals. *So, one might ask, do we still need surgical textbooks?*

The debate about whether textbooks are obsolete is not a new one. Opponents of textbooks suggest that they are expensive and inconvenient to access. Their content can be argued to become quickly outdated and to be unengaging to the modern learner who prefers interactive, multimedia content. On the other hand, proponents of textbooks note that evidence is lacking that comprehension is improved with digital technology. Furthermore, textbooks allow teachers to provide content within a clear framework, to ensure uniform delivery of content, and to have ease in re-referencing information.

*What is the right answer?* Modern and future learners should have textbooks available to them in multiple media formats. One media type does not fit all learners. Like surgery, optimal learning must be personalized based on an individual’s preferences. The editors and publishing company behind *Schwartz’s Principles of Surgery* have embraced this idea—the hardcover continues to be the best-selling general surgery textbook worldwide and there are no plans to eliminate the printed version. At the same time, the content is widely available on an interactive digital platform—Access Surgery—that includes access to multiple textbooks, quick references, a video atlas, and test review questions.

Regardless of the format, knowledge must come from a reliable source of information. For example, each chapter in the 11th edition of *Schwartz’s Principles of Surgery* is written by at least one, and often two or more, authors who are experts in the subject matter. These authors have frequently built on work by those who have preceded them. Furthermore, each chapter is supported by the evidence and vetted by one or more senior surgeons serving as editors. This new edition continues to provide up-to-date information on age-old topics in surgery such as the physiologic basis of disease as well as on the clinical diagnosis and management of surgical diseases.

The 11th edition deftly balances core knowledge that has stood the test of time with contemporary advances in science and technology. Examples include updated chapters on “Molecular Biology, The Atomic Theory of Disease, and Precision Surgery” and “Minimally Invasive Surgery, Robotics, and Natural Orifice Transluminal Endoscopic Surgery.” Additionally, there are multiple chapters focused on non-technical skills, which are often more important than technical skills, such as the first chapter of the textbook on “Leadership in Surgery.” This 11th edition also boasts five new chapters: “Enhanced Recovery after Surgery,” “Understanding and Evaluating Evidence for Surgical Practice,” “Ambulatory/Outpatient Surgery,” “Skills and Simulation,” and “Web-Based Education and Implications of Social Media.”

The fact that the 11th edition of *Schwartz’s Principles of Surgery* marks the textbook’s 50th anniversary is a testament to its continued relevance and contributions to surgical education. Moreover, its longevity is also a reflection of far-sighted editors-in-chief, first Dr. Seymour Schwartz followed by Dr. F. Charles Brunicardi, who have been able to not only keep up with but also to anticipate changes in the surgical landscape. Not only is surgery a continuously changing discipline, but also the world in which surgeons practice is constantly evolving, as reflected by the digital era. Nonetheless, textbooks and the knowledge they carry will continue to play an important role, regardless of their format and packaging.

Lillian S. Kao, MD
Jack H. Mayfield, MD, Chair in Surgery
Professor and Chief, Division of Acute Care Surgery

Vice Chair of Quality of Care
Co-Director, Center for Surgical Trials and Evidence-based Practice (C-STEP)
Department of Surgery
McGovern Medical School at the University of Texas Health Science Center at Houston
For more free medical ebooks go to extern.ir
With the publication of its 11th edition, Schwartz’s Principles of Surgery celebrates its 50th anniversary. It is remarkable to consider the number of students, residents, fellows, surgeons, and patients who have benefitted from the collective knowledge compiled in this text over the last half-century. It is an honor for the current editorial board to carry forward the tradition of excellence in education established by Dr. Seymour Schwartz and previous editors. We recognize that surgeons have entered into an era of surgery in which the outcomes of operations and patient satisfaction scores are carefully monitored, demanding excellence through enhanced evidenced-based knowledge, patient-family–centered care, and the highest levels of professionalism.

The first chapter on leadership has taken on special meaning in light of the new demands placed on surgeons for both technical and nontechnical skills, underscoring the importance of instituting a formal leadership-training program for surgery students of all ages with an emphasis on mentoring. We have also entered into the dawn of a new era of surgery with advances in minimally invasive surgery using robots, molecular contrast, and full computerization, thus enhancing the safety of surgery and allowing surgeons a more comfortable environment in which to work. We recognize that the use of “omic” information is ushering in an era of precision surgery and the importance of surgeons, who have access to the tissues of the human body on a daily basis for “omic” profiling that will guide targeted therapies to enhance the outcomes of surgery.

Taking these constructs into consideration, the editors and authors of this 11th edition have done their very best to revise each chapter and convey the current state-of-the-art in surgery. Continuing in this effort, five new chapters have been added: Understanding and Evaluating Evidence for Surgical Practice, Enhanced Recovery after Surgery, Ambulatory/Outpatient Surgery, Skills and Simulation, and Web-based Education and Implications of Social Media. This edition contains the latest in leadership training, surgical science, surgical techniques, and therapy for students, residents, fellows, and surgeons. Another important component of this new edition is the artwork. We acknowledge the outstanding artistic team of Jason M. McAlexander & Associates who directed the full color art program, which provides clear and consistent learning aids throughout the text and visually reflects the comprehensive and updated nature of this book.

The editors are thankful that this text is a trusted source for training and crafting surgeons worldwide. Such success is due in large part to the extraordinary efforts of our contributors—leaders in their fields—who not only train up-and-coming surgeons but also impart their knowledge and expertise to benefit patients across the globe. The inclusion of many international authors to the chapters within is ultimately a testament to mentorship, albeit on a broader scale, and we thank these authors and mentors, both near and far. To our fellow editorial board members who have tirelessly devoted their time and knowledge to the integrity and excellence of their craft and this textbook, we extend our gratitude. We are thankful to Andrew Moyer, Christie Naglieri, and all at McGraw-Hill who continued to believe in and support this work, and we wish to thank Katie Elsbury for her dedication to the organization and editing of this edition. Lastly, we would like to thank our families for their support and love.

F. Charles Brunicardi, MD, FACS
Dedication

We, the editors of this leading textbook of surgery, *Schwartz’s Principles of Surgery* are pleased to dedicate the 11th edition to Dr. Frank Gordon Moody. While most academic surgeons recognize Dr. Moody, as a top echelon surgical leader of the last half century, we choose to dedicate this edition to him because of the profound influence he had on the careers of many of the editors of this textbook. To some of us, Dr Moody was our surgical chair and academic inspiration. To others he was a research collaborator. For those of us who are not direct descendants, academically speaking, Frank Moody had the ability to recognize and provide the gift of mentorship to talented academic surgeons, irrespective of their academic pedigree.

Dr. Moody was born in Franklin, New Hampshire, attended Dartmouth College and Dartmouth Medical School (when it was a two-year school) then received his MD from Cornell. He stayed at Cornell throughout his surgical training, enticed into upper GI surgery by Dr. Frank Glenn. His academic career started at the University of California, San Francisco, under the legendary leadership of Dr. Bert Dunphy. He was subsequently recruited to the University of Alabama, Birmingham, where he rose to the rank of professor. In 1971, he became the Chair of Surgery at the University of Utah, coupling his love for skiing and hiking with an intense desire to bring scientific inquiry to the Wasatch Front. There, his passion for mentorship was uncovered. Eight of his trainees became department chairs, and many more visited Utah where the academic ‘bug’ was inoculated. In 1982, Dr. Moody took his talents to the University of Texas, Houston, where he served as the Denton Cooley Chair of Surgery. While he stepped down as Chair 12 years later, Dr. Moody remained in Texas for the rest of his career. Dr. Moody’s influence was truly global; he was active in the International Surgical Society and was a founder of the International Surgical Group. It was often said that there was never a meeting that Dr. Moody missed— and at every meeting he truly “showed up”, contributing to the program, asking challenging questions, and spurring new lines of investigation for the many GI surgeons lucky enough to have Dr. Moody engage with their line of discovery. Nearly continuously funded by the National Institutes of Health (NIH) from 1967 to 2008, Dr. Moody was a force for surgical science, encouraging active participation by surgeons in the NIH study sections.

To many of the editors, the connection to Dr. Moody was even more personal. Attracted to training in Utah by the combination of skiing, science, and great surgical training, I first met Dr. Moody in the pages of the 3rd edition of this textbook, in which he authored the chapter on gallbladder disease. After many years of learning in the operating room and the laboratory, it is an honor to follow in his footsteps as the author of this chapter in this and the prior three editions of this classic surgical book. Dr. Moody, we will miss you, and hope to carry your many gifts forward, the greatest of which were your support and mentorship of the many who have been lucky enough to follow in your footsteps.

John G. Hunter MD and the editors of *Schwartz’s Principles of Surgery, 11th edition*
This page intentionally left blank
INTRODUCTION

The field of surgery has evolved greatly from its roots, and surgical practice now requires the mastery of modern leadership principles and skills as much as the acquisition of medical knowledge and surgical technique. Historically, surgeons took sole responsibility for their patients and directed proceedings in the operating room with absolute authority, using a command-and-control style of leadership. Modern surgical practice has now evolved from single provider–based care toward a team-based approach, which requires collaborative leadership skills. Surgical care benefits from the collaboration of surgeons, anesthesiologists, internists, radiologists, pathologists, radiation oncologists, nurses, pharmacists, social workers, therapists, hospital staff, and administrators. Occupying a central role on the healthcare team, surgeons have the potential to improve patient outcomes, reduce medical errors, and improve patient satisfaction through their leadership of the multidisciplinary team. Thus, in the landscape of modern healthcare systems, it is imperative that surgical training programs include formal instruction on leadership principles and skills to cultivate their trainees’ leadership capabilities.

Many medical and surgical communities, including residency training programs, acknowledge the need for improved physician leadership. Specifically, surveyed surgical residents felt a lack of confidence in multiple areas of leadership, particularly in conflict resolution. Surgical trainees identify leadership skills as important, but they report themselves as “not competent” or “minimally competent” in this regard. While a small number of surgical training programs have implemented formal curricula focused on teaching leadership principles, it is now imperative that all surgical training programs teach these important skills to their trainees. Interviews of academic chairpersons identified several critical leadership success factors, including mastery of visioning, communication, change management, emotional intelligence, team building, business skills, personnel management, and systems thinking. These chairpersons stated that the ability of emotional intelligence was “fundamental to their success and its absence the cause of their failures,” regardless of medical knowledge. Thus, residency programs need to include leadership training to prepare future surgeons for success in modern healthcare delivery.

In the United States, the Accreditation Council for Graduate Medical Education (ACGME) has established six core competencies—patient care, medical knowledge, practice-based learning and improvement, interpersonal and communication skills, professionalism, and systems-based practice (Table 1-1)—that each contain principles of leadership. The ACGME has mandated the teaching of these core competencies but has not established a formal guide on how to teach the leadership skills described within the core competencies. Therefore, this chapter offers a review of fundamental principles of leadership and an introduction of the concept of a leadership training program for future surgeons.

DEFINITIONS OF LEADERSHIP

Many different definitions of leadership have been described. Former First Lady Rosalynn Carter once observed that “A leader takes people where they want to go. A great leader takes people
Key Points

1. Effective surgical leadership improves patient care, safety, and clinical outcomes.
2. A fundamental principle of leadership is to provide a vision that people can live up to, thereby providing direction and purpose to the constituency.
3. Surgical leaders have the willingness to lead through an active and passionate commitment to the vision.
4. Surgical leaders have the willingness to commit to lifelong learning.
5. Surgical leaders have the willingness to communicate effectively and resolve conflict.
6. Surgical leaders must practice effective time management.
7. Different leadership styles are tools to use based on the team dynamic.
8. Surgical trainees can be taught leadership principles in formal leadership training programs to enhance their ability to lead.
9. Mentorship provides wisdom, guidance, and insight essential for the successful development of a surgical leader.

Levels of Leadership

When working toward organizational success, strong leadership is a critical component. The best study of the relationship between leadership skill and organizational success is in the field of business. In business, the processes of customer satisfaction, product development, and organization efficiency are the equivalent of patient satisfaction, medical advancement, and efficient delivery of care. Jim Collins, author of *Good to Great*, studied the success and leadership styles of Fortune 500 companies over a 30-year period. He found that leadership is strongly correlated with corporate success, and most importantly for our study, that leadership strength can be broken down by level and characteristic (See figure 1-1).

Of 11 particularly outstanding organizations identified, great leadership was the single major defining characteristic that distinguished them from their peers. These organizations were led by what Collins called the “Level 5 Leader,” one whose personal humility and professional will drove team success. Under this system of leadership study, surgeon-leaders begin at the bottom level and, through study, hard work, and professional development, advance to the ultimate level of leadership.

**FUNDAMENTAL PRINCIPLES OF LEADERSHIP**

Leadership is a complex concept. Surgeons should strive to adopt leadership qualities that provide the best outcomes for their patients, based on the following fundamental principles: vision, willingness, time management, conflict resolution,
recruitment, and culture (See Table 1-2). Surgeon-leaders will develop a team of faculty, residents, and other healthcare personnel who are aligned on mission, vision, and values. The team and leader must be willing to address complex problems with honest communication and well-developed conflict resolution skills. A culture must be established where faculty and staff will work towards the advancement of the medical arts and the greater good of society.9

**Vision**

The first and most fundamental principle of leadership is to establish a vision that people can live up to, thus providing direction and purpose to the constituency. Creating a vision is a declaration of the near future that inspires and conjures motivation.10 A classic example of a powerful vision that held effective impact is President Kennedy’s declaration in 1961 that “... this nation should commit itself to achieving the goal, before this decade is out, of landing a man on the moon and returning him safely to the earth.” Following his declaration of this vision with a timeline to achieve it, the United Sates mounted a remarkable unified effort, and by the end of the decade, Neil Armstrong took his famous walk and the vision had been accomplished (Fig. 1-2).

On a daily basis, surgeons are driven by a powerful vision: the vision that our surgical care will improve patients’ lives. The great surgical pioneers, such as Hunter, Lister (Fig. 1-3), Halsted, von Langenbeck, Billroth, Kocher (Fig. 1-4), Carrel, Gibbon, Blalock, Wangensteen, Moore, Rhoads, Huggins, Murray, Kountz, Longmire, Starzl, and DeBakey (Fig. 1-5), each possessed a vision that revolutionized the field of surgery. In the 19th century, Joseph Lister changed the practice of surgery with his application of Pasteur’s germ theory. He set a young boy’s open compound leg fracture, a condition with a 90% mortality rate at that time, using carbolic acid dressings and aseptic surgical technique. The boy recovered, and Lister gathered nine more patients. His famous publication on the use of aseptic technique introduced the modern era of sterile technique. Emil Theodor Kocher was the first to master the thyroidectomy, thought to be an impossible operation at the time, and went on to perform thousands of thyroidectomies with a mortality of less than 1%. He was awarded the Nobel Prize in Physiology or Medicine in 1909 for describing the thyroid’s physiologic role in metabolism. Michael E. DeBakey’s powerful vision led to the development of numerous groundbreaking procedures that helped pioneer the field of cardiovascular surgery. For example, envisioning an artificial artery for arterial bypass operations, Dr. DeBakey invented the Dacron graft, which has helped millions of patients suffering from vascular disease and enabled the development of endovascular surgery. Dr. Frederick Banting, the youngest recipient of the Nobel Prize in Physiology or Medicine, had a vision to discover the biochemical link between diabetes and glucose homeostasis. His vision and perseverance led to the discovery of insulin.11 In retrospect, the power and clarity of their visions were remarkable, and their willingness and dedication were inspiring. By studying their careers and accomplishments, surgical trainees can be inspired by the potential impact of a well-developed vision.

Generating Belief in Your Vision

Surgical leaders with great visions will inevitably require help from colleagues, other healthcare professionals, scientists, administrators, patients, and nonmedical personnel. To get this help, surgical leaders must inspire their team and understand motivation. For the surgeon-leader, it is critical to know that people do not follow leaders because of what they do; people follow leaders because of why they do what they do. The people who help the leader execute the vision are motivated by the leader’s beliefs and attitudes more than the leader’s policy or agenda. This concept, based on Simon Sinek’s *Start With Why*, is rooted in understanding of the anatomy and function of the human brain. See figure 1-6.

For example, take a surgeon-leader who wants to implement a new perioperative checklist to reduce surgical errors. The “what” is very simple: a checklist to reduce errors. The operating room team may make a rational decision to adopt the checklist; however, it is also possible that the checklist may be perceived as “another piece of paperwork” and rejected, or that the checklist may have its implementation fought, undermined, delayed, or ignored. A surgeon-leader who does not understand how people are motivated might argue rationally, telling the team that the checklist was created with great care, that all of the best evidence was incorporated in its creation, and that the checklist is short and efficient. This is the “how,” and once again it appeals to the rational and analytical side of the team. With these arguments, the surgeon-leader’s vision remains susceptible to rejection for many of the same reasons. A leader who understands how to motivate a team towards a vision will start with “why.” Before ever discussing the checklist in detail with the team, the leader will speak of their shared mission to offer the best patient care possible, ask the team to imagine how they might want a family member treated, and emphasize that a careless error could lead to patient harm and embarrassment for the team. With these arguments, which constitute an emotional appeal to the team’s belief system, the leader can expect this vision for better patient care via a new surgical checklist to be adapted by the team. The team will be receptive to implementing a new checklist, not because they believe in the checklist as a tool, but because they believe in the surgeon-leader’s vision for optimizing patient care.

There is a biological reason why this concept works. “Why,” “how,” and “what” are correlated to the functions

---

**Figure 1-6.** When leaders seek to generate belief in their vision, it is best to appeal to the team with “why” statements. (Data from Sinek S. *Start with why*: how great leaders inspire everyone to take action. London: Portfolio/Penguin; 2013.)
of separate anatomical levels in the human brain. The neocortex is, evolutionarily, the newest area of our brains, and it is responsible for the analytical and rational thoughts and decisions that we make. It corresponds to the “what” and the “how.” When the surgeon-leader in the previous example started with the checklist and its rational arguments, the leader was appealing to their team’s neocortex, and the vision was rejected. However, when the surgeon started with the “why,” the vision for better patient care was emotionally accepted by the team, who became receptive to the checklist as a tool for achieving the vision.

Surgery is a field that requires extraordinary dedication and great personal sacrifice. The very nature of vision—steps forward into a better future—implies that change and difficult work will be required of the leader. See figure 1-7. For this reason, surgeon-leaders should establish visions about which they are deeply passionate and committed so that when obstacles are encountered the leader has the strength of will to progress forward. Leaders should be selective about which options they pursue. Each opportunity and idea requires great effort to execute; ultimately only a few can be brought to completion. Therefore, leaders should understand what drives their organization’s economic engine: the ideas and opportunities that will bring patients better care, bring the organization more patients, and create new treatments, etc. Thousands of hospitals, companies, innovators, and physicians are addressing many of the same problems in healthcare, such as growing burdens of chronic disease, an aging population, and rising health costs. The best opportunities lie where talent and ability align, so leaders and organizations should be cognizant of choosing projects for which they have the potential to be the “best in the world” at doing. Once the vision is set and the project is chosen, it is up to the leader to generate momentum.

Momentum is either a cumulative effect of continuous steps towards improvement or, alternatively, in the negative sense, movements towards failure or stagnation. The “flywheel effect,” depicted in Fig. 1-8, demonstrates the building of momentum with (a) initial steps forward, (b) an accumulation of visible results, (c) realignment of the team in the new direction (accounting for new information and data), and then (d) an accumulation of momentum followed by more steps forward. Careful attention to the aforementioned principles is essential in building a successful surgical career, department, or division.

**Willingness**

The Willingness Principle represents the active commitment of the leader toward his or her vision. To do so, a surgical leader must be willing to lead, commit to lifelong learning, communicate effectively, and resolve conflict.

**To Lead.** A key characteristic of all great leaders is the willingness to serve as the leader. Dr. Martin Luther King Jr, who championed the civil rights movement with a powerful vision of equality for all based on a commitment to nonviolent methods, did so at a time when his vocalization of this vision ensured harassment, imprisonment, and threats of violence against himself, his colleagues, and his family and friends (Fig. 1-9). King, a young, highly educated pastor, had the security of employment and family, yet was willing to accept enormous responsibility and personal risk and did so in order to lead a nation toward his vision of civil rights, for which he was awarded the Nobel Peace Prize in 1964.

Willingness to lead is a necessity in any individual who desires to become a surgeon. By entering into the surgical theater, a surgeon accepts the responsibility to care for and operate on patients, despite the risks and burdens involved. They do so, believing fully in the improved quality of life that can be achieved. Surgeons must embrace the responsibility of leading surgical teams that care for their patients, as well as leading surgical trainees to become future surgeons. A tremendous sacrifice is required for the opportunity to learn patient care. Surgical trainees accept the hardships of residency with its accompanying steep learning curve, anxiety, long work hours, and time spent away from family and friends. The active, passionate commitment to excellent patient care reflects a natural willingness to lead based on altruism and a sense of duty toward those receiving care. Thus, to ensure delivery of the utmost level of care, surgical trainees should commit to developing and refining leadership skills. These skills include a commitment to lifelong learning, effective communication, and conflict resolution.

**To Learn.** Surgeons and surgical trainees, as leaders, must possess willingness to commit to continuous learning. Modern surgery is an ever-changing field with dynamic and evolving healthcare systems and constant scientific discovery and innovation. Basic and translational science relating to surgical care is growing at an exponential rate. The sequencing of the human
Basic Considerations

Part I

Genome and the enormous advances in molecular biology and signaling pathways are leading to the transformation of pre-cinematic medicine and personalized surgery in the 21st century (see Chapter 15). Performing prophylactic mastectomies with immediate reconstruction for BRCA1 mutations and thyroidectomies with thyroid hormone replacement for RET proto-oncogene mutations are two of many examples of genomic information guiding surgical care. Technologic advances in minimally invasive surgery and robotic surgery as well as electronic records and other information technologies are revolutionizing the craft of surgery. The expansion of minimally invasive and endovascular surgery over the past three decades required surgeons to retrain in new techniques using new skills and equipment. In this short time span, laparoscopy and endovascular operations are now recognized as the standard of care for many surgical diseases, resulting in shorter hospital stay, quicker recovery, and a kinder and gentler manner of practicing surgery. Remarkably, during the last century, the field of surgery has progressed at an exponential pace and will continue to do so with the advent of using genomic analyses to engineer cancer cells with molecular imaging agents that will guide personalized surgery, which will transform the field of surgery during this century. Therefore, surgical leadership training should emphasize and facilitate the continual pursuit of knowledge.

Willingness to learn encompasses the surgeon’s commitment to lifelong learning. This has been exemplified by the surgeons of the past several decades who have dedicated their peak practicing years to perfecting minimally invasive surgical techniques, including the use of robotic surgery. The field continues to advance, offering many advantages to patients including faster recovery, sometimes decreased pain depending on procedure type, and shorter hospital stays.16-18

Fortunately, surgical organizations and societies provide surgeons and surgical trainees a means to acquire new knowledge on a continuous basis. There are numerous local, regional, national, and international meetings of surgical organizations that provide ongoing continuing medical education credits, also required for the renewal of most medical licenses. The American Board of Surgery requires all surgeons to complete meaningful continuing medical education to maintain certification.19 These societies and regulatory bodies enable surgeons and surgical trainees to commit to continual learning and ensure their competence in a dynamic and rapidly growing field.

Surgeons and trainees now benefit from the rapid expansion of web-based education as well as mobile handheld technology. These are powerful tools to minimize nonproductive time in the hospital and make learning and reinforcement of medical knowledge accessible. Currently web-based resources provide quick access to a vast collection of surgical texts, literature, and surgical videos. Surgeons and trainees dedicated to continual learning should be well versed in the utilization of these information technologies to maximize their education. The next evolution of electronic surgical educational materials will likely include simulation training similar to laparoscopic and Da Vinci device training modules. The ACGME, acknowledging the importance of lifelong learning skills and modernization of information delivery and access methods, has included them as program requirements for residency accreditation.

To Communicate Effectively. The complexity of modern healthcare delivery systems requires a higher level and collaborative style of communication. Effective communication directly impacts patient care. In 2000, the U.S. Institute of Medicine published To Err Is Human: Building a Safer Health System, which raised awareness concerning the magnitude of medical errors. This work showcased medical errors as the eighth leading cause of death in the United States with an estimated 100,000 deaths annually.20 Subsequent studies examining medical errors have identified communication errors as one of the most common causes of medical error.21-23 In fact, the Joint Commission identifies miscommunication as the leading cause of sentinel events. Information transfer and communication errors cause delays in patient care, waste surgeon and staff time, and cause serious adverse patient events.23 Effective communication among surgeons, nurses, ancillary staff, and patients is not only a crucial element to improved patient outcomes, but it also leads to less medical litigation.24-26 A strong correlation exists between communication and patient outcomes.

Establishing a collaborative atmosphere is important since communication errors leading to medical mishaps are not simply failures to transmit information. Communication errors “are far more complex and relate to hierarchical differences, concerns with upward influence, conflicting roles and role ambiguity, and interpersonal power and conflict.”22,27-29 Errors frequently originate from perceived limited channels of communication and hostile, critical environments. To overcome these barriers, surgeons and surgical trainees should learn to communicate in an open, universally understood manner and remain receptive to any team member’s concerns. A survey of physicians, nurses, and ancillary staff identified effective communication as a key element of a successful leader.30 As
leaders, surgeons, and surgical trainees who facilitate an open, effective, and collaborative style of communication can reduce errors and enhance patient care. A prime example is that successful communication of daily goals of patient care from the team leader improves patient outcomes. In one recent study, the modest act of explicitly stating daily goals in a standardized fashion significantly reduced patient length of intensive care unit stay and increased resident and nurse understanding of goals of care.31 Implementing standardized daily team briefings in the wards and preoperative units led to improvements in staff turnover rates, employee satisfaction, and prevention of wrong-site surgery.27 In cardiac surgery, improving communication in the operating room and transition to the postanesthesia care unit was an area identified to decrease risk for adverse outcomes.32 Behaviors associated with ineffective communication, including absence from the operating room when needed, playing loud music, making inappropriate comments, and talking to others in a raised voice or a condescending tone, were identified as patient hazards; conversely, behaviors associated with effective collaborative communication, such as leading the time-out process and closed-loop communication technique, resulted in improved patient outcomes.

One model to ensure open communication is through standardization of established protocols. A commonly accepted protocol is the “time out” that is now required in the modern operating room. During the time-out protocol, all team members introduce themselves and state a body of critical information needed to safely complete the intended operation. This same standardization can be taught outside the operating room. Within the Kaiser system, certain phrases have been given a universal meaning: “I need you now” by members of the team is an understood level of urgency and generates a prompt physician response 100% of the time.27 As mentioned earlier, standardized forms can be useful tools in ensuring universally understood communication during sign-out. The beneficial effect of standardized team communication further demonstrates how effective communication can improve patient care and is considered a vital leadership skill.

Effective communication with patients in the modern era, necessitates understanding that many patients access health information via the internet and that patients are often ill equipped to evaluate the individual source.33,34 Discrepancies exist between surgeon’s self-perceived ability to communicate and patient’s actual satisfaction. A patient’s perceived interaction with their physician has an enormous impact on patient health outcomes, malpractice, and financial reimbursement;35,36 specifically, the association between poor doctor–patient communication and a patient’s perception that their doctor does not care about them. Good bedside manner has been shown to decrease litigation even in situations of error or undesirable outcome.37,38 Physicians who demonstrate concern, actively know their patients, and share responsibility for decision-making are more likely to be trusted by their patients.26,41,42 Strong doctor–patient relationships and effective communication skills have been incentivized by the Agency for Healthcare Research and Quality and the Centers for Medicare & Medicaid Services through their Hospital Consumer Assessment of Healthcare Providers and Systems (HCAHPS) and Clinical and Group Consumer Assessment of Healthcare Providers and Systems (CGCAHPS) programs, which measure patient satisfaction.43

To Resolve Conflict. Great leaders are able to achieve their vision through their ability to resolve conflict. Delivery of modern surgical care is complex; numerous conflicts arise on a daily basis when surgeons and surgical trainees provide high-quality care. Therefore, the techniques for conflict resolution are essential for surgical leaders.

To properly use conflict resolution techniques, it is important for the surgeon and surgical trainee to always remain objective and seek personal flexibility and self-awareness. The gulf between self-perception and the perception of others can be profound; in a study of cooperation and collaboration among operating room staff, the quality of their own collaboration was rated at 80% by surgeons, yet was rated at only 48% by operating room nurses.44 Systematic inclusion of modern conflict resolution methods that incorporate the views of all members of a multidisciplinary team help maintain objectivity. Reflection is often overlooked in surgical residency training, but it is a critical component of learning conflict resolution skills. Introspection allows the surgeon to understand the impact of his or her actions and biases. Objectivity is the basis of effective conflict resolution, which can improve satisfaction among team members and help deliver optimal patient care.

Modern conflict resolution techniques are based on objectivity, willingness to listen, and pursuit of principle-based solutions.45 For example, an effective style of conflict resolution is the utilization of the “abundance mentality” model, which attempts to achieve a solution that benefits all involved and is based on core values of the organization, as opposed to the utilization of the traditional fault-finding model, which identifies sides as right or wrong.46 Application of the abundance mentality in surgery elevates the conflict above the affected parties and focuses on the higher unifying goal of improved patient care. “Quality Improvement” (previously or alternatively “Morbidity and Mortality”) conferences are managed in this style and have the purpose of practice improvement and improving overall quality of care within the system, as opposed to placing guilt or blame on the surgeon or surgical trainees for the complication being reviewed. The traditional style of command-and-control technique based on fear and intimidation is no longer welcome in any healthcare system and can lead to sanctions, lawsuits, and removal of hospital privileges or position of leadership.

Another intuitive method that can help surgical trainees learn to resolve conflict is the “history and physical” model of conflict resolution. This model is based on the seven steps of caring for a surgical patient that are well known to the surgical trainee: (a) the “history” is the equivalent of gathering subjective information from involved parties with appropriate empathy and listening; (b) the “laboratory/studies” are the equivalent of collecting objective data to validate the subjective information; (c) a “differential diagnosis” is formed out of possible root causes of the conflict; (d) the “assessment/plan” is developed in the best interest of all involved parties; the plan, including risks and benefits, is openly discussed in a compassionate style of communication; (e) “preoperative preparation” includes the acquisition of appropriate consultations for clearances, consideration of equipment and supplies needed for implementation, and the “informed consent” from the involved parties; (f) the “operation” is the actual implementation of the agreed-upon plan, including a time-out; (g) and “postoperative care” involves communicating the operative outcome, regular postoperative follow-up, and the correction of any complications that arise. This seven-step method is an example of an objective, respectful method of conflict resolution.47 Practicing different styles of conflict resolution and effective communication in front of the entire group of
surgical trainees attending the leadership training program is an effective means of teaching conflict resolution techniques.

**Time Management**

It is important for leaders to practice effective time management. Time is the most precious resource, as it cannot be bought, saved, or stored. Thus, management of time is essential for a productive and balanced life for those in the organization. The effective use of one’s time is best done through a formal time management program to improve one’s ability to lead by setting priorities and making choices to achieve goals. The efficient use of one’s time helps to improve both productivity and quality of life.48-50

It is important for surgeons and surgical trainees to learn and use a formal time-management program. There are ever-increasing demands placed on surgeons and surgical trainees to deliver the highest quality care in highly regulated environments. Furthermore, strict regulations on limitation of work hours demand surgical trainees learn patient care in a limited amount of time.48-50 All told, these demands are enormously stressful and can lead to burnout, drug and/or alcohol abuse, and poor performance.48-50 A time-motion study of general surgery trainees analyzed residents’ self-reported time logs to determine resident time expenditure on educational/service-related activities (Fig. 1-10).30 Surprisingly, senior residents were noted to spend 13.5% of their time on non-service/mainly educational value activities (Fig. 1-10).50

Time is the most precious resource, as it cannot be bought, saved, or stored. Thus, management of time is essential for a productive and balanced life for those in the organization. The effective use of one’s time is best done through a formal time management program to improve one’s ability to lead by setting priorities and making choices to achieve goals. The efficient use of one’s time helps to improve both productivity and quality of life.48-50

It is important for surgeons and surgical trainees to learn and use a formal time-management program. There are ever-increasing demands placed on surgeons and surgical trainees to deliver the highest quality care in highly regulated environments. Furthermore, strict regulations on limitation of work hours demand surgical trainees learn patient care in a limited amount of time.48-50 All told, these demands are enormously stressful and can lead to burnout, drug and/or alcohol abuse, and poor performance.48-50

A frequently used basic technique is the “prioritized list,” also known as the ABC technique. Individuals list and assign relative values to their tasks. The use of the lists and categories serves solely as a reminder, thus falling short of aiding the user in allocating time wisely. Another technique is the “time management matrix technique.”49 This technique plots activities on two axes: importance and urgency, yielding four quadrants (Fig. 1-11). Congruous with the Pareto’s 80/20 principle and Parkinson’s law, the time management matrix technique channels efforts into quadrant II (important but nonurgent) activities. The activities in this quadrant are high yield and include planning, creative activity, building relationships, and maintaining productivity. Too often, surgeons spend a majority of their time attending to quadrant I (important and urgent) tasks. Quadrant I tasks include emergencies and unplanned or disorganized situations that require intensive and often inefficient effort. While most surgeons and surgical trainees have to deal with emergencies, they often develop the habit of inappropriately assigning activities into quadrant I; excess time spent on quadrant I tasks leads to stress or burnout for the surgeon and distracts from long-term goals. Efficient time management allows surgeons and surgical trainees to be proactive about shifting energy from quadrant I tasks to quadrant II, emphasizing preplanning and creativity over always attending to the most salient issue at hand, depending on the importance and not the urgency.

Finally, “the six areas of interest” is an alternative effective time management model that can help surgeons and surgical trainees achieve their goals, live a better-balanced lifestyle, and improve the quality of their lives.49 The process begins by performing a time-motion study in which the activities of 6-hour increments of time over a routine week are chronicled. At the end of the week, the list of activities is analyzed to determine how the 168 hours in 1 week have been spent. The surgical trainee then selects six broad categories of areas of interest.
LEADERSHIP IN SURGERY
CHAPTER 1
(i.e., family, clinical care, education, health, community service, hobbies) and sets a single activity goal in each category every day and monitors whether those goals are achieved. This technique is straightforward and improves one’s quality of life by setting and achieving a balanced set of goals of personal interest, while eliminating time-wasting activities.

A formal time management program is essential for modern leadership. The practice and use of time management strategies can help surgeons and surgical trainees achieve and maintain their goals of excellent clinical care for their patients, while maintaining a more balanced lifestyle.

Self-Care and Wellness
The challenges of practicing medicine place unique stresses on surgeons. A departmental program for improving wellness and teaching self-care can help alleviate these stresses. Acknowledging these stresses is an important step for any leader to help peers at risk. Quality of life surveys have identified individual protective factors that can be implemented prophylactically. These factors for improving self-care and wellness include regular exercise programs, maintenance of routine medical care, and health screening. The following may not apply to all physicians; however, religious practices, reflective writing, and maximizing work-life balance have also been demonstrated to be protective.

Surgeons and physicians overall experience increased rates of suicide, depression, substance abuse, marital and family problems, and other stress-related health effects as compared to the general population. Suicide rates in physicians are higher among those who are divorced, widowed, or never married. Depression is a common challenge, with rates as high as 30% among trainees, and higher when lifetime risk is considered. Drug and alcohol abuse among physicians mirrors the general population; however, physicians have higher rates of prescription drug abuse. The ability to self-medicate likely contributes to prescription drug abuse by physicians. Divorce and marriage unhappiness among physicians has been attributed to the “psychology of postponement,” compulsive personality traits that are reinforced and selected for during medical training, and lack of work-life balance. Residents, due to their inexperience, may be at higher risk than practicing physicians. For physicians who do not seek professional help, fear of losing their medical license is the most commonly provided reason. Departmental wellness programs may provide an alternative source of support for these surgeons.

The past 10 years have seen a significant increase in attention to the issue of physician wellness. Physician wellness has become an issue transcending specialties and resulting in significant research. The creation of wellness and self-care programs within departments represents an opportunity for surgeons to demonstrate leadership qualities.

Recruitment
The challenges of modern medicine and ever-larger medical centers have created a reality where no single surgeon-leader can exercise complete control—it takes a team of leaders with shared vision, mission, and goals. To this end, the previously discussed “level 5 leader” who embodies personal humility and professional will is essential. Previous generations whose leaders and departments were composed of self-proclaimed giants dominated and suppressed alternative points of view, communication, and innovation. In recent years, there has been a change to building teams with authentic leaders who have high ethical standards and well-developed nontechnical skills, who lead by example, and who never compromise excellence. The surgeon-leader must build a team where talented individuals are placed in the right job for their skills. The essence of a leader is one who enables others to succeed. Team work is imperative to change, and trust is the make-or-break component. Simply put, teams that trust each other work well, and teams that do not trust each other do not work well.

Creating a Culture of Empathy, Patient-Family-Centered Care, and Personalized Surgery
Creating the right culture is the most challenging of all the surgeon-leader’s tasks. Modern surgical departments should focus on creating a culture of empathy, patient–family-centered care, and personalized surgery. Instilling a positive culture requires both discipline and consistency because it may take considerable time to change how people think, feel, and behave. Organizational culture is built around the leader’s vision and values. Coming up with strong values requires genuine commitment. A leader should realize that staying true to his or her values can be challenging when conflicts arise.

WHY WE LEAD
Choosing to Become a Leader
There are many benefits to becoming a leader. Humankind has pondered the question of whether leaders are born or made for millennia. The best evidence to date indicates that leaders are both born and made. Leadership potential is a skill that all persons are born with, to some degree, and that can be formally trained, learned through observation, and honed with practice. The positive effects of a leader on others are innumerable, including a leader’s positive influence on innovation, diversity, culture, and quality. For modern surgeons, leadership skills are essential for the delivery of quality patient care; therefore, it is the duty of the surgeon to study leadership.

For the surgeon studying to be a better leader, effective leadership also has many individual benefits, including recognition from one’s peers, promotion, and autonomy. Modern leaders are increasingly required to be humble about their accomplishments in order to be successful and effective. Beyond recognition, promotion, and autonomy there are more selfless reasons for surgeons to desire leadership. Leadership is a tool to help make a difference. Leadership is a good path towards a career as an educator, which offers the leader a sense of accomplishment and satisfaction in seeing others succeed. Some choose to become leaders out of a sense of selfless service, taking on leadership for the benefit of others, or out of a desire to solve problems. Leadership may come with material rewards, including wealth and power, which motivate some.

Whatever the motivation, surgeons, in their role as leaders of patient care teams, have a duty to develop some skill in leadership. It would be best for individuals, departments, and patients if all surgeons sought to develop leadership skills and experience in some area of administration, patient care, education, or research. The benefits to the individual are numerous.

Leadership’s Effect on Healthcare Cost and Clinical Outcomes
Much attention has rightly been paid to historical leaders’ impact on humanity. Surgical leaders of the past have made great contributions on which we may build. All surgeons have a responsibility to be leaders, whether at the team level or in
an administrative or organizational capacity. To that end, it is worth noting the benefits of formal leadership education.

Large observational studies using trained observers assessed the effects of different surgical leadership styles on operative cases. Team cohesion and collective efficiency were reduced when leaders utilized abusive supervision or over-controlling methods. Abusive supervision alone was associated with decreased “psychological safety.” Surgeons perceived having positive leadership characteristics by their staff have lower 30-day all-cause mortality. This is likely due to creating a culture of safety where the staff can speak up if they notice an error and feel they have the latitude to do what is best for the patient quickly and autonomously.

With increased recognition and attention on human error, nontechnical skills, including leadership, play a role in patient safety. The landmark study, “To Err Is Human,” estimated that almost 100,000 people die each year due to medical errors. In the surgical setting, 40% to 50% of errors may be attributed to communication breakdown. The Multifactor Leadership Questionnaire scores subjects on their demonstration of transformational leadership behaviors. Transformational leaders exhibit the qualities of charisma, inspired motivation, intellectual stimulation, and individualized consideration. In video analysis of complex surgical operations, surgeons scoring even a single point higher on the transformational leadership score exhibited 3 times more information sharing behaviors, 5 times more positive voice behaviors, and 10 times more supportive behaviors, all while displaying poor behaviors 12.5 times less frequently than their peers. Exhibiting the characteristics of transformational leadership clearly has much to offer the surgeon-leader in preventing serious errors.

The field of trauma contains the largest body of formal study demonstrating the positive effects of leadership on clinical results. Strong leadership skills improve both the speed of resuscitation and completion of the initial trauma evaluation. There is no one optimal style of leadership covering all situations; some call for a more empowering leadership style while others call for a more directive style. The optimal style of leadership varies based on team composition, with less experienced teams better responding to the directive style, while more experienced teams work faster with trust and an empowering style. The formally educated surgical leader should be able to switch easily between styles based on the situation at hand.

Leadership styles affect responses to patient safety concerns and protect the organization as a whole. The surgical leader adopts a supervisory capacity while creating a culture of safety. In detail, frontline staff must be encouraged to participate in safety improvement. Staff ownership of safety must be established and upheld. In order to assure this outcome, whistle-blowers must be protected. A culture of psychological safety, organizational fairness, and continuous learning is required. Subordinates require appropriate authority, autonomy, and latitude to do their jobs and care for patients.

Formal leadership training has been well studied within the Veteran’s Health Administration system using the Surgical Care Improvement Program. The Medical Team Training Program, for instance, has been shown to result in a 18% decrease in 30-day mortality and a 17% decrease in 30-day morbidity.

Also at the organizational level, leaders using an empowering style may improve process of care protocols and increase efficiency. Operating room turnover times specifically have been shown to be reducible. Value-based purchasing benchmarks, such as hospital-acquired infections, which affect reimbursement, can be reduced or eliminated depending on the measure. Medical errors may be reduced, and significant medical errors may have their effects mitigated. Patient satisfaction may be improved. The overall financial performance of the institution can be affected in a positive manner.

There are positive correlations between mutual respect, clinical leadership, and surgical safety. Traditional command and control style leadership negatively impacts psychological safety resulting in the development of more modern leadership styles. The best clinical processes have the potential to break down when there is a toxic work environment and lack of psychological safety within the team.

The Importance of Diversity and Leadership

The past quarter century has seen a steady increase in diversity within the field of surgery. Women, as of 2015, represent 38% of surgical trainees and 10% of academic professors currently, but have doubled their representation in the past 20 years. Some fields, such as head and neck surgery and plastic surgery, have studied their own subspecialty groups with similar findings. African Americans comprise both 6% of medical school graduates, 6% surgical trainees, and 2% to 4% of professors of surgery nationwide. Hispanics represent 5% of graduating medical students, 9% of general surgery trainees, and 4% to 5% of persons at all levels of academic surgery. Physician diversity is crucial and may help to address disparities in social determinants of health.

Studies indicate that the bottleneck in diversity occurs at the level of the medical school application pool, which in turn is caused by educational deficiencies at the primary, secondary, and collegiate level. As an attempted solution, the University of Michigan developed a “pipeline” program that pairs grade-school and high-school students with physicians for experiential learning and the development of mentoring, presentation skills, and networking. It is important for departments of surgery to develop a diversity program for recruitment of residents and faculty. Multi-institutional blinded studies indicate that the implementation of formal leadership and diversity training improves diversity leadership and strategic human resource management.

Leadership Styles

The principles of leadership can be practiced in a variety of styles. Just as there are many definitions of leadership, many classifications of styles exist as well. A landmark study by Daniel Goleman in Harvard Business Review identified six distinct leadership styles, based on different components of emotional intelligence. Emotional intelligence is the ability to recognize, understand, and control the emotions in others and ourselves. By learning different styles, surgeons and trainees can recognize their own leadership style and the effect on the team dynamic. Furthermore, it teaches when the situation may demand change in style for the best outcome. The six leadership styles identified are coercive, authoritative, affiliative, democratic, pacesetting, and coaching.

The coercive leader demands immediate compliance. This style reflects the command and control style that has historically dominated surgery. Excessive coercive leadership erodes team members’ sense of responsibility, motivation, sense of participation in a shared vision, and ultimately, performance. The phrase, “Do what I tell you!” brings to mind the coercive leader. However, it is effective in times of crisis to deliver clear,
concise instruction. This style should be used sparingly and is best suited for emergencies.

The authoritative leader embodies the phrase “Come with me,” focusing on mobilizing the team toward a common, grand vision. This type of leader allows the team freedom to innovate, experiment, and devise its own means. Goleman’s research indicates this style is often the most effective. These leaders display self-confidence, empathy, and proficiency in initiating new ideas and leading people in a new direction. This is best used when a shift in paradigm is needed.

The affiliative leader creates harmony and builds emotional bonds. This requires employment of empathy, building relationships, and emphasis on communication. An affiliative leader frequently gives positive feedback. This style can allow poor performance to go uncorrected if too little constructive/critical advice is given. Affiliative leadership is most useful when motivating people during stressful circumstances or healing rifts in a team.

The coaching style of leadership focuses on developing people for the future. Coaching is leadership through mentorship. The coach gives team members challenging tasks, counsels, encourages, and delegates. Unlike the affiliative leader who focuses on positive feedback, the coach helps people identify their weaknesses and improve their performance, and ties their work into their long-term career aspirations. This leadership style builds team capabilities by helping motivated learners improve. However, this style does not work well when team members are defiant and unwilling to change or learn, or if the leader lacks proficiency.

The democratic leader forges consensus through participation. This leadership style listens to and values each member’s input. It is not the best choice in an emergency situation, when time is limited, or when teammates cannot contribute informed guidance to the leader. It can also be exasperating if a clear vision does not arise from the collaborative process. This style is most appropriate when it is important to obtain team consensus, quell conflict, or create harmony.

The pacesetter leader sets high standards for performance and exemplifies them. These leaders identify poor performers and demand more from them. However, unlike the coach, the pacesetter does not build the skills of those who are not keeping up. Rather, a pacesetter will either take over the task himself or delegate the task to another team member. This style can be summed up best by the phrase, “Do as I do, now.” This leadership style works well when it is important to obtain high-quality results and there is a motivated, capable team. However, pacesetters can easily become micromanagers who have difficulty delegating tasks to team members, which leads to burn out on the part of the leader. Additionally, team members can feel overwhelmed and demoralized by the demands for excellence without an empathic counter balance.

Each of the above styles of leadership has strengths and weakness. Importantly, leaders who are the most successful do not rely only on one leadership style alone. They use several of them seamlessly depending on the situation and the team members at hand. Therefore, the more styles a leader has mastered, the better, with particular emphasis on the authoritative, affiliative, democratic, and coaching styles. Each leadership style is a tool that is ultimately employed to guide a team to realizing a vision or goal. Thus, leadership training programs should teach the proper use of all leadership styles while adhering to the principles of leadership.

for physicians with an MBA or management background but have not been incorporated into the core residency training program.80 Also, there are many institutions that have published experiences with leadership retreats or seminars for residents or young physicians.31-34 The ACGME hosts multiple leadership skills workshops for chief residents, mostly targeted toward pediatricians, family practitioners, and psychiatrists.85 Similarly, the American College of Surgeons leads an annual 3-day leadership conference focusing on leadership attributes, consensus development, team building, conflict resolution, and translation of leadership principles into clinical practice.86-87 These programs were all received well by participants and represent a call for a formal leadership program for all surgical trainees.

An innovative leadership curriculum first implemented in 2000, prior to work-hour restrictions, taught general surgery trainees’ collaborative leadership skills at a time when the traditional command-and-control leadership style predominated.2,39,90 Surgical residents participated in 18-hour-long modules based on the leadership principles and skills listed in Table 1-2, taught by the surgical faculty. A number of leadership techniques, including time management techniques and applied conflict resolution techniques described earlier, were designed and implemented as part of this leadership training program. Within 6 months of implementation, residents’ self-perceived total commitment to the highest personal and professional standards, communication skills, visualization of clear missions of patient care, and leadership of others toward that mission increased significantly.2,89,90 Remarkably, the positive impact of this leadership curriculum was significant when measured using tools, such as the Multifactor Leadership Questionnaire (MLQ), social skills inventory, personality inventory, and internal strength scorecard.2,89,90 The MLQ is a well-validated instrument that objectively quantifies leadership beliefs and self-perceived outcomes across medical and nonmedical disciplines. Based on the MLQ, surgical residents more often use a passive-avoidance style of leadership that emphasizes taking corrective action only after a problem is “significant and obvious.” This tool can also be used to track progress toward more effective, collaborative styles of leadership. These studies demonstrated the ability to measure leadership behavior of surgical trainees in a standardized, quantifiable format.2,89,90 Taken together, these studies support the concept that leadership skills can and should be taught to surgical trainees, and there are validated tools to measure outcomes.

**Designing the Program**

Success in designing a formal leadership development program can be achieved through the following method. First, select the right participants at the right time in their career. Junior surgeons new to practice are ideal; however, they should be given a chance to get their clinical and research interests off the ground before they are asked to lead others. Candidates, should be open to taking on leadership roles and have the right combination of introspection and humility that lends to professional development. High-quality speakers from the business, legal, creative, and medical worlds should be brought as guest speakers. Topics could include leadership overall, strategy, finance, management skills, feedback, and coaching. Constructive criticism is essential because prospective leaders will need guidance and mentoring. Surgeons who have been through a formal leadership training program will become proficient at team-building skills and management and will become self-empowered individuals.91

Formal leadership training is not restricted to faculty alone. Leadership training should begin early and continue throughout residency. Surgical residents’ leadership styles have been studied in environments where they are given an assistant to supervise, as if they were an attending. Most residents were able to adapt to difficult operative challenges, in this setting, by providing a more directed style of leadership to their assistants. When faced with a less challenging task, or when the surgery resident’s confidence was particularly high, their leadership score was also high. For the surgical resident preparing to move on to the attending level, such skills are necessary to develop.92

Nontechnical surgical skills, such as leadership, demonstrate a number of desired effects for the operative team. Patient safety, including all cause 30-day mortality, is improved by stronger nontechnical skills.59 Development of clear and effective communication, situational awareness, team skills, and decision-making all are correlated with reduced surgical errors. Interruptions, such as needing to answer a page during an operation, are the only nontechnical factors in surgical error that are not directly attributable to leadership style.93

Surgical leaders have a responsibility to make ethical decisions. At this time, there is no standard curriculum to formally train surgical residents in ethics, despite interest from a majority of residency program directors.94-97 Several solutions have been proposed. A case-based approach to ethics training appears to have some merit, where monthly hour long ethical dilemmas are discussed in an informal, nonhierarchical setting.98 In another study, an ICU-based simulation model demonstrated promise for teaching compassion and end-of-life ethics to surgical residents. In this model, surgery residents have their first end-of-life conversations with standardized patients simulating the surgical ICU environment.99,100

**Practicing Leadership Skills and Assessing Leadership Formally With Objective Structured Clinical Examination (OSCE) and Simulation**

The past decade has seen a demonstrable increase in our knowledge of how to develop leadership skills, particularly through simulation, as well as leadership evaluation through OSCE and other tools. Multiple groups have assessed multidisciplinary teams, typically composed of nurses, anesthesia groups, and surgeons for the leadership associated nontechnical skills of communication, teamwork, and situational awareness. Through increasingly validated instruments and assessment tools, these nontechnical skills have been found to be trainable.101 The OSCE has been established as the gold standard102 for the training and assessment of a wide range of clinical and nontechnical skills with high reliability and validity.103-106

The OSCE was developed by Harden, at the Ninewells Hospital in Dundee, Scotland, and first published in 1975.107 He subsequently coined the term “OSCE” in his 1979 publication “Assessment of Clinical Competence Using an Objective Structured Clinical Examination (OSCE).”108 The purpose of the OSCE was to address the lack of a reliable method to evaluate the clinical abilities of physicians and featured a comprehensive assessment of history-taking and physical examination skills. Early versions also assessed nontechnical skills, patient interaction, and professionalism. Since its inception, the OSCE has matured, been subjected to rigorous tests of reliability and validity, and has seen widespread adoption.109-111

OSCEs remain a critical portion of resident evaluation. They have been well validated for teaching leadership skills in
trauma and interacting with simulated patients in difficult scenarios. OSCEs can be tailored to a variety of circumstances, including practicing breaking bad news or discussing end of life care, dealing with angry or aggressive patients, and simulating disagreements with other providers or family members.109-112 The potential for OSCEs to train, test, and perfect nontechnical skills, such as leadership, is extraordinary.

A pilot project for the Medical Council of Canada was conducted by the University of Toronto and published in 1988 describing the use of an OSCE for evaluating the clinical skills of international medical graduates applying to Canadian residency.113 Effective communication and language proficiency have been key components since the beginning. A comprehensive review of this program 2 years later confirmed the reliability and validity of using an OSCE for this purpose.114 The Medical Council of Canada has subsequently mandated a requirement for an OSCE evaluation of all international graduates applying for positions in Canada. In place for the past two decades, the program has ensured a baseline proficiency of skill, attitude, knowledge, and other nontechnical skills.115

OSCEs quickly gained acceptance as an established tool to assess learners in a comprehensive manner and became the inspiration for the creation of the USMLE Step 2 Clinical Skills (CS) examination, required for all U.S. medical students prior to licensure.116 Indeed, medical students whose schools use OSCE as practice do better on USMLE Step 2.117 The USMLE Step 2 CS examination meets the criteria, discussed in the following section, for a thorough and well-designed OSCE examination, due to its 12-station design which takes 8 hours to complete. It has been found to be a valid and comprehensive evaluation of a student’s clinical abilities, admittedly at massive expense to medical students.118 In the United States, osteopathic medical students take the OSCE-style Level 2 Performance Evaluation.

Although station number and total duration are not completely agreed upon, data indicate that the OSCE examination should be between 3 and 6 hours and 8 to 10 stations in length in order to obtain reliable \( r = 0.7 \) communication, history, and physical examination skills. A guideline was that at least seven cases are needed in any domain to achieve reliability. The testing period may be spread over several sessions making up an aggregate score in order to maintain validity. Many medical schools prepare their students for clinical practice with OSCE-style examinations throughout the year, which, taken together, are summative of a high-quality, multistation, valid OSCE. Checklists are typically the standard scoring tools; however, checklists alone may not be as reliable as a more comprehensive review by more experienced clinicians—particularly when assessing more advanced students and residents.119 All of the licensure examinations, discussed previously, meet the criteria for a well-designed OSCE based on number of stations and time duration.

Beginning in 2003, the ACGME mandated the use of OSCEs within residency programs. At the time, residents were wary of its adoption, particularly fearing its use as a tool for determining promotion. Residents’ perceptions of the examination, over time, did change to reflect an acceptance of its use for grading both technical and nontechnical skills.120-123

In the United States, the OSCE assesses technical and nontechnical skills in an accurate and valid fashion. The OSCE demonstrates a rapid progression of technical skills highly correlated to a postgraduate year, whereas clinical skills improve at a more moderate rate124 (Fig. 1-12).
By using simulated patients, patient-centered models, and intensive and immersive training, nontechnical skills including communication can improve interview techniques.\textsuperscript{137,138} Post communication skills training at the 12-month follow-up demonstrated that the training was effective, and with real clinical practice after the training communication skills had improved even more.\textsuperscript{139}

Lastly, there appears to be a positive feedback loop tying nontechnical leadership skills with self-perceived operating room prowess. Those surgeons who rate their own technical skills highly are also more likely to engage in positive leadership skills, including teaching in the operating room, handle difficult situations, and provide more clear instructions.\textsuperscript{140}

Simulation may be particularly critical for preventing technical skill decline in residents on dedicated research time or for attending surgeons whose research, clinic, or administrative duties decrease the amount of time they can spend in the operating room. Simulation represents the future of medicine and an excellent opportunity for research and development. Medicine, including surgery, has much ground to make up in regards to simulation training compared to other high-risk fields, such as the military, space, and aeronautics. Modern surgical leaders should recognize surgical simulation as critical to their organization’s success.

skills. Additionally, most have been tied to performance evaluations and even salary and discipline up to and including loss of licensure. To our knowledge, this is the first comprehensive listing of the various agencies that evaluate surgeon performance.141

MENTORING AND DEVELOPMENT

Mentoring

A formal leadership training program for surgical trainees should include mentoring. Mentoring is the active process by which an experienced, empathetic person guides another individual in the development and self-recognition of their own vision, learning, core competencies, and professional development. Halstead established the concept of a surgical mentor who directly provided the trainees with professional and technical guidance. Halstead’s concept went beyond a simple preceptorship by emphasizing clinical decision making based on scientific evidence. His goal was to develop surgeons who would go on to become outstanding leaders and innovators in the field. Although surgery has changed dramatically since Halstead’s era, mentorship remains crucial in surgical training. In addition to teaching technical skills, clinical judgment, and scientific inquiry, modern-day mentors must also model effective communication, empathy, humanism, and the prioritization of competing professional and personal activities.

The mentor must also be an experienced and trusted advisor committed to the success of the mentee. A greater level of trust and commitment distinguishes the mentor from the teacher. More than a teacher, a mentor is a coach. The goal of a teacher is to pass on a defined level of knowledge for each stage of a student’s education. The underlying premise is a limited level of advancement for the student. The coach, on the other hand, has the sole purpose to make his or her student the best at their game, with an unlimited level of advancement. Modern mentorship implies a partnership between the mentor and the mentee. Surgical residency program chairs and program directors must recruit and develop faculty “coaches” to mentor residents to optimize their potential. Emeritus Chair of the University of California, Los Angeles Head and Neck Surgery, Dr. Paul Ward, said it best: “We strive to produce graduates of our residency program who are among those who change the way we think and practice.” 142 Having more than 25 former residents become chairs of academic head and neck surgical programs, Dr. Ward embodied the role as a surgeon’s coach. The responsibilities of an effective mentor are summarized by Barondess: “Mentoring, to be effective, requires of the mentor empathy, maturity, self-confidence, resourcefulness, and willingness to commit time and energy to another. The mentor must be able to offer guidance for a new and evolving professional life, to stimulate and challenge, to encourage self-realization, to foster growth, and to make more comprehensible the landscape in which the protégé stands.”143

One of the major goals of mentors is to assess the aptitudes and abilities of mentees with regard to the appropriateness of their vision for their surgical career. Proper selection of the appropriate mentor can bring to the mentee much needed wisdom, guidance, and resources and can expand the scope of his or her vision. In addition, the mentor can refine the leadership skills taught to mentees in formal training programs. Highly successful surgeons most often have had excellent surgical mentors. It is impressive to note that more than 50% of United States’ Nobel laureates have served under other Nobel laureates in the capacity of student, postdoctoral fellow, or junior collaborator.144 In academic medicine, evidence-based studies have shown benefits to the mentees that include enhanced research productivity, higher likelihood of obtaining research grants, and greater success in obtaining desired positions in practice or at academic institutions.145 Mentoring provides benefits to the mentors themselves, including refinement of their own personal leadership skills and a strong sense of satisfaction and accomplishment.

Mentorship is essential to accomplish the successful development of surgical trainees and to help cultivate their vision. Therefore, formal leadership training programs that have a goal of training the future leaders in surgery should include mentoring.

Modeling Leadership for Medical Students and the “Hidden Curriculum”

Medical students enter school with great empathy, excitement, optimism, and an idealistic vision. They have self-selected to enter a profession of healing and achieved entry into a highly coveted graduate training program with centuries of tradition. Yet, these medical students are naive to the actual practice of medicine and its professional norms. Along the way to becoming a doctor, many medical students lose some of the optimism, empathy, and excitement, particularly during their first and third years of school. Some students come to see the patient-physician relationship as an afterthought to providing care.145,146 Through the “hidden curriculum,” formal leadership training, and modeling of professional behavior, surgical residents, and attendings can help medical students to realize their vision of becoming empathic physicians.

Traditionally, medical schools and professors have unknowingly relied on a hidden curriculum to mold these idealistic students into capable professionals. The hidden curriculum is the informal social norms learned by students implicitly, based on their observations of resident and attending behavior. The hidden curriculum has always been present in education, for better or worse, and may be unmasked and studied, but cannot be eliminated. Medical students actively engage in seeking out mentors, and naturally and subconsciously look to their mentors for cues on how to conduct themselves as physicians, the same way in which a child learns how to behave from a parent or older sibling. Whether or not the witnessed behavior is a positive example of professionalism, the student will begin to perceive that behavior as normal and acceptable. For better or worse, the professional norms of medicine (the Hippocratic oath, respect to patients and colleagues, ethical conduct, personal accountability, empathy, and altruism) are modeled in every personal encounter. It is imperative that all resident and attending surgeons understand that the medical students are observing them closely. When resident and attending surgeons model professional behavior, the hidden curriculum becomes a useful tool for professional development.147,150 This consistent modeling of professional behavior is one necessary component of leadership.

During their clinical years, medical students experience both an exponential growth in knowledge and a measurable decline in empathy towards their patients. Initially, medical students are filled with excitement and wonder during their first patient encounters. The rapid pace of clinical work, acquisition of knowledge, and intense experiences create stress for the student, both positively and negatively. Scrubbing into the operating room, witnessing the passing of a patient, helping deliver a baby, and studying for boards are impactful milestones that each student experiences in a matter of months. Due to the
challenges of their work, students naturally have doubts about their own career choices and abilities, even as they experience growth and success. However, as students gain knowledge and abilities, they also come to see commonly encountered clinical problems as routine work. As familiarity and comfort with clinical problems increases, the excitement and wonder experienced by the student decreases. It is during this time that a decline in student empathy occurs, typically in their third year of medical school. In medicine, even routine clinical work still requires extraordinary attention to detail, and compassionate care must be delivered to every patient, every time. This attention to detail and compassionate delivery of care are the hallmark of the true professional. It is important that surgical residents and attendings always model positive behavior.

Previously, medical schools instructed students in anatomy, physiology, pathology, and clinical medicine, but left the acquisition of professionalism to the informal hidden curriculum. The Carnegie Report, published in 2010 at the 100-year anniversary of the Flexner Report, called for medical education to promote “the progressive formation of the physician’s professional identity.” To this end, many medical schools nationwide emphasize early professional education and an integrated curriculum. The Liaison Committee on Medical Education (LCME) sets standards for administrative and faculty leadership that manage the curricular model and educational affairs of students; however, formal leadership education is not explicitly required at this time. However, career exploration, mentoring, and advising are instrumental responsibilities of each medical school and a requirement of the LCME. Establishing a leadership program that is perpetual and coexists within an integrated curriculum will support this endeavor. A longitudinal leadership program beginning at the onset of medical school can establish a pattern of ethical behavior, professionalism, balance, and professional identity.

Tools to Measure Leadership Outcomes in Healthcare

There is evidence that leadership training improves healthcare quality. The ACGME, via its core competencies, has recognized technical skills, surgical judgement, and nontechnical skills as qualities essential to develop in residents. The objective measurement of nontechnical skills is difficult. Table 1-5 includes a list of methods for assessing nontechnical skills currently in use by some residency programs. The Consumer Assessment of Healthcare Providers and Systems (CAHPS) survey is in the early phases of being applied to individual physicians, but it has been applied to hospitals as a whole for several years.

<table>

<tr>
<td>NEO Five-Factor Personality Inventory (NEO)</td>
<td>NEO explores different facets of five different personality traits—neuroticism, extraversion, openness to experience, agreeableness, and conscientiousness—through a questionnaire.</td>
</tr>
<tr>
<td>Surgeon’s Leadership Inventory (SLI)</td>
<td>The SLI is a questionnaire based on literature on leadership in surgery and surgeon’s leadership behaviors observed in the operating room. It includes eight elements of surgeon’s leadership in the operating room, which are maintaining standards, managing resources, making decisions, directing, training, supporting others, communicating, and coping with pressure.</td>
</tr>
<tr>
<td>Patient feedback</td>
<td>Patient complaints are inversely related to leadership effectiveness and can thus be used as opportunities to improve and as a measure of leadership.</td>
</tr>
<tr>
<td>Objective Structured Clinical Examination (OSCE)</td>
<td>The OSCE can be administered in a controlled environment with attending feedback on various aspects of leadership tackled in the practice cases. Videotaped sessions provide further opportunities for improvement as residents will be able to later observe their own behaviors and reflect on ways to improve their approach to the case presented.</td>
</tr>
<tr>
<td>Consumer Assessment of Healthcare Providers and Systems (CAHPS)</td>
<td>CAHPS surveys are based on aspects of healthcare that matter most to patients, such as physician communication. The results are made public and can be used to shed light on areas of leadership physicians can improve on to work towards a patient-centered approach to care.</td>
</tr>
</tbody>
</table>

Leadership can be evaluated through instruments such as the Multifactor Leadership Questionnaire, the NEO Five–Factor Inventory, and the Surgeon’s Leadership Inventory. The Multifactor Leadership Questionnaire (MLQ) analyzes leadership aptitude as either a transactional or a transformational style.\cite{157} Leadership based on transaction focuses on completing and rewarding the tasks, whereas leadership based on transformation focuses more on the motivation for completing the tasks and emphasizes a positive and encouraging working environment for the team.\cite{158,159} In a study applying the questionnaire to five surgeons in a single hospital, surgeons who scored higher on the transformational section were more focused on promoting an open environment for all the attendings, residents, nurses and other staff in the operating room. This transformational style correlated with greater communication. These findings are important in showing that lack of communication is often a leading factor in surgical errors.

The use of an MLQ in 2008 studying surgical residents showed a significant association between transformational leadership and overall perceived team effectiveness and resident satisfaction.\cite{158,159} The questionnaire also found that the residents, as leaders, placed less value on the individual needs of their colleagues, possibly reflecting a high sense of independence and frequent changes in teams due to rotations among services. This finding helped identify an area of leadership training on which the program can focus to help further develop a more supportive team atmosphere amongst the residents. In 2011, a study administered the NEO Five–Factor Personality Inventory (NEO) to a group of surgical residents. NEO, which assesses personality on five broad strokes, including neuroticism, openness, agreeableness, extroversion, and conscientiousness, found that the surgeons scored above the national average on most of the factors tested but below average on agreeableness. This is a measure of altruism and tolerance, among other related factors. This result corresponded with the MLQ administered to the same group of residents and therefore highlighted areas of leadership that required modification.\cite{158,159}

The Surgeon’s Leadership Inventory (SLI) is a helpful guide for residency programs.\cite{160} The SLI grades surgeons on eight different elements of leadership, as listed in Table 1-6. As with the MLQ and NEO questionnaires, the SLI can be used to assess the growth of leadership ability in surgery residents. Table 6 provides a list and description of the different elements assessed by the SLI.\cite{141}

Data correlating patient complaints in a large number of hospitals show that improved leadership is associated with better hospital climate, improved performance, and a lower number of complaints.\cite{161} Reproduced with permission from Jacobs LA: Practical Ethics for the Surgeon. Philadelphia, PA: Wolters Kluwer; 2018.

Leadership training for the prospective surgeon

Prospective surgeons such as medical students and premedical students may have no better source for developing the personal attributes necessary for a successful career than current surgical attending surgeons and current residents. When surveyed, these doctors emphasized accountability, resilience, and high personal standards for oneself as critical tools. Prospective surgeons are advised to pursue perfectionism and be self-critical, cautioning against taking these traits to far towards neurotic behavior. Critical leadership skills of teamwork and learning to take initiative are mandatory in modern medicine and must be learned early. Innovation is highly desirable.\cite{162}

Residents, on the other hand, are closer to becoming independent. To some extent, they have already been selected for their leadership, innovation, and resiliency through the process of the match. During training their progression from novice to expert is necessarily rapid. A graded tool for all procedure based specialties including surgery – OpTrust – has been recently validated to facilitate the resident’s transition to leadership across five domains including questioning, planning, instruction, problem solving, and leadership.\cite{163}

As emphasized throughout this chapter, the concept of training leadership skills early applies particularly to junior faculty and residents. The resident-surgeon-manager conference is one model for integrating department members of various experience levels into a results-based leadership conference. In this conference, various stakeholders including attorneys, persons with business experience, and risk management experts are brought in as guest participants. Exercises were immersive and included case-based discussions, role-playing, simulation, and interactive lecture. Topics included teamwork, learning negotiating techniques, time management, risk management, balance, giving feedback, and creating immediate, goal-oriented action plans.\cite{164}

### EARLY CAREER DEVELOPMENT AND ESTABLISHING ONESELF

A variety of methods have been proposed for the professional development of new attending surgeons. “Speed Mentoring”—10-minute pairings of senior and junior surgeons answering preset questions—have been studied at national conferences with promising results. These sessions could be spread out over several days and integrated into a busy surgeon’s schedule.\cite{164}
A study of department chairs and award-winning surgeon-scientists identified perseverance and team leadership skills as critical factors for development in the young attending surgeon. Chairs advocated protected time for research, financial support, and mentorship as departmental level support that the surgeon scientist should actively seek out in their first position. The surgeon-scientist compared to the pure clinician faces a different set of challenges, particularly the financial challenge of funding research and clinical duties competing for time and attention with research interests.\(^{165}\)

One study addressed surgeon behavior in the operating room to assess the leadership style most associated with strong leadership. Based off of this study, surgeons who are trained to collaborate, consult others appropriately, be polite (simple “please” and “thank you”), and create a safe space for their operating room staff to voice concerns will demonstrate good leadership. However, surgeons who demonstrate nonconstructive criticism, destructive humor, steer conversation away from the current case, and express frustration will be perceived as demonstrating poor leadership. Under this system, surgeon behavior can be categorized—conductor, elucidator, delegator, engagement facilitator, tone setter, being human, and safe space maker—in order to provide individual feedback for professional development.\(^{166}\)

**SENIOR FACULTY DEVELOPMENT: TRANSITIONING TO DEPARTMENTAL LEADERSHIP AND LEGACY BUILDING**

The presence of experienced, senior academic surgeons within a department represents an opportunity. The formal development of a plan for late career transitioning through departmental leadership roles all the way to emeritus status naturally initiates a constructive process when thought out years in advance. The plan should be agreeable to the senior faculty member in question as well as departmental leadership and hospital stakeholders. Once in place, the senior academic surgeon and department will both thrive thanks to a shared vision, mutual understanding, and clear goals and transition points. Departmental leadership can use the transition plan to look ahead at the future of their department years down the line.\(^{167}\)

Recognition of senior academic surgeons with departmental leadership, promotions, and emeritus status is a privilege earned by the academician over a lifetime of work; however, for the department it represents an opportunity to shape the values and culture of the faculty body as a whole. The continued visibility, model, and influence of such leaders will have a trickle-down effect on the rest of the department. Surgical leaders are part of a large and extraordinary network facilitated by mentorship and decades of professional collaboration. Exceptional senior academic surgeons may often experience the “multiplier-effect” whereby one excellent leader trains several, who go on to train several more until the culture of surgery nationwide is influenced.\(^{168}\)

Although there are no mandatory ages for which surgeons must retire as in other professions, such as airline pilots, the issue of aging and when to cease practice has been controversial. There are some, however few, reports of physicians practicing after the decline of their skill and becoming dangerous. As a whole, the profession has been unable to prevent this. Nationwide, from 1975 to 2015, the number of physicians practicing after age 65 has increased by 374%. Some hospitals and healthcare organizations have implemented mandatory cognitive and physical evaluations as a condition of continued practice. In the absence of more robust professional initiatives our field may see legislative oversight in the future.\(^{169}\) The authors believe that a formally planned transition emphasizing the values of leadership and legacy-building offers a more palatable alternative.

**CONCLUSION**

Although there are several definitions of leadership and a variety of leadership styles, all share the common goal of improving patient care in the modern era. All forms of leadership require a vision and willingness—the willingness to assume the responsibility to lead, continue learning, practice effective communication styles, and resolve conflict. Effective leadership can change surgical departments and improve patient care through innovation. A growing body of evidence suggests the mastery of leadership requires practice through intentional curricula and reinforcement through mentorship.

Surgical leadership is bred through its training programs. Thus, innovation in surgical training programs is needed to enhance the development of leadership skills of surgical trainees, to prepare them for practice in modern healthcare systems, and to optimize patient care, as well as compliance with requirements set forth by regulatory institutions governing surgery and surgical education. A growing body of literature supports the value of effective leadership in improving patient care, productivity, and the work environment while it validates the ability to measure the impact of leadership training. Therefore, it is of paramount importance to teach modern leadership principles and skills to surgical trainees in order to create a new generation of surgeon leaders who will shape the modern era of surgery in the context of rapidly evolving science, technology, and systems of healthcare delivery.

OVERVIEW: INJURY-ASSOCIATED SYSTEMIC INFLAMMATORY RESPONSE

The inflammatory response to injury occurs as a consequence of the local or systemic release of “damage-associated” molecules to mobilize the necessary resources required for the restoration of homeostasis. Minor host insults result in a localized inflammatory response that is transient and, in most cases, beneficial. Major host insults follow a different trajectory. A subset of these patients will die within 24 hours of hospital admission, succumbing to overwhelming tissue injury and immediate organ damage. With advances in prehospital care and improved trauma management, these numbers have diminished. A second subgroup of patients who suffer a major host insult succumb to secondary organ damage remote from the injury site and die later (weeks) in their hospital course. They form an increasing percentage of the in hospital trauma-related deaths. A dysregulated, overwhelming systemic inflammatory response to the injury/hemorrhage and associated ischemia/reperfusion events has been implicated as the cause of multiple organ failure in these patients. Moreover, it has been linked to immune suppression that increases the risk of infectious complications and poor outcome. Finally, a third subgroup, characterized by extended length of stay in the ICU, complicated postdischarge courses, and failure to regain/recover to their preinjury status, has been described and also linked to persistent inflammation and suppressed host protective immunity. The term persistent inflammation, immunosuppression, and catabolism syndrome (PICS) has
been applied to this group. Recent data suggest that severely injured patients who are destined to die from their injuries, whether late in their hospital course or after discharge, differ from survivors only in the degree and duration of their dysregulated acute inflammatory response.

As trauma is the leading cause of mortality and morbidity for individuals under age 45, understanding the complex pathways that regulate the local and systemic inflammatory response following severe traumatic injury is necessary to develop appropriate and targeted therapeutic strategies that will improve outcomes for these patients.

In this chapter, we will review what is known about the soluble and cellular effectors of the injury-induced inflammatory response, how the signals are sensed, transduced, and modulated, and how their dysregulation is associated with alterations in the immune system. We will also discuss how these events are monitored regulated by the central nervous system. Finally, we will review how injury reprograms cellular metabolism, in an attempt to mobilize energy and structural stores to meet the challenge of restoring homeostasis.

**THE DETECTION OF CELLULAR INJURY**

**The Detection of Injury is Mediated by Members of the Damage-Associated Molecular Pattern Family**

Traumatic injury activates the innate immune system to produce a systemic inflammatory response (SIR) in an attempt to limit damage and to restore homeostasis. It includes two general responses: (a) an acute proinflammatory response resulting from innate immune system recognition of ligands, and (b) an anti-inflammatory response that may serve to modulate the proinflammatory phase and direct a return to homeostasis (Fig. 2-1). This is accompanied by a suppression of adaptive immunity. Rather than occurring sequentially, recent data indicate that all three responses are simultaneously and rapidly induced following severe traumatic injury.

The degree of the systemic inflammatory response following trauma is proportional to injury severity and is an independent predictor of subsequent organ dysfunction and resultant mortality. Recent work has provided insight into the mechanisms by which immune activation in this setting is triggered. The clinical features of the injury-mediated systemic inflammatory response, characterized by increased body temperature, heart rate, respirations, and white blood cell count, are similar to those observed with infection (Table 2-1). However, it is widely accepted that systemic inflammation following trauma is sterile, resulting from endogenous molecules that are produced as a consequence of tissue damage or cellular stress. Termed *damage-associated molecular patterns (DAMPs)* or *alarmins*, DAMPs interact with specific cell receptors that are located both on the cell surface and intracellularly.

Trauma DAMPs are structurally diverse endogenous molecules that are immunologically active. Table 2-2 includes a partial list of DAMPs that are released either passively from necrotic/damaged cells or actively from physiologically “stressed” cells by upregulation or overexpression. Once they are outside the cell, DAMPs promote the activation of innate immune cells, as well as the recruitment and activation of antigen-presenting cells, which are engaged in host defense. The best-characterized DAMP with significant preclinical evidence for posttrauma release, as well as a direct link to the systemic inflammatory response, is high-mobility group protein B1 (HMGB1). Additional evidence for other important DAMP molecules that participate in postinjury inflammation is also presented.

**High-Mobility Group Protein B1.** The best-characterized DAMP in the context of the injury-associated inflammatory response is high-mobility group B1 (HMGB1) protein. HMGB1 is highly conserved across species. It is a constitutively expressed, nonhistone chromosomal protein that participates in a variety of nuclear events, including DNA repair and transcription. Inflammatory signaling can redirect HMGB1 to the cytosol in both monocytes and macrophages, as a result of posttranslational modification. HMGB1 is released passively from damaged or necrotic cells and is detected rapidly in the circulation within 30 minutes post injury. It can also be actively secreted from immune-competent cells stimulated by bacterial-derived lipoproteins (e.g., endotoxin) or by inflammatory cytokines (e.g., tumor necrosis factor). For example, macrophages release HMGB1 following the activation of the inflammasomes.
Once outside the cell, HMGB1 has been shown to signal via the Toll-like receptors (TLR2, TLR4, TLR9), the receptor for advanced glycosylation end products (RAGE), CD24, and others. The activation of TLRs by HMGB1 occurs mainly in myeloid cells, whereas RAGE is thought to be the receptor target for HMGB1 in endothelial cells.

The diverse proinflammatory biological responses that result from HMGB1 signaling include: (a) the release of cytokines and chemokines from macrophage/monocytes and dendritic cells; (b) neutrophil activation and chemotaxis; (c) alterations in epithelial barrier function, including increased permeability; and (d) increased procoagulant activity on platelet surfaces; among others.10 In addition, HMGB1 binding to TLR4 triggers the proinflammatory cytokine release that mediates “sickness behavior.”11

The biologic function of HMGB1 is regulated by its redox state. For example, a thiol at C106 is required for HMGB1 to promote macrophage TNF release, while a disulfide bond between C23 and C45 confers proinflammatory properties. With all three cysteines in the thiol (reduced) state, HMGB1 loses its DAMP function, but gains the capacity to serve as a chemotactic mediator. Importantly, shifts between the redox states have been demonstrated and indicate that redox state dynamics are important regulators of HMGB1.12

HMGB1 levels in human subjects following injury correlate with the Injury Severity Score and complement activation, as well as with increases in circulating inflammatory mediators such as tumor necrosis factor. Exogenous administration of HMGB1 to normal animals produces fever, weight loss, epithelial barrier dysfunction, and, possibly, death. Further supporting the HMGB1 role in sterile inflammation, traumatic brain injury (TBI) induced by a cortical injury model has been shown to result in acute lung injury with increased alveolar hemorrhage, neutrophil infiltration, and poor oxygenation. This acute lung injury (ALI) was accompanied by a doubling in serum HMGB1 concentrations along with evidence that necrotic brain cells were a source of HMGB1 following TBI. More recently, in an animal model of hemorrhagic shock, HMGB1 release from intestinal epithelium was linked to acute lung injury. Finally, increased plasma levels of HMGB1 have been shown to correlate with immune suppression and increased infection risk in patients undergoing major surgical procedures. The identification of the receptor for advanced glycation end products as the receptor for HMGB1 in this setting has identified new therapeutic strategy to ameliorate ALI following TBI.

A Role for Mitochondrial DAMPs in the Injury-Mediated Inflammatory Response. Mitochondrial proteins and/or DNA can act as DAMPs by triggering an inflammatory response to cellular necrosis and stress. Specifically, mitochondrial DNA (mtDNA) released from damaged or dysfunctional mitochondria leads both to inflammasome activation and activation of the stimulator of interferon gene pathway (STING). Cell-free mtDNA (cf-mtDNA) has been shown to be thousands of times higher in trauma patients when compared to normal volunteers. In addition, direct injection of mitochondria lysates in an animal model causes remote organ damage, including liver, and lung inflammation. These data suggest that with cellular stress or tissue injury, cf-mtDNA released from damaged/stressed mitochondria contribute to the sterile inflammatory response in injured patients. From an evolutionary perspective, given that eukaryotic mitochondria derive from bacterial origin, it would make sense that they retain bacterial features capable of eliciting a strong response that is typically associated with a pathogen trigger. In addition, the mitochondrial transcription factor A (TFAM), a highly abundant mitochondrial protein, is functionally and structurally homologous to HMGB1. It has also been shown to be released in high amounts from damaged cells where it acts in conjunction with mtDNA to activate TLR9 signaling.

Following trauma, cf-mtDNA levels appear to be higher in nonsurvivors when compared to survivors and correlate with the development of both SIRS and sepsis post injury. Cf-mtDNA has also been linked both ex vivo and in vivo to the formation of neutrophil extracellular traps, which are also associated with sterile inflammation and are a possible cause of secondary tissue injury. Reducing cf-mtDNA, perhaps by targeting enzymes capable of digesting circulating mtDNA is an attractive therapeutic option to prevent development of inflammatory complications of trauma.

Heat-Shock Proteins as DAMPs. Heat shock proteins (HSPs) are a large and diverse family of intracellular proteins that are expressed during times of inflammation and oxidative stress or following tissue injury. Very highly conserved across species, HSPs function as molecular chaperones to monitor and maintain appropriate protein folding. They accomplish this task through the promotion of protein refolding, the targeting of misfolded proteins for degradation, or the sequestering of partially folded proteins for movement to appropriate membrane compartments. HSPs are also capable of binding foreign proteins and thereby function as intracellular chaperones for ligands such as bacterial DNA and endotoxin.

HSPs are presumed to protect cells from the effects of traumatic stress and, when released by damaged cells, alert the immune system of the tissue damage by activating both innate and acquired immunity. HSPs are also released from intact cells via a nonclassical secretory pathway, both via “secretory lysosomes” as well as the exosomal pathway. For example, HSP70-containing exosomes have been implicated in postshock inflammation. Once outside the cell, free HSPs can bind to pattern-recognition receptors (PRR) as well as other cell surface receptors to modulate the inflammatory response. Recently, the role of free HSP-mediated proinflammatory properties via TLR2 and TLR4 has been questioned, as it has been suggested that the presence of contaminating endotoxin in bacterially-produced HSP preparations may explain at least some of these inflammatory effect results. However, the additional evidence suggests that the immunostimulatory properties may be dependent on how HSPs arrive outside the cell. In the context of massive cell damage or large exosome release, HSPs may serve as proinflammatory DAMPs. In contrast, HSPs released by active secretion may exert anti-inflammatory immune dampening signals (Table 2-3). New receptors for HSP have been identified that are members of the sialic acid-binding immunoglobulin-like lectins (siglecs), which may explain these effects. Two members of the family, Siglec-5 and Siglec-14, with similar binding sites for HSP70, exhibit opposite intracellular events in response to HSP binding, being either pro-(Siglec-14) or anti-(Siglec-5) inflammatory.

From a clinical perspective, extracellular HSPs have been demonstrated to be elevated almost immediately post injury in polytraumatized patients (up to 10 times normal) with the degree of elevation being correlated with the severity of illness. Moreover, in the setting of polytrauma, plasma HSP70 levels have been shown to correlate inversely with HLA-DRA expression, a marker of immunosuppression.

Extracellular Matrix Molecules Act as DAMPs. Recent work has explored the role of extracellular matrix (ECM) proteins in the TLR-mediated inflammatory response that follows tissue injury. These molecules, which are sequestered under normal conditions, can be released in a soluble form with proteolytic digestion of the ECM. Proteoglycans, glycosaminoglycans, and glycoproteins such as fibronectin have all been implicated as key players in the DAMP/TLR interaction. Proteoglycans, in particular, have also been shown to activate the intracellular inflammasomes that trigger sterile inflammation. These molecules, which consist of a protein core with one or more covalently attached glycosaminoglycan chains, can be membrane-bound, secreted, or proteolytically cleaved and shed from the cell surface.

Biglycan is one of the first proteoglycans to be described as a TLR ligand. It consists of a protein core containing leucine-rich repeat regions, with two glycosaminoglycan (GAG) side-chains (chondroitin sulfate or dermatan sulfate). While biglycan typically exists in a matrix bound form, with tissue injury it is released from the ECM in a soluble form where it interacts with TLR2 or TLR4 to generate an immediate inflammatory response. Various proinflammatory cytokines and chemokines including tumor necrosis factor (TNF)-α and interleukin (IL)-1β are...
downstream effector molecules of biglycan/TLR2/4 signaling. Among these, the mechanism of biglycan-mediated autonomic synthesis and secretion of mature IL-1β is unique. Usually, release of mature IL-1β from the cell requires two signals: one that is needed to initiate synthesis (TLR2/4-mediated), and the other to process pro-IL-1β to its mature form (inflammasome-mediated). How is it possible for biglycan to provide both signals? Current evidence indicates that when soluble biglycan binds to the TLR, it simultaneously serves as a ligand for a purinergic receptor, which facilitates the inflammasome activation required for IL-1β processing. These data support the idea that DAMP-mediated signals can initiate a robust inflammatory response.  

**S100 Proteins as DAMPs.** S100 proteins are a group of calcium-binding proteins that participate in the regulation of intracellular calcium. There are at least 25 members identified to date, with diverse functions that are cell-type dependent. While regulation and management of calcium storage is a primary function of S100 proteins, additional specialized roles include cytoskeletal organization, protein trafficking and transcriptional regulation. They are loosely grouped according to their functional capability: those that work exclusively inside the cell, outside the cell, or in both locations.

**Heme as DAMP.** Heme is the oxygen-binding moiety found in hemoglobin and other hemoproteins in the muscle and mitochondria. It is a very highly conserved molecule composed of a tetrapyrrole ring surrounding a single iron. When red blood cells are damaged, hemoglobin is released, where it is bound by plasma proteins such as haptoglobin. In turn, the hemoglobin-haptoglobin complexes are scavenged by the reticuloendothelial system in the liver and spleen to form bilirubin as the ultimate end product. When the amount of free hemoglobin exceeds the binding capacity of haptoglobin and other specialized binding proteins, it is loosely bound to other plasma proteins where it can be readily oxidized. Ultimately, this can result in the release of the prosthetic heme group from hemoglobin, generating labile heme, which is a pro-oxidant.  

In vitro experiments demonstrate that labile heme induces cell activation, via both TLR4-dependent processes and the inflammasome, resulting in cytokine release. Moreover,
heme-induced neutrophils activation leads to extracellular traps (NETs) release through a mechanism dependent on reactive oxygen species. However, unlike the other DAMPs discussed, labile heme can also have direct cytotoxic effects on cells by a direct interaction with membrane phospholipids and the catalysis of membrane lipid peroxidation, leading to programmed cell death. In macrophages, labile heme can induce necroptosis, rather than apoptosis.

**DAMPs Are Ligands for Pattern Recognition Receptors**

The inflammatory response that occurs following traumatic injury is similar to that observed with pathogen exposure. Not surprisingly, surface and cytoplasmic receptors that mediate the innate immune response to microbial infection have also been implicated in the activation of sterile inflammation. In support of this idea, genes have been identified that are dysregulated acutely both in response to a microbial ligand administered to human volunteers and in response to traumatic injury in a large patient population. The classes of receptors that are important for sensing damaged cells and cell debris are part of the larger group of germ-line encoded pattern recognition receptors (PRRs). The best described ligands for these receptors are microbial components, the pathogen-associated molecular patterns (PAMPs). The PRRs of the innate immune system are varied and include Toll-like receptors (TLRs), calcium-dependent (C-type) lectin receptors (CLRs), the nucleotide-binding domain, leucine-rich repeat–containing (NBD-LRR) proteins (NLRs); also nucleotide-binding and oligomerization domain [NOD]-like receptors), receptors for advanced glycation end-products (RAGE), and retinoic acid–inducible gene (RIG)-I-like receptors (RLRs). Following receptor ligation, intracellular signaling modulates transcriptional and posttranslational events necessary for host defense by coordinating the synthesis and release of cytokines and chemokines to either initiate or suppress the inflammatory response. The best described of these receptors, the TLRs, NLRs, CLRs and RAGE, are discussed in the following section.

**Toll-Like Receptors.** The Toll-like receptors are evolutionarily conserved type 1 transmembrane proteins that are the best-characterized PRRs in mammalian cells. They were first identified in *Drosophila*, where a mutation in the *Toll* gene led to its identification as a key component in their immune defense against fungal infection. The first human TLR, TLR4, was identified shortly thereafter. Now, more than 10 human TLR family members have been identified, with distinct ligands that include lipid, carbohydrate, peptide, and nucleic-acid components of various pathogens. TLRs are expressed by both immune and nonimmune cells. At first, the expression of TLR was thought to be isolated to professional antigen-presenting cells such as dendritic cells and macrophages. However, mRNA for TLR family members have been detected in most cells of myeloid lineage, as well as NK cells. In addition, activation of T cells increases their TLR expression and induces their survival and clonal expansion. Direct engagement of TLR in Treg cells promotes their expansion and reprograms them to differentiate into T helper cells, which in turn provides help to effector cells. In addition, B cells express a distinct subset of the TLR family that determines their ability to respond to DAMPs; however, the significance of restricted TLR expression in these cells is not yet clear.

All TLRs consist of a ligand-binding domain, characterized by multiple leucine-rich repeats (LRRs), and a carboxy-terminal, intracellular Toll/interleukin (IL) 1 receptor (TIR) domain. The LRR domains recognize bacterial and viral PAMPs in the extracellular environment (TLR1, TLR2, TLR4, TLR5, TLR6, and TLR11) or in the endolysosomes (TLR3, TLR7, TLR8, TLR9, and TLR10). While the role of TLRs in sepsis has been well described, more recent data indicate that a subset of the TLRs—TLR4 in particular—also recognize DAMPs released from injured cells and tissues. Among the DAMP ligands for surface TLR are HMGB1, HSPs, S100 proteins, and several others. Endosomal TLR ligands include mtDNA and other mitochondrial proteins.

What we know about TLR signaling events has largely been derived from the TLR-mediated response to bacterial pathogens. However, it is largely accepted that the intracellular adaptors required for signal transmission by TLRs are conserved and utilized for “damage” sensing of endogenous (“self”) ligands as well. The intracellular domain structure of TLRs is highly conserved and is characterized by a cytoplasmic Toll/IL-1R homology (TIR) domain. Binding of ligand to the receptor results in a receptor dimer, either a homodimer (e.g., TLR4/TLR4) or heterodimer (e.g., TLR2/TLR1), which recruits a number of adaptor proteins to the TIR domains through TIR-TIR interaction. With one exception (TLR3), the universal adaptor protein central to the TLR signaling complex is myeloid differentiation factor 88 (MyD88), a member of the interleukin-1 receptor subfamily. MyD88 works through the recruitment of a second TIR-containing adaptor, MyD88 adaptor-like protein (Mal), also termed Toll/interleukin-1 receptor-containing adaptor protein, or TIRAP) in the context of TLR4 and TLR2 signaling, which serves as a bridge between MyD88 and activated TLRs to initiate signal transduction. It is interesting that Mal’s adaptor function requires cleavage of the carboxy-terminal portion of the protein by caspase-1, a key effector of the inflammasome. This finding suggests an important synergy between TLRs and the inflammasome that may potentiate TLR-mediated signaling.

Signaling through the MyD88-dependent pathway occurs once the receptor is ligated at the cell surface. Receptor ligation, dimerization, and recruitment of the MyD88/Mal complex results in the activation of numerous cytoplasmic protein kinases, including IL-1 receptor–associated kinases, resulting in an interaction with tumor necrosis factor receptor–associated factor 6 (TRAF6). TRAF6, an E3 ubiquitin ligase, forms a complex with two other proteins, which together activate the complex that subsequently phosphorylates IxB kinase (IKK)-β and the MAP kinases (MAPKs). Ultimately, the phosphorylation of IxB leads to its degradation, which frees NF-κB and allows its translocation to the nucleus and the transcription of NF-κB target genes. Simultaneously, MAP kinase activation is critical for activation of the activator protein-1 (AP-1) transcription factor, and thus production of inflammatory cytokines.

Two other TIR domain-containing adaptor proteins, TIR-domain-containing adapter-inducing interferon-β (TRIF) and TRIF-related adaptor molecule (TRAM), are important to TLR-signaling events that are involved in the MyD88-independent signaling pathways, activated by TLR3 and TLR4. One distinction of MyD88-dependent and -independent TLR signaling is that TLR4/TRIF transduction begins after the signaling complex is internalized into endosomes. The MyD88-independent pathway acts through TRIF to activate NF-κB, similar to the MyD88-dependent pathway. However, TRIF can also recruit other signaling molecules to phosphorylate interferon-regulatory factor 3 (IRF3), which induces expression of type I IFN genes.
The initiation of transcription by TLR activation leads to the upregulation of a large cohort of target genes that include interferons α and β (IFNα/β), nitric oxide synthase 2 (NOS2A), and tumor necrosis factor (TNF), which play critical roles in initiating innate immune responses to cellular injury and stress. Given the importance of TLR triggering of the innate immune response to immune homeostasis, it is no surprise that the process is tightly regulated. TLR signaling is controlled at multiple levels, both posttranslationally via ubiquitination, phosphorylation, and micro RNA actions that affect mRNA stability, and by the localization of the TLRs and their signaling complexes within the cell.

TLR expression is significantly increased following blunt traumatic injury. A recent study of patients undergoing “high-risk” surgical procedures examined immune parameters, including TLR expression, that were associated with the development of SIRS. The investigators demonstrated that patients who developed postoperative SIRS exhibited increased TLR and TLR expression on a subgroup of CD14+ monocytes when compared to those patients with an uneventful recovery. Moreover, the upregulation of TLR in these patients was associated with increased expression of IL-6. Interestingly, the authors hypothesize that preoperatively, a subset of monocytes may already be primed to act in this way and thus may identify a vulnerable patient group.

**Nucleotide-Binding Oligomerization Domain (NOD)-like Receptor (NLR) Family.** The nucleotide-binding oligomerization domain-like receptors (NLRs) are a large family of proteins composed of intracellular PRRs that sense both endogenous (DAMPs) and exogenous (PAMPs) molecules to trigger innate immune activation. The best characterized of the NLRs is the NLR family pyrin domain-containing 3 (NLRP3), which is highly expressed in peripheral blood leukocytes. It forms the key “sensing” component of the larger, multiprotein inflammasome complex, which is composed of NLRP3; the adapter protein apoptosis-associated speck-like protein containing a CARD (ASC); and the effector protein, caspase 1. Activation of the NLRP3 inflammasome is tightly regulated, both transcriptionally and at the posttranslational level. An initial priming event (typically via TLR/nuclear factor [NF]-kB signals) upregulates NLRP3 expression. The receptor then resides in the cytoplasm in an inactive form due to an internal interaction between two adjacent domains. When phagocytosed DAMPs are sensed by NLRP3, this second event releases the self-repression. The protein can then oligomerize and recruit other complex members. The net result is the auto-activation of pro-caspase 1 to caspase 1. This event is pivotal to all known inflammasome signaling pathways. The caspase-1 products assemble to form the IL-1 converting enzyme (ICE), which cleaves the proforms of IL-1β, IL-18, and IL-33 to form their active, mature forms required for secretion from the cell.

The inflammasome-activated cytokines, IL-1β and IL-18, are potent proinflammatory molecules that promote key immune responses essential to host defense. Both IL-1β and IL-18 lack a signal sequence, which is usually necessary for the secretion of cellular proteins. More than 20 proteins in addition to IL-1β and IL-18 undergo unconventional protein secretion independent of the ER and Golgi, including a number of the DAMP molecules. Currently, the mechanisms responsible for unconventional protein secretion are not understood; however, the process is also evident in yeast under conditions of cellular stress. It makes evolutionary sense that a mechanism for rapid secretion of stored proteins essential to the stress response is highly conserved.

Evidence suggests that genetic variations in the NLRP3 gene might affect the magnitude of immune inflammatory responses following trauma. Single nucleotide polymorphisms within the NLRP3 gene were found to be associated with increased risk of sepsis and MODS in patients with major trauma. In an animal model of burn injury, early inflammasome activation has been detected in a variety of immune cells (NK cells, CD4/CD8 T cells, and B cells), as determined by the assessment of caspase 1 cleavage by flow cytometry. Further, inhibition of caspase 1 activity in vivo results in increased burn mortality, suggesting that inflammasome activation may play an unanticipated protective role in the host response to injury that may be linked to increased production of specific cytokines.

CNS trauma induces inflammasome activation in the nervous system. Moreover, exosomes containing inflammasome protein cargo are secreted into cerebral spinal fluid and can be detected in patients with TBI. In an animal model of TBI, controlled cortical impact, exosomes containing inflammasome proteins are detected in the serum and appear to be linked to TBI-related acute lung injury.

**C-Type Lectin and Lectin-Like Receptors.** Macrophages and dendritic cells possess receptors that detect molecules released from damaged or dying cells in order to retrieve and process antigens for T cell presentation. A key family of receptors that directs this process is the C-type lectin (CLR) and C-type lectin-like (CTLR) receptor family that includes the selectin and the mannose receptor families. CLR and CTLR bind carbohydrates in both a calcium-dependent (CLR) and -independent (CTLR) fashion. Best described for their sensing of PAMPs, the CLRs can also act to promote the endocytosis and clearance of cell debris, which can be processed and presented to T cells. CTLR receptor recognition of DAMPs of intracellular origin, such as F-actin and the ribonucleoprotein SAP-130, can trigger multiple signaling pathways leading to NF-kB, type I interferon (IFN), and/or inflammasome activation. Expression of the CTLR, MINCLE (macrophage-inducible C-type lectin), is increased after exposure to proinflammatory stimuli or cell stress. When MINCLE senses self-damage in association with ischemia-reperfusion injury, it promotes proinflammatory cytokine, chemokine, and nitric oxide production.

**Receptor for Advanced Glycation End Products (RAGE).** Another key player in the sterile inflammatory response to injury is the transmembrane receptor, the receptor for advanced glycation endproducts, or RAGE. Highly conserved across species, RAGE is a member of the immunoglobulin superfamily that is constitutively expressed at high levels in the lung, with low/absent expression in other adult cell types. However, proinflammatory stimuli and the presence of RAGE ligands can increase RAGE expression on immune cells such as neutrophils, macrophages, and lymphocytes. RAGE also exists as a soluble form (sRAGE) composed only of the extracellular domain, which can bind to and sequester RAGE ligands, without consequent signaling events. RAGE binds diverse ligands, including HMGB1 and S100, as well as components of the extracellular matrix such as collagen. As a receptor, RAGE recognizes the three-dimensional structure of its ligands that allow it to bind a diverse repertoire of molecules, independent of their amino acid sequence.
Signaling via RAGE is mediated via multiple pathways leading to transcriptional activation and release of proinflammatory mediators. Animal models have linked RAGE to acute lung injury in ischemia-reperfusion models. In clinical studies, high sRAGE levels have been linked to prolonged mechanical ventilation post lung transplant as well as worse outcomes following TBI-associated acute lung injury. These events likely represent a role for an HMGB1-RAGE axis in these pathologic processes.

**Soluble Pattern Recognition Molecules: The Pentraxins.**

Soluble pattern recognition molecules (PRMs) are a molecularly diverse group of molecules that share a conserved mode of action defined by complement activation, agglutination and neutralization, and opsonization. The best described of the PRMs are the pentraxins. PRMs can be synthesized at sites of injury and inflammation by macrophages and dendritic cells, while neutrophils can store PRMs and release them rapidly following activation. In addition, epithelial tissues (the liver in particular) serve as a reservoir source for systemic mass release. The short pentraxin, C-reactive protein (CRP), was the first PRM to be identified. Serum amyloid protein (SAP), which has 51% sequence similarity to human CRP, also contains the pentraxin molecular signature. CRP and SAP plasma levels are low (≤3 mg/L) under normal circumstances. However, CRP is synthesized by the liver in response to interleukin-6, increasing serum levels more than a 1000-fold. Thus, CRP is considered part of the **acute-phase protein response** in humans. For this reason, C-reactive protein has been studied as a marker of the proinflammatory response in many clinical settings, including appendicitis, vasculitis, and ulcerative colitis. CRP and SAP are ancient immune molecules that share many functional properties with antibodies: they bind bacterial polysaccharides, ECM components, apoptotic cells, and nuclear materials, as well as all three classes of Fcγ receptors (FcγR). Both molecules also participate in the activation and regulation of complement pathways. In this way, short pentraxins can link immune cells to the complement system.

Finally, there is significant data to support a role for pentraxin 3 (PTX3), a long pentraxin family member, in the “sterile” inflammatory response associated with cellular stress. While CRP is produced solely in the liver, PTX3 is produced by various cells in peripheral tissues, including immune cells. PTX3 plasma concentrations increase rapidly in various inflammatory conditions, including sepsis. Further, in a recent prospective study of polytraumatized patients, serum PTX3 concentrations were highly elevated, peaking at 24 hours. Further, PTX3 concentrations at admission were associated with injury severity, while higher PTX3 serum concentrations 24 hours after admission correlated with lower probability for survival.

**CENTRAL NERVOUS SYSTEM REGULATION OF INFLAMMATION IN RESPONSE TO INJURY**

The central nervous system (CNS) communicates with the body through ordered systems of sensory and motor neurons, which receive and integrate information to generate a coordinated response. Rather than being an immune-privileged organ, recent work indicates that the CNS receives information with regard to injury-induced inflammation both via soluble mediators as well as direct neural projections that transmit information to regulatory areas in the brain (Fig. 2-2). How does the

---

**Figure 2-2.** Neural circuit relaying messages of localized injury to the brain (nucleus tractus solitarius). The brain follows with a hormone release (adrenocorticotrophic hormone [ACTH], glucocorticoids) into the systemic circulation and by sympathetic response. The vagal response rapidly induces acetylcholine release directed at the site of injury to curtail the inflammatory response elicited by the activated immunocytes. This vagal response occurs in real time and is site specific. EPI = epinephrine; IL-1 = interleukin-1; NOREPI = norepinephrine; TNF = tumor necrosis factor. (Adapted with permission from Tracey KJ: The inflammatory reflex, Nature. 2002 Dec 19-26;420(6917):853-859.)
CNS sense inflammation? DAMPs and inflammatory molecules convey stimulatory signals to the CNS via multiple routes. For example, soluble inflammatory signaling molecules from the periphery can reach neurons and glial cells directly through the fenestrated endothelium of the circumventricular organs (CVO) or via a leaky blood-brain barrier in pathological settings following a traumatic brain injury. In addition, inflammatory stimuli can interact with receptors located on the brain endothelial cells to generate a variety of proinflammatory mediators (cytokines, chemokines, adhesion molecules, proteins of the complement system, and immune receptors) that directly impact the brain parenchyma. Not surprising, this response is countered by potent anti-inflammatory signaling, a portion of which is provided by the HPA axis and the release of systemic glucocorticoids. Inflammatory stimuli in the CNS result in behavioral changes, such as increased sleep, lethargy, reduced appetite, and the most common feature of infection, fever.

Information regarding peripheral inflammation and tissue damage can also be signaled to the brain via afferent neural fibers, particularly those of the vagus nerve. These afferent fibers can interconnect with neurons that project to the hypothalamus to modulate the HPA axis. In addition, afferent vagal nerve impulses modulate cells in the brain stem, at the dorsal motor nucleus of the vagus, from which efferent preganglionic parasympathetic originate. Axons from these cells, which comprise the visceromotor component of the vagus nerve, form an “inflammatory reflex” that feeds back to the periphery to regulate inflammatory signaling events. Mechanistic insight into the “inflammatory reflex” was provided by the observation in several experimental model systems, that vagal stimulation reduced proinflammatory cytokine production from the spleen. This effect was dependent on both vagal efferent signals and on splenic catecholaminergic nerve fibers that originated in the celiac plexus and terminated in the T cell–rich area of the spleen. The vagal efferent fibers that terminated within the celiac ganglion were found to synapse on the cell bodies of the catecholaminergic splenic nerves. Vagal stimulation resulted in the firing of these adrenergic nerves, resulting in the activation of β2-adrenergic receptors on a subset of acetylcholine (ACH)-producing T cells. The ACh released from this T cell population targets α7 nicotinic ACh receptors (a7nACHR) expressed by splenic macrophages. Macrophage ACh receptor ligation blocks cell activation, inhibiting cytokine production and shifting the macrophages towards an M2 anti-inflammatory phenotype. Moreover, ACh-receptor binding inhibits intracellular signaling including the nuclear translocation of NF-κB and the activation of the inflammasome. In a rat model of hemorrhagic shock with reperfusion, vagal nerve stimulation post injury resulted in a decrease in the inflammatory response to hemorrhage.

Neuroendocrine Response to Injury

Traumatic injury results in complex neuroendocrine signaling from the brain that serves to enhance immune defense and rapidly mobilize substrates necessary to meet essential energy and structural needs. The two principle neuroendocrine pathways that orchestrate the host response are the hypothalamic-pituitary-adrenal (HPA) axis, which results in the release of glucocorticoid hormones, and the sympathetic nervous system, which results in release of the catecholamines, epinephrine (EPI), and norepinephrine (NEP). Virtually every hormone of the HPA axis influences the physiologic response to injury and stress (Table 2-4), but some with direct influence on the inflammatory response or immediate clinical impact are highlighted here, including growth hormone (GH), macrophage inhibitory factor (MIF), aldosterone, and insulin.

The Hypothalamic-Pituitary-Adrenal Axis. One of the main mechanisms by which the brain responds to injury-associated stress is through activation of the hypothalamic-pituitary-adrenal (HPA) axis. Following injury, corticotrophin-releasing hormone (CRH) is secreted from the paraventricular nucleus (PVN) of the hypothalamus. This action is mediated in part by circulating cytokines produced as a result of the innate immune response to injury. These include tumor necrosis factor-α (TNF-α) IL-1β, IL-6, and the type I interferons (IFN-α/β). Cytokines that are produced as a result of the adaptive immune response (IL-2 and IFN-γ) are also capable of increasing cortisol release. Direct neural input via afferent vagal fibers that interconnect with neurons projecting to the hypothalamus can also trigger CRH release. CRH acts on the anterior pituitary to stimulate the secretion of adrenocorticotropic hormone (ACTH) into the systemic circulation. Interestingly, the cytokines that act on the hypothalamus are also capable of stimulating ACTH release from the anterior pituitary so that marked elevations in ACTH and in cortisol can occur that are proportional in magnitude to the injury severity. Additionally, pain, anxiety, vasopressin, angiotensin II, cholecystokinin, vasoactive intestinal peptide, and catecholamines all contribute to ACTH release in the injured patient.

ACTH acts on the zona fasciculate of the adrenal glands to synthesize and secrete glucocorticoids (Fig. 2-3). Cortisol is the major glucocorticoid in humans and is essential for survival during significant physiologic stress. The resulting increase in cortisol levels following trauma have several important anti-inflammatory actions.

Cortisol elicits its many actions through a cytosolic receptor, the glucocorticoid receptor (GR). Because it is lipid soluble, cortisol can diffuse through the plasma membrane to interact with its receptor, which is sequestered in the cytoplasm in a complex with heat shock proteins (Fig. 2-4). Upon ligand binding, the GR is activated and can employ a number of mechanisms to modulate proinflammatory gene transcription and signaling events, with a “net” anti-inflammatory effect. For example, the activated GR complex can interact with transcription factors to sequester them in the cytoplasm, promote their degradation, or inhibit them through other mechanisms. Affected target genes include proinflammatory cytokines, growth factors, adhesion molecules, and nitric oxide. In addition, glucocorticoids can negatively affect the access of the transcription factor, nuclear factor-κB (NF-κB), to the promoter regions of its target genes via a mechanism that involves histone deacetylase 2. In this way, glucocorticoids can inhibit a major mechanism by which TLR ligation induces proinflammatory gene expression. The GR complex can also bind to specific nucleotide sequences (termed glucocorticoid response elements) to promote the

Figure 2-3. Steroid synthesis from cholesterol. Adrenocorticotropic hormone (ACTH) is a principal regulator of steroid synthesis. The end products are mineralocorticoids, glucocorticoids, and sex steroids.

Figure 2-4. Simplified schematic of steroid transport into the nucleus. Steroid molecules (S) diffuse readily across cytoplasmic membranes. Intracellularly, the receptors (R) are rendered inactive by being coupled to heat shock protein (HSP). When S and R bind, HSP dissociates, and the S-R complex enters the nucleus, where the S-R complex induces DNA transcription, resulting in protein synthesis. mRNA = messenger RNA.
transcription of genes, which have anti-inflammatory functions. These include interleukin-10 and interleukin-1-receptor antagonists. Further, GR complex activation can indirectly influence TLR activity via an interaction with signaling pathways such as the mitogen-activated protein kinase and transforming growth factor–activated kinase-1 (TAK1) pathways. Finally, a recent report demonstrated that GCs target suppressor of cytokine signaling 1 (SOCS1) and type 1 interferons to regulate TLR-induced signaling events.81

Adrenal insufficiency represents a clinical syndrome highlighted largely by inadequate amounts of circulating cortisol and aldosterone. Classically, adrenal insufficiency is described in patients with atrophic adrenal glands caused by exogenous steroid administration who undergo a stressor such as surgery. These patients subsequently manifest signs and symptoms such as tachycardia, hypotension, weakness, nausea, vomiting, and fever. However, it is now apparent that severe traumatic injury associated with an extended proinflammatory response can increase the risk of critical illness–related corticosteroid insufficiency, or CIRCI.

In the postinjury setting, CIRCI describes a phenomenon in which an exaggerated proinflammatory response is associated with a blunted adrenocortical response.82 Factors that have been linked to CIRCI include dysregulation of the HPA axis with altered adrenal synthesis of cortisol, altered cortisol metabolism, and tissue resistance to corticosteroids with inadequate glucocorticoid receptor activity. As a consequence, cortisol levels prove insufficient for the severity of stress. Investigators have determined that CIRCI in trauma patients occurs more frequently than previously thought.83 In one recent study, CIRCI occurred in 38 of 70 patients with multiple injuries. In most cases, the diagnosis was made within the first 48 hours following injury.84 Laboratory findings in adrenal insufficiency include hypoglycemia from decreased gluconeogenesis, hyponatremia from impaired renal tubular sodium resorption, and hyperkalemia from diminished kaliuresis. Recommended guidelines to diagnose CIRCI include measuring delta cortisol (change in baseline cortisol at 60 min of <9 µg/dL) after cosyntropin (250 µg) administration and a random plasma cortisol of <10 µg/dL. Treatment strategies remain controversial in the setting of trauma.85,86

Macrophage Migration Inhibitory Factor Modulates Cortisol Function. Macrophage migration inhibitory factor (MIF) is a proinflammatory cytokine expressed by a variety of cells and tissues, including the anterior pituitary, macrophages and T lymphocytes. MIF is also classified as an atypical chemokine that binds to the CXCR4 receptor.87 Several important functions of MIF in innate and adaptive immune responses and in inflammation have been described supporting the idea that MIF may function to counteract the anti-inflammatory activity of glucocorticoids.88 For example, MIF has been reported to play a central role in the exacerbation of inflammation associated with acute lung injury, where it has been detected in the affected lungs and in alveolar macrophages. MIF has also been reported to upregulate the expression of Toll-like receptor 4 (TLR4) in macrophages,89 and an early increase in plasma MIF has been detected in severely injured patients and was found to correlate with NF-κB translocation and respiratory burst in PMNs derived from severely injured patients. Further, nonsurvivors were shown to have higher serum MIF concentrations early after injury than survivors.90 These data suggest that targeting MIF with available small molecule inhibitors may be a novel therapeutic strategy for preventing early PMN activation and subsequent organ failure in severely injured patients.

Growth Hormone, Insulin-Like Growth Factor, and Ghrelin. Growth hormone (GH) is a neurohormone expressed primarily by the pituitary gland that has both metabolic and immunomodulatory effects. GH promotes both protein synthesis and insulin resistance while enhancing the mobilization of fat stores. GH secretion is upregulated by hypothalamic GH–releasing hormone and downregulated by somatostatin. GH primarily exerts its downstream effects through direct interaction with GH receptors and through the enhanced hepatic synthesis of insulin-like growth factor-1 (IGF-1), an anabolic growth factor that is known to improve the metabolic rate, gut mucosal function, and protein loss after traumatic injury. Less than 5% of IGF-1 circulates free in the plasma, with the remainder bound principally to one of six IGF-binding proteins (IGFBPs), the majority to IGFBP-3. In the liver, IGF-1 stimulates protein synthesis and glycosogenesis; in adipose tissue, it increases glucose uptake and lipid utilization; and in skeletal muscles, it mediates glucose uptake and protein synthesis. In addition to its effects on cellular metabolism, GH enhances phagocytic activity of immune cells and tissues, including the anterior pituitary, macrophages and T lymphocytes. MIF is also classified as an atypical chemokine expressed by a variety of cells and tissues, including the anterior pituitary, macrophages and T lymphocytes. MIF is also classified as an atypical chemokine that binds to the CXCR4 receptor.87 Several important functions of MIF in innate and adaptive immune responses and in inflammation have been described supporting the idea that MIF may function to counteract the anti-inflammatory activity of glucocorticoids.88 For example, MIF has been reported to play a central role in the exacerbation of inflammation associated with acute lung injury, where it has been detected in the affected lungs and in alveolar macrophages. MIF has also been reported to upregulate the expression of Toll-like receptor 4 (TLR4) in macrophages,89 and an early increase in plasma MIF has been detected in severely injured patients and was found to correlate with NF-κB translocation and respiratory burst in PMNs derived from severely injured patients. Further, nonsurvivors were shown to have higher serum MIF concentrations early after injury than survivors.90 These data suggest that targeting
inflammatory markers. Moreover, the high ghrelin levels were a positive predictor of ICU-survival in septic patients, matching previous results from animal models. Based on these data, ghrelin seems to exert anti-inflammatory effects that are mediated by diverse pathways. Recent work has linked ghrelin to a novel pathway mediated by upregulation of uncoupling protein 2 (UCP2) particularly in the setting of traumatic brain injury.95

**The Role of Catecholamines in Postinjury Inflammation.**
Injury-induced activation of the sympathetic nervous system results in secretion of acetylcholine from the preganglionic sympathetic fibers innervating the adrenal medulla. The adrenal medulla is a special case of autonomic innervation and is considered a modified postganglionic neuron. Thus, acetylcholine signaling to the resident chromaffin cells ensures that a surge of epinephrine (EPI) and norepinephrine (NE) release into the circulation takes place in a ratio that is tightly regulated by both central and peripheral mechanisms. Circulating levels of EPI and NE are three- to fourfold elevated, an effect that persists for an extended time. The release of EPI can be modulated by transcriptional regulation of phenylethanolamine N-methyltransferase (PNMT), which catalyzes the last step of the catecholamine biosynthesis pathway methylating NE to form EPI. PNMT transcription, a key step in the regulation of epinephrine production, is activated in response to stress and tissue hypoxia by hypoxia-inducible factor 1α (HIF1A).

Catecholamine release almost immediately prepares the body for the “fight or flight” response with well-described effects on the cardiovascular and pulmonary systems, and on metabolism. These include increased heart rate, myocardial contractility, conduction velocity, and blood pressure; the redirection of blood flow to skeletal muscle; increased cellular metabolism throughout the body; and mobilization of glucose from the liver via glycogenolysis, gluconeogenesis, lipolysis, and ketogenesis. To compound the resulting hyperglycemia, insulin release is decreased mainly through the stimulation of α-adrenergic pancreatic receptors. Hyperglycemia, as will be discussed, contributes to the proinflammatory response and to further mitochondrial dysfunction.

The goal of this well-orchestrated catecholamine response is to reestablish and maintain the systems’ homeostasis, including the innate immune system. Circulating catecholamines can directly influence inflammatory cytokine production.96 Data indicate that basal EPI levels condition the activity and responsiveness of cytokine-secreting cells, which may explain large inter-individual variability in innate cytokine profiles observed following injury. Epinephrine infusion at higher doses has been found to inhibit production of tumor necrosis factor (TNF) alpha in vivo and to enhance the production of the anti-inflammatory cytokine interleukin IL-10.97 Additionally, in vitro studies indicate that stress levels of glucocorticoids and epinephrine, acting in concert, can inhibit production of IL-12, a potent stimulator of Th1 responses. Further, they have been shown in vitro to decrease Th1 cytokine production and increase Th2 cytokine production to a significantly greater degree compared to either adrenal hormone alone. Thus, catecholamines secreted from the adrenal, specifically epinephrine, play a role in both innate proinflammatory cytokine regulation, as well as adaptive Th responses, and may act in concert with cortisol during the injury response to modulate cytokine activity.98

How are these effects explained? It is well established that a variety of human immune cells (e.g., mononuclear cells, macrophages, and granulocytes) express adrenergic receptors that are members of the family of G-protein coupled receptors that act through the activation of intracellular second messengers such as cAMP and calcium ions influx (discussed in more detail in the following section). These second messengers can regulate a variety of immune cell functions, including the release of inflammatory cytokines and chemokines.

The sympathetic nervous system also has direct immunomodulatory properties via its innervation of lymphoid tissues that contain resting and activated immune cells. The close proximity of sympathetic nerve terminals to immune cells responding to antigens (e.g., in the spleen) allows for a high concentration of norepinephrine to be localized within the microenvironment of antigen-activated immune cells. Norepinephrine can then interact with β,-adrenergic receptors expressed by CD4+ T and B lymphocytes, many of which also express α,-adrenergic receptors. Additionally, endogenous catecholamine expression has been detected in these cells (both CD4+ CD25+ T cells and phagocytes) as has the machinery for catecholamine synthesis. For example, monocytes contain inducible mRNA for the catecholamine-generating enzymes, tyrosine-hydroxylase, and dopamine-β-hydroxylase, and there is data to suggest that cells can regulate their own catecholamine synthesis in response to extracellular cues. Immune cell release of NE provides a way in which cells may exert additional regulation of inflammatory cell activation. For example, mature dendritic cells express both functional α- and β-adrenergic receptor (AR) types, as do monocytes and monocyte-derived macrophages, whereas B cells and Th1 cells express β,-AR exclusively.99 Exposure of PBMCs to NE triggers a distinct genetic profile that indicates a modulation of Th cell function. Thus, stimulation of AR results in varied signaling events to regulate both immune cell phenotype as well as mature cell function.100

**Aldosterone.** Aldosterone is a mineralocorticoid released by the zona glomerulosa of the adrenal cortex. It binds to the mineralocorticoid receptor (MR) of principal cells in the collecting duct of the kidney where it can stimulate expression of genes involved in sodium reabsorption and potassium excretion to regulate extracellular volume and blood pressure. Mineralocorticoid receptors (MR) have also been shown to have effects on cell metabolism and immunity. For example, recent studies show aldosterone interferes with insulin signaling pathways and reduces expression of the insulin-sensitizing factors, adiponectin and peroxisome proliferator activated receptor–γ (PPAR–γ), which contribute to insulin resistance. In the immune system, monocytes, lymphocytes, dendritic cells, and neutrophils have all been shown to possess a MR that binds aldosterone with high specificity, regulating sodium and potassium flux, as well as plasminogen activator inhibitor-1 and p22 phox expression in these cells.101 In dendritic cells, MR activation by aldosterone induces the secretion of proinflammatory cytokines. Further, aldosterone inhibits cytokine-mediated NF-κB activation in neutrophils, which also possess a functional MR.

**Insulin.** Hyperglycemia and insulin resistance are hallmarks of injury and critical illness due to the catabolic effects of circulating mediators, including catecholamines, cortisol, glucagon, and growth hormone. The increase in these circulating proglycemic factors, particularly epinephrine, induces glycogenolysis, lipolysis, and increased lactate production independent of available oxygen in a process that is termed “aerobic glycolysis.” Although there is an increase in insulin production at the
same time, severe stress is frequently associated with insulin resistance, leading to decreased glucose uptake in the liver and the periphery contributing to acute hyperglycemia. Insulin is a hormone secreted by the pancreas, which mediates an overall host anabolic state through hepatic glycogenesis and glycolysis, peripheral glucose uptake, lipogenesis, and protein synthesis.102

The insulin receptor (IR) is widely expressed and consists of two isoforms, which can form homo- or heterodimers with insulin binding. Dimerization leads to receptor autophosphorylation and activation of intrinsic tyrosine kinase activity. Downstream signaling events are dependent on the recruitment of the adaptor proteins, insulin receptor substrate (IRS-1), and Shc to the IR. Systemic insulin resistance likely results from proinflammatory signals, which modulate the phosphorylation of IRS-1 to affect its function.

Hyperglycemia during critical illness is predictive of increased mortality in critically ill trauma patients.103 It can modulate the inflammatory response by altering leukocyte functions and the resulting decreases in phagocytosis, chemotaxis, adhesion, and respiratory burst activities are associated with an increased risk for infection. In addition, glucose administration results in a rapid increase in NF-κB activation and proinflammatory cytokine production. Insulin therapy to manage hyperglycemia has grown in favor and has been shown to be associated with both decreased mortality and a reduction in infectious complications in select patient populations. However, the trend towards tight glycemic control in the intensive care unit failed to show benefit when examined in several reviews.104 Thus, the ideal blood glucose range within which to maintain critically ill patients and to avoid hypoglycemia has yet to be determined.

THE CELLULAR STRESS RESPONSES

Reactive Oxygen Species and the Oxidative Stress Response

Reactive oxygen and nitrogen species (ROS, RNS, respectively) are small molecules that are highly reactive due to the presence of unpaired outer orbit electrons. They can cause cellular injury to host cells and invading pathogens through the oxidation of cell membrane substrates, cellular proteins, and DNA. ROS has also been shown to have important roles as signaling messengers, particularly in the immune system.105,106

Oxygen radicals (superoxide anion, hydroxyl radical, hydrogen peroxide) are produced as a by-product of oxygen metabolism. The main areas of ROS production are oxidative processes involving the mitochondrial electron transport chain as well as those mediated by NADPH oxidases (NOX), a large class of ROS producing enzymes. Additional metabolic enzymes such as lipoxygenases, cytochrome P-450 and b5, and cyclooxygenases also produce ROS as by-products of their reactions.107 The synthesis of ROS is regulated at several checkpoints and via complex signaling mechanisms, including Ca2+ signaling, phosphorylation, and small G protein activation, which influence both the recruitment of the molecules required for NOX function and the synthesis of ROS in the mitochondria. Not surprisingly, NOX activation is triggered by a number of inflammatory mediators (e.g., TNF, chemokines, lysophospholipids, complement, and leukotrienes).

Host cells are protected from the damaging effects of ROS through a number of mechanisms. The best described of these is via the upregulation and/or activation of endogenous antioxidant enzymes such as superoxide dismutases, catalases, and glutaredoxins. Pyruvate kinase also provides negative feedback for ROS synthesis as do molecules that react nonenzymatically with ROS. Under normal physiologic conditions, ROS production is balanced effectively by these antioxidative strategies. As a consequence, ROS can act as signaling molecules through their ability to modulate cysteine residues by oxidation, and thus influence the functionality of target proteins.108 ROS can also contribute to transcriptional activity both indirectly through its effects on transcription factor lifespan, and directly through the oxidation of DNA.

The role for ROS has been well described in phagocytes, which utilize these small molecules for pathogen killing. A second important role for ROS is in the regulation of the inflammasome. As discussed previously, the inflammasome mediates the activation of inflammatory caspases leading to the production and secretion of mature cytokines in macrophages.109 Importantly, the best described inflammasome, NLRP3, is redox sensitive. Increased intracellular ROS enables the assembly of the protein complex.110 ROS also appears to be involved in adaptive immunity by influencing immune cell response.110 ROS can alter thiol group oxidative states on the cell surface and, in turn, affect cell signaling. Moreover, intracellular ROS can inhibit DNA transcription. ROS has been described as a prime source of phosphatase activation in both B and T lymphocytes, which can regulate the function of key receptors and intracellular signaling molecules in these cells by affecting phosphorylation events. Finally, large amounts of ROS cannot only suppress cell function, but also can result in cell death.111

The Unfolded Protein Response

Secreted, membrane-bound, and organelle-specific proteins fold in the lumen of the endoplasmic reticulum (ER) where they also receive their posttranslational modifications. Cellular stress disrupts the quality control required for this process leading to the accumulation of misfolded or unfolded proteins. These occurrences are sensed by a highly conserved array of signaling proteins in the ER that try to reestablish appropriate folding, while at the same time decreasing protein synthesis.112 The important proteins involved in this process include inositol requiring enzyme 1 (IRE1), protein kinase RNA (PKR)–like ER kinase (PERK), and activating transcription factor 6 (ATF6). Together, these proteins form a complex that generates the unfolded protein response (UPR). The UPR is a mechanism by which ER distress signals are sent to the nucleus to modulate transcription in an attempt to restore homeostasis. While obviously important to secretory epithelial cells, the UPR is also important to cells of the immune system.113

Significant protein misfolding results in an alarm signal that, if not addressed, can result in cell death. Genes activated in the UPR result not only in the inhibition of translation, but also other potentially immunomodulatory events including induction of the acute phase response, activation of NF-κB, and the generation of antibody-producing B cells.114 Activation of the UPR is also an alternative mechanism for activation of the inflammasome115 and can increase proinflammatory cytokine production.116

Markers of ER stress during critical illness have been demonstrated conclusively in burn patients,114,117 and in animal models they have been detected following hemorrhagic shock, correlating with the degree of organ dysfunction. Burn injury in particular leads to the marked reduction in ER calcium levels
and activation of UPR sensing proteins. Moreover, recent data in a series of burn patients strongly links the UPR to insulin resistance and hyperglycemia in these patients. Thus, a better understanding of the UPR, which is triggered by severe inflammation, may allow the identification of novel therapeutic targets for injury-associated insulin resistance.

Fibroblast growth factor-21 (FGF21), a recently identified hormone that regulates systemic metabolic homeostasis, is upregulated following mitochondrial damage and may be part of an integrated stress response that includes ER stress and the UPR. In animal models, induction of ER stress with chemical ER stressors results in increased FGF21 expression. A recent study examining FGF21 in critically ill patients demonstrated that serum FGF21 concentrations were eightfold higher in the critically ill patients as compared with the matched controls, regardless of the presence of sepsis. While FGF21 concentrations gradually decreased over time, they remained highly elevated at all studied time points and correlated with patient mortality. These data support the idea that the UPR may play an important role in the response to severe injury.

**Autophagy**

Under normal circumstances, cells need to have a way of disposing of damaged organelles and debris aggregates that are too large to be managed by proteosomal degradation. In order to accomplish this housekeeping task, cells utilize a process referred to as “macroautophagy” (autophagy), which is thought to have originated as a stress response. The steps of autophagy include the engulfment of cytoplasm/organelle by an “isolation membrane,” which is also called a phagophore. The edges of the phagophore then fuse to form the autophagosome, a double-membraned vesicle that sequesters the cytoplasmic material and is a characteristic feature of autophagy. The autophagosome then fuses with a lysosome to form an autolysosome, where the contents, together with the inner membrane, are degraded. This process is controlled by numerous autophagy-specific genes and by the specific kinase, mammalian target of rapamycin (mTOR).

As noted previously, autophagy is a normal cellular process that occurs in quiescent cells for cellular maintenance. However, under conditions of hypoxia and low cellular energy, autophagy is induced in an attempt to provide additional nutrients for energy production. The induction of autophagy promotes a shift from aerobic respiration to glycolysis and allows cellular components of the autophagosome to be hydrolyzed to energy substrates. Increased levels of autophagy are typical in activated immune cells and are a mechanism for the disposal of ROS and phagocytosed debris.

Recent data support the idea that autophagy plays an important role in the immune response. Autophagy is stimulated by Th1 cytokines and with activation of TLR in macrophages but is inhibited by Th2 cytokines. It is also recognized as an important regulator of cytokine secretion, particularly those cytokines of the IL-1 family that are dependent on inflammatory processing for activation. For example, autophagosomes can sequester and degrade pro-IL-1β and inflammasome components. In animal models of sepsis, inhibition of autophagy results in increased proinflammatory cytokine levels that correlate with increased mortality. These data suggest that autophagy is a protective mechanism whereby the cell can regulate the levels of cytokine production.

**Apoptosis**

Apoptosis (regulated cell death) is an energy-dependent, organized mechanism for clearing senescent or dysfunctional cells, including macrophages, neutrophils, and lymphocytes, without promoting an inflammatory response. This contrasts with cellular necrosis, which results in a disorganized sequence of intracellular molecular releases with subsequent immune activation and inflammatory response. Systemic inflammation modulates apoptotic signaling in active immunocytes, which subsequently influences the inflammatory response through the loss of effector cells.

Apoptosis proceeds primarily through two pathways: the extrinsic pathway and the intrinsic pathway. The extrinsic pathway is activated through the binding of death receptors (e.g., Fas, TNFR), which leads to the recruitment of Fas-associated death domain protein and subsequent activation of caspase 3 (Fig. 2-5). On activation, caspases are the effectors of apoptotic signaling because they mediate the organized breakdown of nuclear DNA. The intrinsic pathway proceeds through protein mediators (e.g., Bcl-2, Bcl-2-associated death promoter, Bcl-2–associated X protein, Bim) that influence mitochondrial membrane permeability. Increased membrane permeability leads to the release of mitochondrial cytochrome C, which ultimately activates caspase 3 and thus induces apoptosis. These pathways do not function in a completely autonomous manner because there is significant interaction and crosstalk between mediators of both extrinsic and intrinsic pathways. Apoptosis is modulated by several regulatory factors, including inhibitor of apoptosis proteins and regulatory caspases (e.g., caspases 1, 8, 10).

Apoptosis during sepsis may influence the ultimate competency of the acquired immune response. In a murine model of peritoneal sepsis, increased lymphocyte apoptosis was associated with mortality, which may be due to a resultant decrease in IFN-γ release. In postmortem analysis of patients who expired from overwhelming sepsis, there was an increase in lymphocyte apoptosis, whereas macrophage apoptosis did not appear to be affected. Clinical trials have observed an association between the degree of lymphopenia and disease severity in sepsis. In addition, after the phagocytosis of apoptotic cells by macrophages, anti-inflammatory mediators such as IL-10 are released that may exacerbate immune suppression during sepsis. Neutrophil apoptosis is inhibited by inflammatory products, including TNF, IL-1, IL-3, IL-6, GM-CSF, and IFN-γ. This retardation in regulated cell death may prolong and exacerbate secondary injury through neutrophil free radical release as the clearance of senescent cells is delayed.

**Necroptosis**

Cellular necrosis refers to the premature uncontrolled death of cells in living tissue typically caused by accidental exposure to external factors, such as ischemia, inflammation or trauma, which result in extreme cellular stress. Necrosis is characterized by the loss of plasma membrane integrity and cellular collapse with extrusion of cytoplasmic contents, but the cell nuclei typically remain intact. Recent data have defined a process by which necrosis occurs through a series of well-described steps that are dependent on a signaling pathway that involves the receptor-interacting protein kinase (RIPK) complex. Termed “necroptosis,” it occurs in response to specific stimuli, such as TNF- and TLR-mediated signals. For example, ligation of the tumor necrosis factor receptor 1 (TNFR1) under conditions in which caspase-8 is inactivated (e.g., by pharmacological
agents) results in the over-generation of ROS and a metabolic collapse. The net result is programmed necrosis (necroptosis). The effect of cell death by necroptosis on the immune response is not yet known. However, it is likely that the “DAMP” signature that occurs in response to necrotic cell death is an important contributor to the systemic inflammatory response. Evidence to support this concept was provided by investigators who examined the role of necroptosis in murine model of sepsis. They demonstrated that Ripk3−/− mice were capable of recovering body temperature better, exhibited lower circulating DAMP levels, and survived at higher rates than their WT littermates.126 These data suggest that the cellular damage that occurs with programmed necrosis exacerbates the sepsis-associated systemic inflammatory response.

**Pyroptosis**

Pyroptosis is a form of regulated cell death that is dependent on the activity of the proinflammatory caspase enzymes associated with the inflammasome and is thus an inflammatory form of cell death.127 Pyroptosis shares some features with apoptosis, including DNA fragmentation and positive annexin V staining, among others. However, it is associated with the activation of caspase-1 and the formation of caspase-1–dependent pores that allow early permeabilization of the cell membrane, electrolyte movement into the cells, and, finally, osmotic lysis of the cell.128 As a form of cell death, pyroptosis seems to be largely observed in macrophages, dendritic cells, and neutrophils, although it has been documented in other cells as well, especially if they express high levels of caspase-1. As noted, pyroptosis is linked to activation of the inflammasome, which can occur in response to diverse cell alarm signals, including DAMPs. Not surprising, the mechanism of cell death leads to the release of additional intracellular DAMPs, including HMGB1 and S100 proteins.

A recent study examined pyroptosis in peripheral blood mononuclear cells in a cohort of 60 trauma patients.129 The investigators found that the percentages of pyroptotic PBMCs were significantly higher in trauma patients than those in healthy

---

**Figure 2-5.** Signaling pathway for tumor necrosis factor receptor 1 (TNFR-1) (55 kDa) and TNFR-2 (75 kDa) occurs by the recruitment of several adapter proteins to the intracellular receptor complex. Optimal signaling activity requires receptor trimerization. TNFR-1 initially recruits TNFR-associated death domain (TRADD) and induces apoptosis through the actions of proteolytic enzymes known as caspases, a pathway shared by another receptor known as CD95 (Fas). CD95 and TNFR-1 possess similar intracellular sequences known as death domains (DDs), and both recruit the same adapter proteins known as Fas-associated death domains (FADDs) before activating caspase 8. TNFR-1 also induces apoptosis by activating caspase 2 through the recruitment of receptor-interacting protein (RIP). RIP also has a functional component that can initiate nuclear factor-kB (NF-kB) and c-Jun activation, both favoring cell survival and proinflammatory functions. TNFR-2 lacks a DD component but recruits adapter proteins known as TNFR-associated factors 1 and 2 (TRAF1, TRAF2) that interact with RIP to mediate NF-kB and c-Jun activation. TRAF2 also recruits additional proteins that are antiapoptotic, known as inhibitor of apoptosis proteins (IAPs). DED = death effector domain; I-kB = inhibitor of kB; I-kB/NF-kB = inactive complex of NF-kB that becomes activated when the I-kB portion is cleaved; JNK = c-Jun N-terminal kinase; MEKK1 = mitogen-activated protein/extracellular regulatory protein kinase kinase-1; NIK = NF-kB–inducing kinase; RAIDD = RIP-associated interleukin-1b-converting enzyme and ced-homologue-1–like protein with death domain, which activates proapoptotic caspases. (Adapted with permission from Vincent JL: Marshall JC, Cohen J: Update in Intensive Care and Emergency Medicine: Vol. 31: Immune Response in Critical Illness. Berlin: Springer-Verlag; 2002.)
controls and correlated with injury severity. Moreover, increase in pyroptotic PBMCs significantly correlated with elevated cytokine levels (IL-10, IL-18, and MCP-1) and was a strong predictor for the development of sepsis.

**MEDIATORS OF INFLAMMATION**

**Cytokines**

Cytokines are a class of protein signaling compounds that are essential for both innate and adaptive immune responses. Cytokines mediate a broad sequence of cellular responses, including cell migration, DNA replication, cell turnover, and immunocyte proliferation (Table 2-5). When functioning locally at the site of injury and infection, cytokines mediate the eradication of invading microorganisms and also promote wound healing. However, an exaggerated proinflammatory cytokine response to inflammatory stimuli may result in hemodynamic instability (i.e., septic shock) and metabolic derangements (i.e., muscle wasting). Anti-inflammatory cytokines also are released, at least in part, as an opposing influence on the proinflammatory cascade. These anti-inflammatory mediators may also result in immunocyte dysfunction and host immunosuppression. Cytokine signaling after an inflammatory stimulus can best be represented as a finely tuned balance of opposing influences and should not be oversimplified as a “black and white” proinflammatory/anti-inflammatory response. A brief discussion of the important cytokine molecules is included below.

**Tumor Necrosis Factor-α**. Tumor necrosis factor-α (TNF-α) is a potent inflammatory mediator that is rapidly mobilized in response to stressors such as injury and infection. It is primarily synthesized by immune cells, such as macrophages, dendritic cells, and T lymphocytes, and is generated in a precursor form that is expressed as a trimer on the surface of activated cells. After being processed by the metalloproteinase, TNF-α-converting enzyme (TACE, also known as ADAMS 17), a smaller, soluble form of TNF is released, which mediates its biological activities through types 1 and 2 TNF receptors (TNFR-1; TNFR-2). Transmembrane TNF-α also binds to TNFR-1 and -2, but its biological activities are likely mediated through TNFR-2. While the two receptors share homology in their ligand-binding regions, there are distinct differences that regulate their biologic function. For example, TNFR-1 is expressed by a wide variety of cells, but it is typically sequestered in the Golgi. Following appropriate cell signaling, TNFR-1 is mobilized to the cell surface, where it sensitizes cells to TNF or it can be cleaved from the surface in the form of a soluble receptor that can neutralize TNF. In contrast, TNFR-2 expression is confined principally to immune cells where it resides in the plasma membrane. Both TNF receptors are capable of binding intracellular adaptor proteins that lead to activation of complex signaling processes and mediate the effects of TNF.

Although the circulating half-life of soluble TNF is brief, it acts upon almost every differentiated cell type, eliciting a wide range of cellular responses. Moreover, it is one of the first cytokines to be released following trauma. In particular, TNF elicits many metabolic and immunomodulatory activities. It stimulates muscle breakdown and cachexia through increased catabolism, insulin resistance, and redistribution of amino acids to hepatic circulation as fuel substrates. TNF also mediates coagulation activation, cell migration, and macrophage phagocytosis and enhances the expression of adhesion molecules, prostaglandin E₂, platelet-activating factor, glucocorticoids, and eicosanoids. TNF-α increases endothelial cell permeability and activates macrophages, NK cells and lymphocytes to induce the secretion of various cytokines. While TNF is clearly playing a role in injury-induced inflammation, reports are conflicting whether postinjury TNF concentrations correlated with the development of multiple organ dysfunction syndrome.

**Interleukin-1 Family.** The IL-1 family of proteins contains 11 members. The best-studied of these are IL-1α and IL-1β and IL-1 receptor antagonist (IL-1Ra), but member cytokines also include IL-18, IL-33, IL-36, IL-3,7 and IL-38. IL-1α and IL-1β, which are encoded by two distinct IL-1 genes, share similar biologic functions despite limited sequence homology. They utilize the same cell surface receptor, termed IL-1 receptor type 1 (IL-1RI), which is present on nearly all cells. Once bound to its receptor, IL-1 initiates signaling events that result in the synthesis and release of a variety of inflammatory mediators. Members of the IL-1 family are expressed as proforms (pIL-1) that are matured through enzymatic cleavage. The IL-1α precursor is constitutively expressed and stored in a variety of healthy cells, including epithelium and endothelium, and its expression can be increased in response to proinflammatory or stress-associated stimuli.

Both the precursor and mature forms of IL-α have nearly identical biologic activities as measured by their ability to trigger IL-6 and TNF release. With appropriate signals, IL-1α can move both to the cell membrane, where it can act on adjacent cells bearing the IL-1R and to the nucleus where it can stimulate gene transcription. Pro-IL-1α can also be released passively from damaged injured cells in its active form. In this way, IL-1α is believed to function as a DAMP, which promotes the synthesis of inflammatory mediators, such as chemokines and eicosanoids. These mediators attract neutrophils to the injured site, facilitate their exit from the vasculature, and promote their activation. Once they have reached their target, neutrophil lifespan is extended by the presence of IL-1α.

IL-1β is a multifunctional proinflammatory cytokine whose expression and synthesis is tightly regulated and confined to activated cells, such as monocytes, tissue macrophages, and dendritic cells. In contrast to IL-1α, IL-1β is synthesized as an inactive precursor, pro-IL-1β, which is processed by the inflammasome in response to various stimuli, including cytokines and foreign pathogens, via pattern recognition receptors such as TLR4 as well as ROS. Mature IL-1β is then released from the cell via an unconventional secretory pathway. IL-1β has a spectrum of proinflammatory effects that are largely similar to those induced by TNF, and injection of IL-1β alone is sufficient to induce an acute inflammatory response. High doses of either IL-1β or TNF are associated with profound hemodynamic compromise. Interestingly, low doses of both IL-1β and TNF administered together elicit hemodynamic events similar to those elicited by high doses of either mediator, which suggests a synergistic effect.

There are two primary receptor types for IL-1: IL-1R1 and IL-1R2. IL-1R1 is widely expressed and mediates inflammatory signaling on ligand binding. IL-1R2 is proteolytically cleaved from the membrane surface to soluble form on activation and thus serves as another mechanism for competition and regulation of IL-1 activity. IL-1α or IL-1β bind first to the IL-1R1, which is considered the ligand-binding chain. This is followed by recruitment of a transmembrane co-receptor, termed the

ARDS = acute respiratory distress syndrome; GM-CSF = granulocyte-macrophage colony-stimulating factor; IFN = interferon; Ig = immunoglobulin; IL = interleukin; NK = natural killer; Th1 = helper T cell subtype 1; Th2 = helper T cell subtype 2; TNF = tumor necrosis factor.

accessory protein (IL-1RαcP). A complex is formed of IL-1RI plus IL-1 plus the coreceptor. The signal is initiated with recruitment of the adaptor protein MyD88 to the Toll-IL-1 receptor (TIR) domains of the receptor complex and signal transduction via intermediates, which are homologous to the signal cascade initiated by TLRs. These events culminate in the activation of NF-κB and its nuclear translocation. Recent animal studies have implicated postinjury IL-1β in the exacerbation of traumatic brain injury. In a mouse model of polytrauma, which included both cortical brain injury and tibial fracture, mice that received both injuries demonstrated increased neuroinflammation, brain damage, and behavioral deficits compared to mice given an isolated-TBI. These changes correlated with increased IL-1β levels in the brain. Treatment...
with IL-1R antagonist post injury reduced volume loss in the injured cortex as well as markers of axonal injury, resulting in improved outcome in these animals.

IL-18 is also a member of the IL-1 superfamily of cytokines. \(^{138}\) First noted as an IFN-\(\gamma\)-inducing factor produced by LPS-stimulated macrophages, IL-18 expression is found both in immune cells and nonimmune cells at low to intermediate levels. However, activated macrophages and Kupffer cells produce large amounts of mature IL-18. Similar to IL-1\(\beta\), IL-18 is synthesized and stored as an inactive precursor form (pro-IL-18), and activation requires activation of the inflammasome resulting in the processing of pro-IL-18 by caspase-1. \(^{139}\) It then exits the cell through a nontraditional secretory pathway. The IL-18 receptor (IL-18R) is composed of two subunits, IL-18R\(\alpha\) and IL-18R\(\beta\), and is a member of the IL-1R superfamily that is structurally similar in their cytoplasmic domains to the TLR. One unique biological property of IL-18 is the potential, in conjunction with IL-12, to promote the Th1 response.

IL-18 induces IFN\(\gamma\) production by CD4\(^+\) T cells. IFN\(\gamma\), in turn, activates macrophages to produce inflammatory cytokines. Independent of its ability to induce interferon, IL-18 can act similarly to other proinflammatory cytokines by acting directly to increase in cell adhesion molecule expression, nitric oxide synthesis, and chemokine production by macrophages. \(^{140}\)

In a cohort of critically ill patients with acute lung injury and ARDS, inflammasome-related mRNA transcripts (CASP1, IL1B, and IL18) were increased in peripheral blood. Moreover, plasma IL-18 were also elevated and served as a marker of mortality risk. \(^{141}\) Recent studies suggest that IL-18 therapy may hold promise as effective therapy in promoting immune recovery after severe surgical stress. \(^{142}\)

IL-33, a second important IL-1 family member, is mainly expressed in surface epithelium and endothelium, where it is normally bound via an N-terminal chromatin-binding motif. \(^{143}\) Nuclear localization is important for its function and perhaps its regulation. Expression in mice of an IL-33 that lacks the nuclear localization sequence, results lethal inflammation, suggesting that nuclear localization acts to prevent unregulated extracellular release. \(^{144}\) Similar to HMGB1 and other IL-1 family members, IL-33 lacks a signal sequence for active secretion so that its release is injury-dependent. Once released from damaged cells, full length IL-33 is biologically active, but can be further processed by inflammatory proteases to a mature form that exhibits ten- to thirtyfold higher activity. IL-33 can binds to a member of the IL-1R family, ST2, leading to activation of NF-κB-mediated transcriptional events. ST2+ cells include macrophages, mast cells, Th2 cells, and tissue regulatory T cells (Tregs) which are important controllers of immune homeostasis.

**Interleukin-2 Family.** Interleukin-2 (IL-2) is a multifunctional cytokine produced primarily by CD4\(^+\) T cells after antigen activation, which plays pivotal roles in the immune response. Other cellular sources for IL-2 include CD8\(^+\) and NK T cells, mast cells, and activated dendritic cells. Discovered as a T cell growth factor, IL-2 also promotes CD8\(^+\) T cell and natural killer cell cytolytic activity and modulates T cell differentiation programs in response to antigen. Thus, IL-2 promotes naive CD4\(^+\) T cell differentiation into T helper 1 (Th1) and T helper 2 (Th2) cells while inhibiting T helper 17 (Th17) and T follicular helper (Tfh) cell differentiation. Moreover, IL-2 is essential for the development and maintenance of T regulatory (Treg) cells and for activation-induced cell death, thereby mediating tolerance and limiting inappropriate immune reactions. The upregulation of IL-2 requires calcium as well as protein kinase C signaling, which leads to the activation of transcription factors such as nuclear factor of activated T cells (NFAT) and NF-κB. MicroRNAs also play a role in the regulation of IL-2 expression. \(^{145}\)

IL-2 binds to IL-2 receptors (IL-2R), which are expressed on leukocytes. IL-2Rs are formed from various combinations of three receptor subunits: IL-2R\(\alpha\), IL-2R\(\beta\), and IL-2R\(\gamma\). These subunits form in low, medium, and high affinity forms of the receptor depending on the subunit combination. IL-2R\(\gamma\) has been renamed the common cytokine receptor γ chain (γc), which is now known to be shared by IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21. Constitutive IL-2 receptor expression is low and is inducible by T cell receptor ligation and cytokine stimulation. Importantly, the transcription of each receptor subunit is individually regulated via a complex process to effect tight control of surface expression. Once the receptor is ligated, the major IL-2 signaling pathways that are engaged include Janus Kinase (JAK)-signal transducer and activator of transcription (STAT), Shc-Ras-MAPK, and phosphoinositol-3-kinase (PI3-K)-AKT. Partly due to its short half-life of <10 minutes, IL-2 is not readily detectable after acute injury. IL-2 receptor blockade induces immunosuppressive effects and can be pharmacologically used for organ transplantation. Attenuated IL-2 expression observed during major injury or blood transfusion may contribute to the relatively immunosuppressed state of the surgical patient. \(^{146}\)

**Interleukin-6 Family.** Following burn or traumatic injury, damage-associated molecular patterns (DAMPs) from damaged or dying cells stimulate TLRs to produce IL-6, a proinflammatory cytokine that plays a central role in host defense. IL-6 levels in the circulation are detectable by 60 minutes post injury, peak between 4 and 6 hours, and can persist for as long as 10 days. Further, plasma levels of IL-6 are proportional to the degree of injury. In the liver, IL-6 strongly induces a broad spectrum of acute-phase proteins such as C-reactive protein (CRP) and fibrinogen, among others, while it reduces expression of albumin, cytochrome P 450, and transferrin. In lymphocytes, IL-6 induces B cell maturation into immunoglobulin-producing cells and regulates Th17/Treg balance. IL-6 modulates T cell behavior by inducing the development of Th17 cells and inhibiting Treg cell differentiation in conjunction with transforming growth factor-β. IL-6 also promotes angiogenesis and increased vascular permeability, which are associated with local inflammatory responses. To date, ten IL-6 family cytokines have been identified, including IL-6, oncostatin M, neuropoietin, IL-11, IL-27, and IL-31. \(^{147}\)

The interleukin-6 receptor (IL-6R, gp80) is expressed on hepatocytes, monocytes, B cells, and neutrophils in humans. However, many other cells respond to IL-6 through a process known as trans-signaling. \(^{148}\) In this case, soluble IL-6Rs (sIL-6R) exist in the serum and bind to IL-6, forming an IL-6/sIL-6R complex. The soluble receptor is produced by proteolytic cleavage from the surface of neutrophils in a process that is stimulated by C-reactive protein, complement factors, and leukotrienes. The IL6/sIL6R complex can then bind to the gp130 receptor, which is expressed ubiquitously on cells. Upon IL-6 stimulation, gp130 transduces two major signaling pathways: the JAK-STAT3 pathway and the SHP2-Gab-Ras-Erk-MAPK pathway, which is regulated by cytoplasmic suppressor of cytokine signaling (SOCS3). These signaling events can lead to increased expression of adhesion molecules as well as proinflammatory chemokines and cytokines. High plasma IL-6 levels have been associated with mortality during
intra-abdominal sepsis. Moreover, prolonged (more than 3 days) elevation of IL-6 concentrations has been reported to correlate with the occurrence of complications and mortality following severe traumatic injury. More recently, a meta-analysis analyzed the predictive value of IL-6 for the development of complications and mortality after trauma and found that the concentration of IL-6 in the first 24 hours after trauma was predictive for the development of multiple organ failure and death.

**Interleukin-10 Family.** We have talked almost exclusively about the factors that initiate the proinflammatory response following cellular stress or injury. The reestablishment of immune homeostasis following these events requires the resolution of inflammation and the initiation of tissue repair processes. Interleukin-10 (IL-10) plays a central role in this anti-inflammatory response by regulating the duration and magnitude of inflammation in the host.

The IL-10 family currently has six members, including IL-10, IL-19, IL-20, IL-22, IL-24, and IL-26. IL-10 is produced by a variety of immune cells of both myeloid and lymphoid origin. Its synthesis is up-regulated during times of stress and systemic inflammation; however, each cell type that produces IL-10 does so in response to different stimuli, allowing for tight control of its expression. IL-10 exerts effects by binding to the IL-10 receptor (IL-10R), which is a tetramer formed from two distinct subunits, IL-10R1 and IL-10R2. Specifically, IL-10 binds first to the IL10R1 subunit, which then recruits IL-10R2, allowing the receptor complex to form. While IL-10R2 is widely expressed, IL-10R1 expression is confined to leukocytes so that the effects of IL-10 are confined to the immune system. Once receptor ligation occurs, signaling proceeds by the activation of JAK1 and STAT3. In particular, STAT3 in conjunction with IL-10 is absolutely required for the transcription of genes responsible for the anti-inflammatory response (AIR). IL-10 inhibits the secretion of proinflammatory cytokines, including TNF and IL-1, partly through the downregulation of NF-κB and thereby functions as a negative feedback regulator of the inflammatory cascade. In macrophages, IL-10 suppresses the transcription of 20% of all LPS-induced genes. Further, experimental models of inflammation have shown that neutralization of IL-10 increases TNF production and mortality, whereas restitution of circulating IL-10 reduces TNF levels and subsequent deleterious effects. Increased plasma levels of IL-10 also have been associated with mortality and disease severity after traumatic injury.

**Interleukin-12 Family.** Interleukin-12 (IL-12) is unique among the cytokines in being the only heterodimeric cytokine. This family, which includes IL-12, IL-23, IL-27, and IL-35, consists of an α-chain that is structurally similar to the IL-6 cytokine and a β-chain that is similar to the class I receptor for cytokines. The individual IL-12 family members are formed from various combinations of the α and β subunits. Despite the sharing of individual subunits, and the similarities of their receptors, the IL-12 cytokines have different biological functions. IL-12 and IL-23 are considered proinflammatory, stimulatory cytokines with key roles in the development of Th1 and Th17 subsets of helper T cells. In contrast, both IL-27 and IL-35 appear to have immunoregulatory functions that are associated with cytokine inhibition in specific Treg cell populations, particularly the Th17 cells. The effects of these cytokines require specific receptor chains that are also shared among the cytokines. The complexity of signaling is evidenced by the fact that these receptor chains can function both as dimers and as monomers. Ligation of the IL-12 receptors initiate signaling events via the JAK-STAT pathway.

IL-12 synthesis and release is increased during endotoxemia and sepsis. Together with IL-18, it stimulates lymphocytes to increase secretion of IFN-γ. IL-12 also stimulates NK cell cytotoxicity and helper T cell differentiation in this setting. IL-12 release is inhibited by IL-10, and its deficiency inhibits phagocytosis in neutrophils. In experimental models of inflammatory stress, IL-12 neutralization conferred a mortality benefit in mice during endotoxemia.

IL-23, an important IL-12 family member, is a heterodimeric cytokine comprised of a unique p19 subunit linked to a p40 subunit that is common with IL-12. IL-23 appears to be an important survival signal for a specific subset of T helper (Th) cells, Th-17 cells, where it provides a secondary stimulus for Th-17 differentiation. The Th-17 population of cells has recently been demonstrated to expand following traumatic injury and may mark an early phenotypic shift in cell population that has prognostic significance.

**Interleukin-17 Family.** IL-17A (also called IL-17) is the major effector cytokine predominantly produced by a subset of helper T cells, the T helper (Th)-17 cells. It is the founding member of the IL-17 family of cytokines, which includes IL-17A through F. The original described activity for IL-17A was to promote the differentiation of bone marrow progenitor cells along the granulopoietic lineage. Subsequent studies have confirmed that IL-17A is required for increasing circulating neutrophil numbers following stress. In the setting of infection, it is now known that IL-17 acts in conjunction with IL-23 to upregulate granulocyte-colony stimulating factor to promote granulopoiesis. IL-17A has also been shown to regulate the production of specific chemokines in both gut and lung epithelial cells and thus can modulate both the emigration of neutrophils into these tissues and their activation at the site. IL-17 also induces the expression of matrix metalloproteinases, which can make the extracellular matrix more accessible for immune cell recruitment.

IL-17 has the ability to induce the expression of important proinflammatory cytokines, including IL-1β, IL-6, and TNF from macrophages and other cells, and in this way, creates a self-sustaining loop that enhances its own production and strengthens its overall effects. Recent data supports a pivotal role for IL-17 in the posttrauma immune response and has identified associations between increased IL-17 expression associated with Th17- immune response outcomes following blunt trauma.

**Interferons.** Interferons were first recognized as soluble mediators that inhibited viral replication through the activation of specific antiviral genes in infected cells. Interferons are categorized into three types based on receptor specificity and sequence homology. The two major types, type I and type II are discussed in the following section.

Type I interferon family is composed of twenty distinct proteins. These include IFN-α, IFN-β, and IFN-ω, which are structurally related and bind to a common receptor. They are likely produced by most cell types and tissues after the detection of PAMPs/ DAMPs by cytosolic or membrane receptors, including TLR in macrophages and dendritic cells. Type 1 IFNs bind to a heterodimeric transmembrane receptor interferon (α and β) receptor 1, resulting in STAT activation and nuclear translocation. In the nucleus, dimeric STATs recruit an additional
transcriptional factor to form a complex capable of binding to interferon-stimulated response elements, inducing hundreds of IFN-stimulated genes.

Type I interferons influence adaptive immune responses by inducing the maturation of dendritic cells and by stimulating class I MHC expression. IFN-α and IFN-β also enhance immune responses by increasing the cytotoxicity of natural killer cells both in culture and in vivo. Further, they have been implicated in the enhancement of chemokine synthesis, particularly those that recruit myeloid cells and lymphoid cells. Thus, IFN/STAT signaling has important effects on the mobilization, tissue recruitment, and activation of immune cells that compose the inflammatory infiltrate. In contrast, type I IFNs appear to inhibit inflammasome activity, possibly via IL-10.159

The single type II interferon, IFN-γ is secreted by various T cells, NK cells, and antigen-presenting cells in response to bacterial antigens and cytokines. It functions as a key regulator of macrophage activation toward the “M1” proinflammatory phenotype.160 In response to IFN-γ, macrophages produce high levels of proinflammatory cytokines such as IL-1β, IL-12, IL-23, and TNF-α as well as reactive nitrogen and oxygen species. As a consequence, macrophages demonstrate enhanced phagocytosis and killing. In addition, IFN-γ signaling generates additional cytokines and inflammatory factors to sustain inflammation and help to maintain Th1 responses. IFN-γ regulation of macrophage activity may contribute to acute lung injury after major surgery or trauma. A diminished IFN-γ level, as seen in knockout mice, is associated with increased susceptibility to both viral and bacterial pathogens. In addition, IFN-γ promotes differentiation of T cells to the helper T cell subtype 1 and also enhances B-cell isotype switching to immunoglobulin G.158

Receptors of all IFN subtypes belong to the class II of cytokine receptors and utilize JAK-STAT signaling pathway for nuclear signaling, although different STAT activation (e.g., STAT1 and STAT2) is favored by individual receptors.

**Granulocyte-Macrophage Colony-Stimulating Factor/Interleukin-3/Interleukin-5 Family.** Granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-3, and IL-5 compose a small family of cytokines that regulates the growth and activation of immune cells. They are largely the products of activated T cells, which when released, stimulate the behavior of myeloid cells by inducing cytokine expression and antigen presentation. In this way, GM-CSF, IL-3, and IL-5 are able to link the innate and acquired immune responses. With the exception of eosinophils, GM-CSF/IL-3/IL-5 are not essential for constitutive hematopoietic cell function. Rather, they play an important role when the host is stressed by serving to increase the numbers of activated and sensitized cells required to bolster host defense.161 Currently, GM-CSF is in clinical trials for administration to children with an injury severity score >10 following blunt or penetrating trauma. The goal of the study is to provide evidence of the effectiveness of GM-CSF as an agent that can ameliorate posttraumatic immune suppression.

Receptors for the GM-CSF/IL-3/IL-5 family of cytokines are expressed at very low level on hematopoietic cells. Similar to the other cytokine receptors discussed, they are heterodimers composed of a cytokine-specific α subunit and a common β subunit (βc), which is shared by all three receptors and is required for high affinity signal transduction. The binding of cytokine to its receptor activates JAK2-STAT, MAPK, and PI3-K—mediated signaling events to regulate a variety of important cell behaviors, including effector function in mature cells.

**Eicosanoids**

**Omega-6 Polyunsaturated Fat Metabolites: Arachidonic Acid.** Eicosanoids are derived primarily by oxidation of the membrane phospholipid, arachidonic acid (AA), which is relatively abundant in the membrane lipids of inflammatory cells. The major precursor of arachidonic acid is the omega-6 (n-6) polyunsaturated fatty acid (PUFA) linolenic acid, a major source of which is soybean oil. Not surprisingly, an excess of linolenic acid is thought to promote inflammation via increased availability of AA, and in turn, eicosanoids.

Eicosanoids generated from AA include prostaglandins, thromboxanes, and leukotrienes. When a cell senses the proper stimulus, AA is released from phospholipids or diacylglycerols by the enzymatic activation of phospholipase A2 (Fig. 2-6A). Prostanoids, which include all of the prostaglandins (PG) and the thromboxanes, result from the sequential action of the cyclooxygenase (COX) enzyme and terminal synthetases on arachidonic acid. In contrast, arachidonic acid may be oxidized along the lipoxygenase pathway via the central enzyme 5-lipoxygenase, to produce several classes of leukotrienes and lipoxins, which have anti-inflammatory functions. In general, the effects of eicosanoids are mediated via specific receptors, which are members of a superfamily of G protein-coupled receptors.

Eicosanoids are not stored within cells but are instead generated rapidly in response to many proinflammatory stimuli, including hypoxic injury, direct tissue injury, endotoxin (lipopolysaccharide), norepinephrine, vasopressin, angiotensin II, bradykinin, serotonin, acetylcholine, cytokines, and histamine. They have a broad range of physiologic roles, including neurotransmission, and vasomotor regulation. Eicosanoids are also involved in immune cell regulation (Table 2-6), by modulating the intensity and duration of inflammatory responses.

Glucocorticoids, NSAIDs, and leukotriene inhibitors can successfully block the end products of eicosanoid pathways to modulated inflammation.

The production of eicosanoids is cell- and stimulus-specific. Therefore, the signaling events that are initiated will depend on the concentrations and types of eicosanoids generated, as well as the unique complement of receptors expressed by their target cells. For example, prostaglandin E2 (PGE2) suppresses the effector function of macrophages (i.e., phagocytosis and intracellular pathogen killing) via a mechanism that is dependent on increased cAMP levels. PGE2 also modulates chemokine production and enhances local accumulation of regulatory T cells and myeloid-derived suppressor cells. Prostacyclin (PGI2) has an inhibitory effect on Th1 and Th2-mediated immune responses, while enhancing Th17 differentiation and cytokine production. Leukotrienes are potent mediators of capillary leakage as well as leukocyte adherence, neutrophil activation, bronchoconstriction, and vasoconstriction. Leukotriene B4 is synthesized from arachidonic acid in response to acute Ca2+ signaling induced by inflammatory mediators.162 High affinity leukotriene receptors (BLT1) are expressed primarily in leukocytes, including granulocytes, eosinophils, macrophages, and differentiated T cells, whereas the low affinity receptor is expressed in many cell types. Leukotrienes, most notably leukotriene B4 (LTB4), has been implicated in the development of both acute lung injury and acute kidney injury following hemorrhagic shock in animal models.163,164
Omega-3 Polyunsaturated Fat Metabolites: All-cis-5, 8, 11, 14, 17-Eicosapentaenoic Acid. The second major family of PUFAs is the omega-3 fatty acid, α-linolenic acid, which is found primarily in cold water fish. α-Linolenic acid is the metabolic precursor of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Omega-3 PUFAs are also substrates for the cyclooxygenase and lipoxygenase enzymes that produce eicosanoids, but the mediators produced have a different structure from the AA-derived mediators, and this influences their actions (Fig. 2-6B). For example, omega-3 fatty acids are reported to have specific anti-inflammatory effects, including inhibition of NF-κB activity, TNF release from hepatic Kupffer cells, and leukocyte adhesion and migration. Key derivatives of omega-3 PUFAs have also been identified and synthesized. These include resolvins, protectins, and maresins. In a variety of model systems, resolvins have been shown to attenuate the inflammatory phenotypes of a number of immune cells by decreasing neutrophil recruitment, reducing synthesis of pro-inflammatory cytokines and regulating transcription factor activation.165,166

The ratio of dietary omega-6 to omega-3 PUFA is reflected in the membrane composition of various cells, including cells of the immune system, which has potential implications for the inflammatory response. For example, a diet that is rich in omega-6 PUFA will result in cells whose membranes are “omega-6 PUFA rich.” When omega-6 PUFAs are the main plasma membrane lipid available for phospholipase activity, more proinflammatory PUFAs (i.e., 2-series prostaglandins) are generated. Many lipid preparations are soy-based and thus primarily composed of omega-6 fatty acids. These are thought to be “inflammation-enhancing.” Nutritional supplementation with omega-3 fatty acid has the potential to dampen inflammation by shifting the cell membrane composition in favor of omega 3-PUFAs. In a study of surgical patients, preoperative supplementation with omega-3 fatty acid was associated with reduced need for mechanical ventilation, decreased hospital length of stay, and decreased mortality with a good safety profile.167

Plasma Contact System

Complement. Following traumatic injury, there is almost immediate activation of the complement system, which is a major effector mechanism of the innate immune system. The complement system was thought to act initially as the required “first line of defense” for the host against pathogens, by binding and clearing them from the circulation. Recent data indicate...

5-HETE = 5-hydroxyeicosatetraenoic acid; 12-HPETE = 12-hydroperoxyl-HEs6-ketoprostaglandin E₂; LT = leukotriene; PG = prostaglandin; PGE-m = 13,14-dihydro-15-keto-PGE₁ (major urine metabolite of PGE₂); TXA₂ = thromboxane A₂.

that complement is also participates in the elimination of immune complexes as well as damaged and dead cells. In addition, complement is recognized as contributing to mobilization of hematopoietic stem/progenitor cells (HSPC) and lipid metabolism. Although complement activation is typically depicted as a linear process in which parallel pathways are activated, it actually functions more like a central node that is tightly networked with other systems. Then, depending on the activating signal, several initiation and regulatory events act in concert to heighten immune surveillance.

Complement activation proceeds via distinct pathways. Pathway initiation occurs by the binding and activation of a specific recognition unit to its designated ligand. The classical pathway, which is often referred to as “antibody-dependent” is initiated by direct binding of C1q to its common ligands, which include IgM/IgG aggregates. Alternately, C1q can activate complement by binding to soluble pattern recognition molecules such as pentraxins (e.g., C-reactive protein [CRP]). In a series of subsequent activation and amplification steps, the pathway ultimately leads to the generation of C3a and C5a, which are potent anaphylatoxins, in addition to C3b, which acts as an opsonin. An additional product, C5b, initiates the formation of the membrane attack complex, which becomes inserted into cell membrane to form a lytic pore. The subsequent effect of complement signaling is neutrophil activation leading to ROS production, as well as protease and vasoactive mediator secretion. The complement cascade also results in the release of proinflammatory cytokines synergistically with TLR-signaling, which contributes to systemic inflammation and generalized capillary leak following severe injury.

An additional means of complement activation via the lectin pathway is initiated by mannose-binding lectins (MBL) or ficolins, which bind specific carbohydrate structures. This pathway has been speculated to be a major mechanism for complement activation post injury by interactions with matrix fragments and mitochondrial DAMPs. In addition, both low pH and serine proteases of the coagulation cascade may contribute to complement activation. As a consequence, high levels of activated complement components may help to continue to drive systemic inflammation post injury.

Kallikrein-Kinin System. The kallikrein-kinin system, also referred to as the “contact” system, is a group of proteins that contribute to both coagulation and inflammation. Prekallikrein circulates in the plasma bound to high molecular weight kininogen (HK). A variety of stimuli lead to the binding of prekallikrein-HK complex to Hageman factor (factor XII) to initiate the intrinsic clotting cascade. This results in formation of the serine protease kallikrein, which is both proinflammatory and procoagulant. HK is cleaved by kallikrein to form bradykinin (BK).

The kinins (e.g., BK) mediate several physiologic processes, including vasodilation, increased capillary permeability, tissue edema, and neutrophil chemotaxis. They also increase renal vasodilation and consequently reduce renal perfusion pressure. Kinin receptors are members of the rhodopsin family of G-protein-coupled receptors and are located on vascular endothelium and smooth muscle cells. Kinin receptors are rapidly upregulated following TLR4 and cytokine signaling and appear to have important effects on both immune cell behavior and on immune mediators. For example, activation of the kinin receptor, B1, results in increased neutrophil chemotaxis, while increased B2 receptor expression causes activation of arachidonic-prostaglandin pathways. Bradykinin and kallikrein levels are increased following hemorrhagic shock and tissue injury. The degree of elevation in the levels of these mediators has been associated with the magnitude of injury and mortality.
Serotonin

Serotonin is a monoamine neurotransmitter (5-hydroxytryptamine; 5-HT) derived from tryptophan. Serotonin is synthesized by neurons in the CNS as well as by intestinal enterochromaffin cells, which are the major source of plasma 5-HT. Once in the plasma, 5-HT is taken up rapidly into platelets via the serotonin transporter (SERT), where it is either stored in the dense granules in millimolar concentrations or targeted for degradation. It is interesting that the surface expression of SERT on platelets is sensitive to plasma 5-HT levels, which in turn modulates platelet 5-HT content. Receptors for serotonin are widely distributed in the periphery and are found in the GI tract, cardiovascular system, and some immune cells.172 Serotonin is a potent vasoconstrictor and also modulates cardiac inotropy and chronotropy through nonadrenergic cyclic adenosine monophosphate (cAMP) pathways. Serotonin is released at sites of injury, primarily by platelets. Recent work has demonstrated an important role for platelet 5-HT in the local inflammatory response to injury. Using mice that lack the nonneuronal isoform of tryptophan hydroyxylase (Tph1), the rate-limiting step for 5-HT synthesis in the periphery, investigators demonstrated fewer neutrophils rolling on mesenteric venules.173 Tph1−/− mice, in response to an inflammatory stimulus, also showed decreased neutrophil extravasation. Together, these data indicate an important role for nonneuronal 5-HT in neutrophil recruitment to sites of inflammation and injury.

Histamine

Histamine is a short-acting endogenous amine that is widely distributed throughout the body. It is synthesized by histidine decarboxylase (HDC), which decarboxylates the amino acid histidine. Histamine is either rapidly released or stored in neurons, skin, gastric mucosa, mast cells, basophils, and platelets and plasma levels are increased with hemorrhagic shock, trauma, thermal injury, and sepsis.174 Not surprisingly, circulating cytokines can increase immune cell expression of HDC to further contribute to histamine synthesis. There are four histamine receptor (HR) subtypes with varying physiologic roles, but they are all members of the rhodopsin family of G-protein coupled receptors. H1R binding mediates vasodilation, bronchoconstriction, intestinal motility, and myocardial contractility. H1R knockout mice demonstrate significant immunologic defects, including impaired B and T cell responses.

H2R binding is best described for its stimulation of gastric parietal cell acid secretion. However, H2R can also modulate a range of immune system activities, such as mast cell degranulation, antibody synthesis, Th1 cytokine production, and T-cell proliferation. H3R was initially classified as a presynaptic autoreceptor in the peripheral and central nervous system (CNS). However, data using H3R knockout mice demonstrates that it also participates in inflammation in the CNS. H3R knockout mice display increased severity of neuroinflammatory diseases, which correlates with dysregulation of blood-brain barrier permeability and increased expression of macrophage inflammatory protein 2, IFN-inducible protein 10, and CXCR3 by peripheral T cells. H4R is expressed primarily in bone marrow, but it has also been detected in leukocytes, including neutrophils, eosinophils, mast cells, dendritic cells, T cells, and basophils. H4R is emerging as an important modulator of chemotraction and cytokine production in these cells. Thus, it is clear that cells of both the innate and adaptive immune response can be regulated by histamine, which is up-regulated following injury.175

CELLULAR RESPONSE TO INJURY

Cytokine Receptor Families and Their Signaling Pathways

Cytokines act on their target cells by binding to specific membrane receptors. These receptor families have been organized by structural motifs and include type I cytokine receptors, type II cytokine receptors, chemokine receptors, tumor necrosis factor receptors (TNFR), and transforming growth factor receptors (TGFβ). In addition, there are cytokine receptors that belong to the immunoglobulin receptor superfamilies. Several of these receptors have characteristic signaling pathways that are associated with them. These will be briefly reviewed in the following section.

JAK-STAT Signaling

A major subgroup of cytokines, comprising roughly 60 factors, bind to receptors termed type I/II cytokine receptors. Cytokines that bind these receptors include type I IFNs, IFN-γ, many interleukins (e.g., IL-6, IL-10, IL-12, and IL-13), and hematopoietic growth factors. These cytokines play essential roles in the initiation, maintenance, and modulation of innate and adaptive immunity for host defense. All type I/II cytokine receptors selectively associate with the Janus kinases (JAK1, JAK2, JAK3, TYK2), which represent a family of tyrosine kinases that mediate the signal transduction for these receptors. As such, the JAK-STAT signaling pathway is considered a central communication hub for the immune system.176

JAKs are constitutively bound to the cytokine receptors, and on ligand binding and receptor dimerization, activated JAKs phosphorylate the receptor to recruit signal transducer and activator of transcription (STAT) molecules (Fig. 2-7). Activated STAT proteins further dimerize and translocate into the nucleus where they modulate the transcription of target genes. Rather than being a strictly linear pathway, it is likely that individual cytokines activate more than one JAK-STAT combination. The molecular implications for this in terms of cytokine signaling are still being unraveled, but the development of JAK-specific inhibitors (jakinibs) is moving the field forward quickly.177 Interestingly, STAT-DNA binding can be observed within minutes of cytokine binding. STATs have also been shown to modulate gene transcription via epigenetic mechanisms. Thus, JAKs and STATs are central players in the regulation of key immune cell function, by providing a signaling platform for proinflammatory cytokines (IL-6 via JAK1 and STAT3); anti-inflammatory cytokines (IL-10 via STAT3) and integrating signals required for helper and regulatory T cell development and differentiation. The JAK/STAT pathway is inhibited by the action of phosphatase, the export of STATs from the nucleus, as well the interaction of antagonistic proteins.178 JAK/STAT signaling has also been implicated in the secondary muscle wasting that occurs with chronic, persistent inflammation.179

Suppressors of Cytokine Signaling

Suppressor of cytokine signaling (SOCS) molecules are a family of proteins that function as a negative feedback loop for types I and II cytokine receptors by terminating JAK/STAT signaling. There are currently eight family members (SOCS1-7 and CIS [cytokine-inducible SH2-containing protein]) that are associated with cytokine receptor signaling. Pattern recognition receptors, including both TLR and C-type lectin receptors, also activate SOCS.180 Interestingly, induction of SOCs proteins is also achieved through activators of JAK/STAT signaling, creating an inhibitory feedback loop through which cytokines...
Figure 2-7. The Janus kinase/signal transducer and activator of transcription (JAK/STAT) signaling pathway also requires dimerization of monomeric units. STAT molecules possess “docking” sites that allow for STAT dimerization. The STAT complexes translocate into the nucleus and serve as gene transcription factors. JAK/STAT activation occurs in response to cytokines (e.g., interleukin-6) and cell stressors, and has been found to induce cell proliferation and inflammatory function. Intracellular molecules that inhibit STAT function, known as suppressors of cytokine signaling (SOCSs), have been identified. P = phosphate.

SOCS molecules can effectively self-regulate by extinguishing their own signal. SOCS molecules can positively and negatively influence the activation of macrophages and dendritic cells and are crucial for T-cell development and differentiation. All SOCS proteins are able to regulate receptor signaling through the recruitment of proteasomal degradation components to their target proteins, whether the target is a specific receptor or an associated adaptor molecule. Once associated with the SOCS complex, target proteins are readily ubiquinated and targeted for proteasomal degradation. SOCS1 and SOCS3 can also exert an inhibitory effect on JAK-STAT signaling via their N-terminal kinase inhibitory region (KIR) domain, which acts as a pseudo-substrate for JAK.

SOCS3 has been shown to be a positive regulator of TLR4 responses in macrophages via inhibition of IL-6 receptor-mediated STAT3 activation. A deficiency of SOCS activity may render a cell hypersensitive to certain stimuli, such as inflammatory cytokines and growth hormones. Interestingly, in a murine model, SOCS knockout resulted in a lethal phenotype in part because of unregulated interferon signaling.

Chemokine Receptors Are Members of the G-Protein-Coupled Receptor Family All chemokine receptors are members of the G-protein-coupled seven transmembrane family of receptors (GPCR), which is one of the largest and most diverse of the membrane protein families. GPCRs function by detecting a wide spectrum of extracellular signals, including photons, ions, small organic molecules, and entire proteins. After ligand binding, GPCRs undergo conformational changes, causing the recruitment of heterotrimeric G proteins to the cytoplasmic surface (Fig. 2-8). Heterotrimeric G proteins are composed of three subunits, Gα, Gβ, and Gγ, each of which have numerous members, adding to the complexity of the signaling. When signaling, however, G proteins perform functionally as dimers because the signal is communicated either by the Gα subunit or the Gβγ complex. The GPCR family includes the receptors for catecholamines, bradykinins, and leukotrienes, in addition to a variety of other ligands important to the inflammatory response. In general, GPCRs can be classified according to their pharmacological properties into four main families: class A rhodopsin-like, class B secretin-like, class C metabotropic glutamate/pheromone, and frizzled receptors. As noted above, GPCR activation by ligand binding results in an extracellular domain shift, which is then transmitted to cytoplasmic portion of the receptor to facilitate coupling to its principle effector molecules, the heterotrimeric G proteins. Although there are more than 20 known Gα subunits, they have been divided into four families based on sequence similarity, which has served to define both receptor and effector coupling. These include Gαq and Gα12, which signal through the activation (Gαq) or inhibition (Gα12) of adenylate cyclase to increase or decrease cyclic adenosine monophosphate (cAMP) levels, respectively. Increased intracellular cAMP can activate gene transcription through the activity of intracellular signal transducers such as protein kinase A. The Gα subunits also include the Gq pathway, which stimulates phospholipase C-β to produce the intracellular messengers inositol triphosphate and diacylglycerol. Inositol triphosphate triggers the release of calcium from intracellular stores, while diacylglycerol recruits protein kinase C to the plasma membrane for activation. Finally, Gα12/13 appears to act through Rh and Ras-mediated signaling.

Tumor Necrosis Factor Superfamily

Signaling pathway for tumor necrosis factor receptor 1 (TNFR-1) (55 kDa) and TNFR-2 (75 kDa) occurs by the recruitment of several adapter proteins to the intracellular receptor complex. Optimal signaling activity requires receptor trimerization. TNFR-1 initially recruits TNFR-associated death domain (TRADD) and induces apoptosis through the actions of proteolytic enzymes known as caspases, a pathway shared by another receptor, CD95 (Fas). CD95 and TNFR-1 possess similar intracellular sequences known as death domains (DDs), and both recruit the same adapter proteins (Fas-associated death domains [FADDs]) before activating caspase 8. TNFR-1 also induces apoptosis by activating caspase 2 through the recruitment of receptor-interacting protein (RIP). RIP also has a functional component that can initiate nuclear factor κB (NF-κB) and c-Jun activation, both favoring cell survival and proinflammatory functions. TNFR-2 lacks a DD component but recruits adapter proteins known as TNFR-associated factors 1 and 2 (TRAF1, TRAF2) that interact with RIP to mediate NF-κB and c-Jun activation. TRAF2 also recruits additional proteins that are antiapoptotic, known as inhibitors of apoptosis proteins (IAPs).

Transforming Growth Factor-β Family of Receptors

Transforming growth factor-β1 (TGF-β1) is a pleiotropic cytokine expressed by immune cells that has potent immunoregulatory activities. Specifically, recent data indicate that TGF-β is
essential for T cell homeostasis, as mice deficient in TGF-β1 develop a multiorgan autoimmune inflammatory disease and die a few weeks after birth, an effect that is dependent upon the presence of mature T cells. The receptors for TGF-β ligands are the TGF-β superfamily of receptors, which are type I transmembrane proteins that contain intrinsic serine/threonine kinase activity. These receptors comprise two subfamilies, the type I and the type II receptors that are distinguished by the presence of a glycine/serine-rich membrane domain found in the type I receptors. Each TGF-β ligand binds a characteristic combination of type I and type II receptors, both of which are required for signaling. Whether the type I or the type II receptor binds first is ligand-dependent, and the second type I or type II receptor is then recruited to form a heteromeric signaling complex. When TGF-β binds to the TGF-βR, heterodimerization activates the receptor which then directly recruits and activates a receptor-associated Smad (Smad 2 or 3) through phosphorylation. An additional “common” Smad is then recruited. The activated Smad-complex translocates into the nucleus and, with other nuclear cofactors, regulates the transcription of target genes. TGF-β can also induce the rapid activation of the Ras-extracellular signal-regulated kinase (ERK) signaling pathway in addition to other MAPK pathways (JNK, p38MAPK). How does TGF-β inhibit immune responses? One of the most important effects is the suppression of interleukin-2 production by T cells. It also inhibits T cell proliferation. More recently, it was noted that TGF-β can regulate the maturation of differentiated dendritic cells and dendritic cell-mediated T-cell responses. Importantly, TGF-β can induce “alternative activation” macrophages, designated M2 macrophages, which express a wide array of anti-inflammatory molecules, including IL-10 and arginase1.

Figure 2-8. G-protein–coupled receptors are transmembrane proteins. The G-protein receptors respond to ligands such as adrenaline and serotonin. On ligand binding to the receptor (R), the G protein (G) undergoes a conformational change through guanosine triphosphate–guanosine diphosphate conversion and in turn activates the effector (E) component. The E component subsequently activates second messengers. The role of inositol triphosphate (IP₃) is to induce release of calcium from the endoplasmic reticulum (ER). cAMP = cyclic adenosine triphosphate.

**TRANSCRIPTIONAL AND TRANSLATIONAL REGULATION OF THE INJURY RESPONSE**

Transcriptional Events Following Blunt Trauma

Investigators have examined the transcriptional response in circulating leukocytes in a large series of patients who suffered severe blunt trauma. This work identified an overwhelming shift in the leukocyte transcriptome, with more than 80% of the cellular functions and pathways demonstrating some alteration in gene expression. In particular, changes in gene expression for pathways involved in the systemic inflammatory, innate immune, compensatory anti-inflammatory, and adaptive immune responses were simultaneous and marked. Moreover, they occurred rapidly (within 4–12 hours), and were prolonged for days and weeks. When different injuries (i.e., blunt trauma, burn injury, human model of endotoxemia) were compared, the patterns of gene expression were surprisingly similar, suggesting that the stress response to both injury and inflammation is highly conserved and may follow a universal pathway that includes common denominators. Finally, delayed clinical recovery and organ injury were not associated with a distinct pattern of transcriptional response elements. These data describe a new paradigm based on the observation of a rapid and coordinated transcriptional response to severe traumatic injury that involves both the innate and adaptive immune systems. Further, the data support the idea that individuals who are destined to die from their injuries are characterized primarily by the degree and duration of their deregulated inflammatory response rather than a “unique signature” indicative of a “second hit.”

**Transcriptional Regulation of Gene Expression**

Many genes are regulated at the point of DNA transcription and thus influence whether messenger RNA (mRNA) and its subsequent product are expressed (Fig. 2-9). Gene expression relies on the coordinated action of transcription factors and coactivators (i.e., regulatory proteins), which are complexes that bind to highly specific DNA sequences upstream of the target gene known as the promoter region. Enhancer sequences of DNA mediate gene expression, whereas repressor sequences are non-coding regions that bind proteins to inhibit gene expression. For example, nuclear factor kB (NF-kB), one of the best-described transcription factors, has a central role in regulating the gene products expressed after inflammatory stimuli (Fig. 2-10). The NF-kB family of transcription factors is composed of five members that share a common domain. They form numerous homo or heterodimers that are normally retained in the cytosol through...
the inhibitory binding of inhibitor of κB (I-κB). In response to an inflammatory stimulus (e.g., TNF, IL-1, or DAMP) a sequence of intracellular mediator phosphorylation reactions leads to the degradation of I-κB and subsequent release of NF-κB to allow nuclear translocation and the initiation of transcription.

Epigenetic Regulation of Transcription
The DNA access of protein machineries involved in transcription processes is tightly regulated by histones, which are a family of basic proteins that associate with DNA in the nucleus. Histone proteins help to condense the DNA into tightly packed nucleosomes that limit transcription. Emerging evidence indicates that transcriptional activation of many proinflammatory genes requires nucleosome remodeling, a process that is regulated by the histone modifying enzymes. There are at least seven identified chromatin modifications, including acetylation, methylation, phosphorylation, ubiquitinylation, sumoylation, ADP ribosylation, deamination, and proline isomerization. Alteration of chromatin packing in this way makes the DNA more or less accessible for transcription. Recently, the development of chromatin immunoprecipitation (ChIP) coupled to massively parallel DNA sequencing technology (ChIP-Seq) has enabled the mapping of histone modifications in living cells. In this way, it has allowed the identification of the large number of posttranslational histone modifications that are “written” and “erased” by histone-modifying enzymes. The role of histone modifications in the regulation of gene expression is referred to as “epigenetic” control.

The addition of an acetyl group to lysine residues on histones is an epigenetic mark associated with gene activation. These acetyl groups are reversibly maintained by histone acetyltransferases (HATs) and histone deacetylases (HDACs). Hemorrhagic shock has been shown to alter the acetylation of histone proteins via an imbalance of HDAC/HAT activity in the heart, lung, and liver in a tissue-specific pattern. In animal models, postshock administration of the HDAC inhibitor valproic acid improved overall survival. Valproic acid is currently in Phase 2 clinical trials for the treatment of hemorrhagic shock.

Translation Regulation of Inflammatory Gene Expression
Once mRNA transcripts are generated, they can also be regulated by a variety of mechanisms, including (a) splicing, which can cleave mRNA and remove noncoding regions; (b) capping, which modifies the 5' ends of the mRNA sequence to inhibit breakdown by exonucleases; (c) and the addition of a polyadenylated tail, which adds a noncoding sequence to the mRNA, to regulate the half-life of the transcript. Recent data has identified microRNAs (miRNAs) as important translational regulators of gene expression via their binding to partially complementary sequences in the 3'-untranslated region (3'-UTR) of target mRNA transcripts. Binding of miRNA to the
mRNA usually results in gene silencing. MicroRNAs are endogenous, single-stranded RNAs of approximately 22 nucleotides in length that are highly conserved in eukaryotes. MicroRNAs are encoded either singly or can be transcribed in a “polycistronic” clusters and produced by an elaborate expression and processing mechanism. After a primary miRNA transcript is generated by RNA polymerase II or III, it is processed in the nucleus to produce a short hairpin precursor miRNA transcript. The precursor is then transported into the cytoplasm where the final mature miRNA is generated by a protein termed Dicer. The mature double-stranded miRNA is then incorporated into the RNA-induced silencing complex (RISC) in the cytoplasm. Once programmed with a small RNA, RISC can silence targeted genes by one of several distinct mechanisms, working at (a) the level of protein synthesis through translation inhibition, (b) the transcript level through mRNA degradation, or (c) the level of the genome itself through the formation of heterochromatin or by DNA elimination. MiRNAs are involved in TLR signaling in the innate immune system by targeting multiple molecules in the TLR signaling pathways.196 Traumatic brain injury alters serum miRNA profiles that may be useful both as biomarkers for severe TBI and as therapeutic targets.189

**CELL-MEDIATED INFLAMMATORY RESPONSE**

**Neutrophils**

Neutrophils (PMNs) are among the first responders to sites of infection and injury and as such are potent mediators of acute inflammation.191 Mobilization of PMNs from the bone marrow is facilitated by reduction in bone-marrow expression of stromal cell-derived factor-1 (SDF1, also CXCL12) and subsequent expression of both SDF1 and its receptor CXCR4 in target tissues.192 This and other chemotactic mediators induce PMN adherence to the vascular endothelium and promote eventual cell migration into the injured tissue. Early signals for PMN recruitment include endogenous “self” molecules released from damaged tissues, like the DAMPs described previously and also include histone proteins as well as adenosine triphosphate. DAMP molecules can also induce secretion of powerful chemokines such as IL-8 (CXCL8), which can bind to tissue glycosaminoglycans, creating a gradient for PMN migration. PMNs generally have short half-lives (4 to 10 hours). However, inflammatory signals may promote their longevity in target tissues, which can contribute to their potential detrimental effects and subsequent bystander injury. In addition, following sterile trauma, large numbers of immature PMNs are recruited from the bone marrow into the circulation.193

Once primed and activated by inflammatory stimuli, including TNF, IL-1, and microbial pathogens, PMNs are capable of amplifying the inflammatory response as well as releasing toxic effectors such as ROS and proteolytic enzymes into the extracellular space.194 Neutrophils can also dump their granule contents into the extracellular space, and many of these proteins also have important effects on the innate and adaptive immune responses. When highly activated, neutrophils can extrude a meshwork of chromatin fibers, composed of DNA and histones that are decorated with granule contents. Termed neutrophils extracellular traps or NETs, they were first described as effective mechanism whereby neutrophils can immobilize bacteria to facilitate their killing. In the setting of tissue injury, NETs may allow continued presentation of auto-antigens to the host immune system, which can contribute to further tissue injury.195 NETs may also serve to prime T cells, making their threshold for activation lower.

Neutrophils do facilitate the recruitment of monocytes into inflamed tissues. These recruited cells are capable of phagocytosing apoptotic neutrophils to contribute to resolution of the inflammatory response and to promote tissue repair.196 However, at least some portion of the neutrophil population from the injury site is capable of reentering the bloodstream and returning to the bone marrow in a process regulated by chemokine CXC receptor 4.196 Whether reverse migration of neutrophils is beneficial to the host or likely to cause distant organ injury needs further investigation.

**Monocyte/Macrophages**

Monocytes and macrophages are mononuclear phagocytes that play a critical role in inflammation and the injury response.197 Monocytes are leukocytes derived from bone marrow progenitors that circulate in the bloodstream and given the right stimuli, exit the vasculature, and differentiate into monocyte-derived macrophages (e.g., alveolar macrophages or Kupffer cells) upon migrating into appropriate tissues. Macrophages represent the large number of phagocytes that are resident in tissues under resting conditions. Distinct from monocytes, they are derived from embryonic precursors and can repopulate their numbers either by self-renewal or from monocytes derived from the bone marrow.198 Together, monocytes/macrophages are the main effector cells that sense and respond to “danger signals,” primarily through mechanisms that include phagocytosis of cellular debris, release of inflammatory mediators, and recruitment of additional immune cells to injury sites. Moreover, these cells fulfill homeostatic roles beyond host defense by performing important functions in the remodeling of tissues, both during development and in the adult animal. SDF1 has also been implicated in the recruitment of monocytes to sites of tissue injury.199 Importantly, SDF1 forms a complex with HMGB1, a DAMP molecule, which potently increases its chemotactic function. In conjunction with CXCR4, the SDF1-HMGB1 complex induces early monocyte migration into injured tissues, where they play an important role coordinating between innate and adaptive immunity.

In tissues, mononuclear phagocytes are quiescent. However, they respond to external cues (e.g., PAMPs, DAMPs, activated lymphocytes) by changing their phenotype.200 In response to various signals, macrophages may undergo classical M1 activation (stimulated by TLR ligands and IFN-γ) or alternative M2 activation (stimulated by type II cytokines IL-4/IL-13); these states mirror the Th1–Th2 polarization of T cells described in the following section. The M1 phenotype is characterized by the expression of high levels of proinflammatory cytokines, like TNF-α, IL-1 and IL-6, in addition to the synthesis of ROS and RNS. Activated macrophages can also secrete HMGB1 and in this way, can recruit additional macrophages to form a self-activating loop.

In contrast, M2 macrophages are considered to be involved in the promotion of wound repair and the restoration of immune homeostasis through their expression of arginase-1 and IL-10, in addition to a variety of PRR (e.g., scavenging molecules).201 In truth, this classification system is overly simplistic. In fact, macrophages are highly heterogeneous and possess specialized properties that are precisely adapted to individual tissues. Thus, they are likely to also possess individualized response to local tissue damage.197
In a mouse model of hemorrhagic shock/reperfusion, macrophages play a key role in the recruitment of hematopoietic stem cells from the bone marrow by secreting granulocyte-macrophage colony-stimulating factor (GM-CSF) in response to circulating HMGB1.202 In the lung, alveolar macrophages sense DAMPs and extracellular matrix fragments via pattern recognition receptors. In response, they upregulate their expression of TLR4, which primes the cell for response against potential infection.203 At the same time, they release proinflammatory cytokines and ROS, which contribute injury to the alveolar epithelial cells. More recently, data indicate that an imbalance of M1/M2 macrophage populations in the lung contribute to acute lung injury following hemorrhagic shock (HS).204 In this study, investigators demonstrated that HS/resuscitation resulted in a significant decrease in M2 phenotype macrophages, with a delayed increase in M1. Augmenting the M2 population prior to injury lessened the degree of lung injury as assessed histologically.

**Lymphocytes and T-Cell Immunity**

The expression of genes associated with the adaptive immune response is rapidly altered following severe blunt trauma.3 In fact, significant injury is associated with adaptive immune suppression that is characterized by altered cell–mediated immunity. This correlates with both a decrease in the overall number of lymphocytes as well as the balance between the NK and T cell populations.205

CD4+ T cells (helper) play central roles in the function of the immune system through their effects on B cell antibody production, their enhancement of specific T

Reg cell functions, and their assistance with macrophage activation. CD4+ Th cells are functionally divided into subsets, which include Th1, Th2, and Th17 cells. Each of these groups produces specific effector cytokines that are under unique transcriptional control. The specific functions of these cells include the recognition and killing of intracellular pathogens (cellular immunity, Th1 cells); regulation of antibody production (humoral immunity, Th2 cells); and maintenance of mucosal immunity and barrier integrity (Th17 cells). Historically, activities have been characterized as proinflammatory (Th1) and anti-inflammatory (Th2) respectively, as determined by their distinct cytokine signatures (Fig. 2-11). Given the proinflammatory action of IL-17A produced by Th17 cells, they could also be placed in this category. However, it is clear that the Th17 differentiation is more complex and may involve the two distinct phenotypes, a pathogenic phenotype characterized by increased IL-17 production and a more regulatory phenotype in which IL-10 expression is increased.206

Recent evidence suggests that the population of Th17 cells is altered following severe traumatic injury. Mass cytometry by time-of-flight (CyTOF) was used to collect single cell phenotyping data on circulating peripheral blood mononuclear cells from a cohort of severely injured trauma patients.153 The investigators identified an expansion of Th17 cells at all time points following injury and was associated with an increase in the cytokine profile associated with a Th17 phenotype. This supports prior work also demonstrating a robust type 17 immune response early (within the first 24 hours) among nonsurvivors, which also identified a Th17 profile more consistent with “pathogenic” Th17 cells.154

Successful recovery from injury also depends upon a balanced Th1/Th2 response. Following injury, however, there is a reduction in Th1 cell differentiation and cytokine production in favor of an increased population of Th2 lymphocytes and their signaling products. As a consequence, both macrophage activation and proinflammatory cytokine synthesis are inhibited. This imbalance, which may be associated with decreased IL-12 production by activated monocytes/macrophages, has been associated with increased risk of infectious complications following surgery and trauma. What are the systemic mechanisms responsible for this shift? Several events have been implicated, including the direct effect of glucocorticoids on monocyte IL-12 production and T cell IL-12 receptor expression. In addition, sympathoadrenal catecholamine production has also been demonstrated to reduce IL-12 production and proinflammatory cytokine synthesis. Finally, more recent work has implicated circulating immature myeloid cells, termed myeloid-derived suppressor cells, that have immune suppressive activity particularly through their increased expression of arginase.208 These cells have the potential to deplete the microenvironment of arginine, leading to further T cell dysfunction.

**Dendritic Cells**

Recent studies have focused on the cellular components of the immune system in the context of polytrauma. While the
activation of granulocytes and monocyte/macrophages following trauma has been well described, more recent work has demonstrated that dendritic cells (DC) are also activated in response to damage signals, to stimulate both the innate and the adaptive immune responses. Dendritic cells are the most important antigen-presenting cells (APCs) for initiating T-cell responses against protein antigens. Primary “danger signals” that are recognized and activated by DC include debris from damaged or dying cells (e.g., HMGB1, nucleic acids including single nucleotides, and degradation products of the extracellular matrix). DC are frequently referred to as “professional APCs” since their principal function is to capture, process, and present both endogenous and exogenous antigens, which, along with their co-stimulatory molecules, are capable of inducing a primary immune response in resting naïve T lymphocytes. In addition, they have the capacity to further regulate the immune response, both positively and negatively, through the upregulation and release of immunomodulatory molecules such as the chemokine CCL5 (RANTES) and the CXC chemokine CXCL5. Finally, they have been implicated both in the induction and maintenance of immune tolerance as well as in the acquisition of immune memory. There are distinct classes and subsets of DC, which are functionally heterogeneous. Different levels of damage-sensing receptors (e.g., TLR) that dictate a preferential response to DAMPs at that site. While relatively small in number relative to the total leukocyte population, the diverse distribution of DC in virtually all body tissues underlines their potential for a collaborative role in the initiation of the trauma-induced sterile systemic inflammatory response. Data support a phenotypic alteration in these cells following traumatic injury.

Platelets
Platelets are small (2 μm), circulating fragments of a larger cell precursor, the megakaryocyte that is located chiefly within the bone marrow. Although platelets lack a nucleus, they contain both mRNA and a large number of cytoplasmic and surface proteins that equip them for diverse functionality. While their role in hemostasis is well described, more recent work suggest that platelets play a role in both local and systemic inflammatory responses, particularly following ischemia reperfusion. Platelets express functional scavenger and Toll-like receptors (TLR) that are important detectors of both pathogens and “damage”-associated molecules. At the site of tissue injury, complex interactions between platelets, endothelial cells, and circulating leukocytes facilitate cellular activation by the numerous local alarmins and immune mediators. For example, platelet-specific TLR4 activation can cause thrombocytes to bind to and activate neutrophils to extrude their DNA to form neutrophil extracellular traps or NETs, an action that facilitates the capacity of the innate immune system to trap bacteria but also leads to local endothelial cell damage.

Once activated, platelets adopt an initial proinflammatory phenotype by expressing and releasing a variety of adhesion molecules, cytokines, and other immune modulators, including high mobility group 1 protein (HMGB1), interleukin (IL)-1β, and CD40 ligand (CD40L, CD154). However, activated platelets also express large amounts of the immunosuppressive factor, transforming growth factor-β (TGF-β), that has been implicated in Treg cell homeostasis. Recently, in a large animal model of hemorrhage, TGF-β levels were shown to be significantly increased 2 hours post injury, suggesting a possible mechanism for injury-related immune dysfunction. And, while soluble CD154 was not increased following hemorrhage and traumatic brain injury in that study, in a murine model of mesenteric ischemia-reperfusion injury, platelet expression of CD40 and CD154 was linked to remote organ damage.

Mast Cells
Mast cells are important in the primary response to injury because they are located in tissues. TNF release from mast cells has been found to be crucial for neutrophil recruitment and pathogen clearance. Mast cells are also known to play an important role in the anaphylactic response to allergens. On activation from stimuli including allergen binding, infection, and trauma, mast cells produce histamine, cytokines, eicosanoids, proteases, and chemokines, which leads to vasodilatation, capillary leakage, and immunocyte recruitment. Mast cells are thought to be important cosignalng effector cells of the immune system via the release of IL-3, IL-4, IL-5, IL-6, IL-10, IL-13, and IL-14, as well as macrophage migration–inhibiting factor.

ENDOTHELIUM-MEDIATED INJURY
Vascular Endothelium
Under physiologic conditions, the vascular endothelium has important anticoagulant properties and forms a critical barrier to regulate the tissue migration of circulating cells. Following injury, endothelial cells are differentially modulated, resulting in a procoagulant shift that may lead to microthrombosis and organ injury. Recent work has associated postinjury vascular dysfunction (traumatic endotheliopathy) with circulating levels of syndecan-1, a surrogate marker for disruption of the endothelial cell glycocalyx. In a cohort of over 400 severely injured patients, higher syndecan-1 measurements correlated with ISS and plasma catecholamine levels and, ultimately, with mortality in this group. The authors’ hypothesis that the increased disruption of the endothelial glycocalyx results in endothelial cell injury and an altered phenotype resulting in a prothrombotic state that leads to microvascular thrombosis and ensuing organ dysfunction.

Neutrophil-Endothelium Interaction
The regulated inflammatory response to infection facilitates neutrophil and other immunocyte migration to compromised regions through the actions of increased vascular permeability, chemoattractants, and increased endothelial adhesion factors referred to as selectins that are elaborated on cell surfaces (Table 2-7). In response to inflammatory stimuli released from sentinel leukocytes in the tissues, including chemokines, thrombin, leukotrienes, histamine, and TNF, vascular endothelium are activated and their surface protein expression is altered. Within 10 to 20 minutes, prestored reservoirs of the adhesion molecule P-selectin are mobilized to the cell surface where it can mediate neutrophil recruitment (Fig. 2-12). After 2 hours, endothelial cell transcriptional processes provide additional surface expression of E-selectin. E-selectin and P-selectin bind P-selectin glycoprotein ligand-1 (PSGL-1) on the neutrophils to orchestrate the capture and rolling of these leukocytes and allow targeted immunocyte extravasation. Immobilized chemokines on the endothelial surface create a chemotactic gradient to further enhance immune cell recruitment. Also important are secondary leukocyte-leukocyte interactions in which PGSL-1 and L-selectin binding facilitates further leukocyte tethering.

Although there are distinguishable properties among individual selectins in leukocyte rolling, effective rolling most likely involves a significant degree of functional overlap.²¹⁷

Chemokines

Chemokines are a family of small proteins (8–13 kDa) that were first identified through their chemotactic and activating effects on inflammatory cells. They are produced at high levels following nearly all forms of injury in all tissues, where they are key attractants for immune cell extravasation. There are more than 50 different chemokines and 20 chemokine receptors that have been identified. Chemokines are released from endothelial cells, mast cells, platelets, macrophages, and lymphocytes. They are soluble proteins, which when secreted, bind to glycosaminoglycans on the cell surface or in the extracellular matrix. In this way, the chemokines can form a fixed chemical gradient that promotes immune cell exit to target areas. Supporting the idea of their importance in leukocyte recruitment post injury, a subset of chemokines are elevated early following traumatic injury in both survivors and nonsurvivors.²¹⁸

Chemokines are distinguished (in general) from cytokines by virtue of their receptors, which are members of the G-protein–coupled receptor superfamily. Most chemokine receptors recognize more than one chemokine ligand leading to redundancy in chemokine signaling.

The chemokines are subdivided into families based on their amino acid sequences at their N-terminus. For example, CC chemokines contain two N-terminal cysteine residues that are immediately adjacent (hence the “C-C” designation) while the N-terminal cysteines in CXC chemokines are separated by a single amino acid. The CXC chemokines are particularly important for neutrophil (PMN) proinflammatory function. Members of the CXC chemokine family, which include IL-8 (CXCL8), induce neutrophil migration and secretion of cytotoxic granular contents and metabolites. Additional chemokine families include the C- and CX3C-chemokines.²¹⁶

Recent studies support the idea that a subset of chemokines, monokine induced by γ-interferon (MIG), monocyte chemotactic protein 1 (MCP-1), and interferon γ-induced proteins 10 (IP-10) may work in concert to regulate the inflammatory response post injury and may serve as biomarkers for clinical outcome in trauma patients.²¹⁸,²¹⁹ These investigators propose that MIG, MCP-1, and IP-10 function as a “chemokine switch” in which the relative levels of each chemokine may promote its own expression, which suppresses the expression of the other two according to the severity and type of injury.²²⁰ In this way, the authors propose that the balance between these three chemokines, by regulating inflammatory mediator production (e.g., IL-6) may help to correlate with long-term outcomes.
Nitric Oxide

Nitric oxide (NO) was initially known as endothelium-derived relaxing factor due to its effect on vascular smooth muscle. Normal vascular smooth muscle cell relaxation is maintained by a constant output of NO that is regulated in the endothelium by both flow- and receptor-mediated events. NO can also reduce microthrombosis by reducing platelet adhesion and aggregation (Fig. 2-13) and interfering with leukocyte adhesion to the endothelium. NO easily traverses cell membranes and has a short half-life of a few seconds. Endogenous NO formation is derived largely from the action of NO synthase (NOS), which is constitutively expressed in endothelial cells (NOS3, eNOS). Nitric oxide synthase generates NO by catalyzing the degradation of L-arginine to L-citrulline and NO, in the presence of oxygen and NADPH. There are two additional isoforms of NOS: neuronal NOS (NOS1, nNOS) and inducible NOS (iNOS/NOS2), which is expressed in response to cytokines and bacterial products. The vasodilatory effects of NO are mediated by guanylyl cyclase, an enzyme that is found in vascular smooth muscle cells and most other cells of the body. When NO is formed by endothelium, it rapidly diffuses into adjacent cells where it binds to and activates guanylyl cyclase. This enzyme catalyzes the dephosphorylation of GTP to cGMP, which serves as a second messenger for many important cellular functions, particularly for signaling smooth muscle relaxation.

NO synthesis is increased due to the upregulation of iNOS expression in response to proinflammatory mediators such as TNF-α, and IL-1β, as well as microbial products. In fact, studies in both animal models and humans have shown that severe systemic injury and associated hemorrhage produce an early upregulation of iNOS in the liver, lung, spleen, and vascular system. In these circumstances, NO is reported to function as an immunoregulator, which is capable of modulating cytokine production and immune cell development. In particular, the formation of S-nitrosothiols, which can serve as a molecular switch to regulate protein functions, may explain many signaling effects of both iNOS- and eNOS-derived NO in the immune system with regard to T-cell activation and signaling through the T cell receptor. In T cells, NO effects have been implicated in the regulation of the immune synapse as well as the regulation of mitochondrial bioenergetics indicating that NO may play an important role as a link between innate and adaptive immunity.

Inhibition of NO production seemed initially to be a promising strategy in patients with severe sepsis. However, a randomized clinical trial in patients with septic shock determined that treatment with a nonselective NOS inhibitor was associated with an increase in mortality compared with placebo. More recent data utilizing an ovine model of peritonitis demonstrated that selective iNOS inhibition reduced pulmonary artery hypertension and gas exchange impairment and promoted higher visceral organ blood flow, coinciding with lower plasma cytokine concentrations. These data suggest that specific targeting of iNOS in the setting of sepsis may remain a viable therapeutic option.

Recent work using an animal model of traumatic brain injury (TBI) showed that acute TBI results in endothelial dysfunction in a remote vascular bed. The investigators linked the effect of TBI with impaired nitric oxide (NO) production and also with an increase in arterial arginase activity, implicating the depletion of L-arginine by arginase with the decreased NO production.

Prostacyclin

The immune effects of prostacyclin (PGI2) have been discussed previously. The best-described effects of PGI2 are in the cardiovascular system, however, where it is produced by vascular endothelial cells. Prostacyclin is a potent vasodilator that also inhibits platelet aggregation. In the pulmonary system, PGI2 reduces pulmonary blood pressure as well as bronchial hyperresponsiveness. In the kidneys, PGI2 modulates renal blood flow and glomerular filtration rate. Prostacyclin acts through its receptor (a G-protein–coupled receptor of the rhodopsin family) to stimulate the enzyme, adenylate cyclase, allowing the synthesis of cyclic adenosine monophosphate (cAMP) from ATP.
This leads to a cAMP-mediated decrease in intracellular calcium and subsequent smooth muscle relaxation.

During systemic inflammation, endothelial prostacyclin expression is impaired, and thus the endothelium favors a more procoagulant profile. Exogenous prostacyclin analogues, both intravenous and inhaled, have been utilized to improve oxygenation in patients with acute lung injury. Early clinical studies with prostacyclin have delivered some encouraging results. However, a recent study examining the administration of epoprostenol in the setting of severe injury and TBI demonstrated and attenuation of the inflammatory response as measured by serologic markers had no effect on long-term outcome.

**Endothelins**

Endothelins (ETs) are potent mediators of vasoconstriction ET-1, synthesized primarily by endothelial cells, is the most potent endogenous vasoconstrictor, and is estimated to be 10 times more potent than angiotensin II. ET release is upregulated in response to hypotension, LPS, injury, thrombin, TGF-β, IL-1, angiotensin II, vasopressin, catecholamines, and anoxia. ETs release is transcriptionally regulated and occurs at the abluminal side of endothelial cells. Very little is stored in cells; thus, a plasma increase in ET is associated with a marked increase in production. Three endothelin receptors have been identified and function via the G-protein–coupled receptor mechanism. ET_B receptors are associated with increased NO and prostacyclin production, which may serve as a feedback mechanism. Atrial ET_A receptor activation has been associated with increased inotropy and chronotropy. ET-1 infusion is associated with increased pulmonary vascular resistance and pulmonary edema and may contribute to pulmonary abnormalities during sepsis. At low levels, in conjunction with NO, ETs regulate vascular tone. However, at increased concentrations, ETs can disrupt the normal blood flow and distribution and may compromise oxygen delivery to the tissue. Recent data links endothelin expression in pulmonary vasculature with persistent inflammation associated with the development of pulmonary hypertension. Endothelin expression is linked to posttranslational and transcriptional initiation of the unfolded protein response in the affected cells, which results in the production of inflammatory cytokines. Persistent endothelin-1 stimulation may play a role in decreased vascular reactivity that is evident following hemorrhagic shock.

**Platelet Activating Factor**

Phosphotidylcholine is a major lipid constituent of the plasma membrane. Its enzymatic processing by cytosolic phospholipase A 2 (cPLA 2) or calcium-independent phospholipase A 2 (iPLA 2) generates powerful small lipid molecules, which function as intracellular second messengers. One of these is arachidonic acid, the precursor molecule for eicosanoids. Another is platelet-activating factor (PAF). During acute inflammation, PAF is released by immune cells following the activation of PLA2. The receptor for PAF (PAFR), which is constitutively expressed by platelets, leukocytes, and endothelial cells, is a G-protein–coupled receptor of the rhodopsin family. Ligand binding to the PAFR promotes the activation and aggregation of platelets and leukocytes, leukocyte adherence, motility, chemotaxis, and invasion, as well as ROS generation. Additionally, PAF activation of human PMNs induces extrusion of neutrophil extracellular traps (NETs), while platelet activation induces IL-1 via a novel posttranscriptional mechanism. Finally, PAFR ligation results not only in the upregulation of numerous proinflammatory genes, including COX-2, iNOS, and IL-6, but also in the generation of lipid intermediates such as arachidonic acid and lysophospholipids through the
activation of Phospholipase A2. Antagonists to PAF receptors have been experimentally shown to mitigate the effects of ischemia and reperfusion injury. Of note, human sepsis is associated with a reduction in the levels of PAF-acetylhydrolase, which inactivates PAF by removing an acetyl group. Indeed, PAF-acetylhydrolase administration in patients with severe sepsis has yielded some reduction in multiple organ dysfunction and mortality; however, larger phase III clinical trials failed to show benefit.

Natriuretic Peptides

The natriuretic peptides, atrial natriuretic factor (ANP) and brain natriuretic peptide (BNP), are a family of peptides that are released primarily by atrial and ventricular tissue respectively, but are also synthesized by the gut, kidney, brain, adrenal glands, and endothelium. The functionally active forms of the peptides are C-terminal fragments of a larger pro-hormone, and both N- and C-terminal fragments are detectable in the blood (referred to as N-terminal pro-BNP and pro-ANF, respectively). ANF and BNP share most biological properties, including diuretic, natriuretic, vasorelaxant, and cardiac remodeling properties that are affected by signaling through a common receptor: the guanylyl cyclase- (GC-) A receptor. They are both increased in the setting of cardiac disorders; however, evidence indicates some distinctions in the setting of inflammation. For example, elevated proBNP has been detected in septic patients in the absence of myocardial dysfunction and appears to have prognostic significance. More recently, investigators examined changes in N-terminal pro-BNP (NT-proBNP) in a cohort of severely injured patients and determined that persistently high level of NT-proBNP in major trauma patients is indicative of poor outcome.

**SURGICAL METABOLISM**

The initial hours after surgical or traumatic injury are metabolically associated with a reduced total body energy expenditure and urinary nitrogen wasting. With adequate resuscitation and stabilization of the injured patient, a reprioritization of substrate use ensues to preserve vital organ function and to support repair of injured tissue. This phase of recovery also is characterized by functions that participate in the restoration of homeostasis, such as augmented metabolic rates and oxygen consumption, enzymatic preference for readily oxidizable substrates such as glucose, and stimulation of the immune system. Understanding of the collective alterations in amino acid (protein), carbohydrate, and lipid metabolism characteristic of the surgical patient lays the foundation upon which metabolic and nutritional support can be implemented.

**Metabolism During Fasting**

Fuel metabolism during unstressed fasting states has historically served as the standard to which metabolic alterations after acute injury and critical illness are compared (Fig. 2-14). To maintain basal metabolic needs (i.e., at rest and fasting), a normal healthy adult requires approximately 22 to 25 kcal/kg per day drawn from carbohydrate, lipid, and protein sources. This requirement can substantially increase during severe stress states, such as those seen in patients with burn injuries.

In the healthy adult, principal sources of fuel during short-term fasting (<5 days) are derived from muscle protein and body fat, with fat being the most abundant source of energy (Table 2-8). The normal adult body contains 300 to 400 g of carbohydrates in the form of glycogen, of which 75 to 100 g are stored in the liver. Approximately 200 to 250 g of glycogen are stored within skeletal, cardiac, and smooth muscle cells. The greater glycogen stores within the muscle are not readily available for systemic use due to a deficiency in glucose-6-phosphatase but are available for the energy needs of muscle cells. Therefore, in the fasting state, hepatic glycogen stores are rapidly and preferentially depleted, which results in a fall of serum glucose concentration within hours (<16 hours).

During fasting, a healthy 70-kg adult will utilize 180 g of glucose per day to support the metabolism of obligate glycolytic cells such as neurons, leukocytes, erythrocytes, and the renal medullae. Other tissues that use glucose for fuel are skeletal muscle, intestinal mucosa, fetal tissues, and solid tumors.
Glucagon, norepinephrine, vasopressin, and angiotensin II can promote the utilization of glycogen stores (glycogenolysis) during fasting. Although glucagon, epinephrine, and cortisol directly promote gluconeogenesis, epinephrine and cortisol also promote pyruvate shunting to the liver for gluconeogenesis. Precursors for hepatic gluconeogenesis include lactate, glycerol, and amino acids such as alanine and glutamine. Lactate is released by glycolysis within skeletal muscles, as well as by erythrocytes and leukocytes. The recycling of lactate and pyruvate for gluconeogenesis is commonly referred to as the Cori cycle, which can provide up to 40% of plasma glucose during starvation (Fig. 2-15).

Lactate production from skeletal muscle is insufficient to maintain systemic glucose needs during short-term fasting (simple starvation). Therefore, significant amounts of protein must be degraded daily (75 g/d for a 70-kg adult) to provide the amino acid substrate for hepatic gluconeogenesis. Proteolysis during starvation, which results primarily from decreased insulin and increased cortisol release, is associated with elevated urinary nitrogen excretion from the normal 7 to 10 g/d up to 30 g or more per day. Although proteolysis during starvation occurs mainly within skeletal muscles, protein degradation in solid organs also occurs.

In prolonged starvation, systemic proteolysis is reduced to approximately 20 g/d and urinary nitrogen excretion stabilizes at 2 to 5 g/d (Fig. 2-16). This reduction in proteolysis reflects the adaptation by vital organs (e.g., myocardium, brain, renal cortex, and skeletal muscle) to using ketone bodies as their principal fuel source. In extended fasting, ketone bodies become an important fuel source for the brain after 2 days and gradually become the principal fuel source by 24 days.

Enhanced deamination of amino acids for gluconeogenesis during starvation consequently increases renal excretion of ammonium ions. The kidneys also participate in gluconeogenesis by the use of glutamine and glutamate and can become the primary source of gluconeogenesis during prolonged starvation, accounting for up to one-half of systemic glucose production.

**Figure 2-15.** The recycling of peripheral lactate and pyruvate for hepatic gluconeogenesis is accomplished by the Cori cycle. Alanine within skeletal muscles can also be used as a precursor for hepatic gluconeogenesis. During starvation, such fatty acid provides fuel sources for basal hepatic enzymatic function. RBC = red blood cell; WBC = white blood cell.
Fuel utilization in long-term fasting man (70 kg)

Figure 2-16. Fuel utilization in extended starvation. Liver glycogen stores are depleted, and there is adaptive reduction in proteolysis as a source of fuel. The brain uses ketones for fuel. The kidneys become important participants in gluconeogenesis. RBC = red blood cell; WBC = white blood cell.

Lipid stores within adipose tissue provide 40% or more of caloric expenditure during starvation. Energy requirements for basal enzymatic and muscular functions (e.g., gluconeogenesis, neural transmission, and cardiac contraction) are met by the mobilization of triglycerides from adipose tissue. In a resting, fasting, 70-kg person, approximately 160 g of free fatty acids and glycerol can be mobilized from adipose tissue per day. Free fatty acid release is stimulated in part by a reduction in serum insulin levels and in part by the increase in circulating glucagon and catecholamine. Such free fatty acids, like ketone bodies, are used as fuel by tissues such as the heart, kidney (renal cortex), muscle, and liver. The mobilization of lipid stores for energy importantly decreases the rate of glycolysis, gluconeogenesis, and proteolysis, as well as the overall glucose requirement to sustain the host. Furthermore, ketone bodies spare glucose utilization by inhibiting the enzyme pyruvate dehydrogenase.

Metabolism After Injury

Injuries or infections induce unique neuroendocrine and immunologic responses that differentiate injury metabolism from that of unstressed fasting (Fig. 2-17). The magnitude of metabolic expenditure over time appears to be directly proportional to the severity of insult, with thermal injuries and severe infections having the highest energy demands (Fig. 2-18). Of note, the first few days following both sepsis and trauma are not hypermetabolic states, with the more severe insults associated with increased “metabolic hibernation.” However, by week 2, the total energy expenditure increases dramatically.238 The increase

Figure 2-17. Acute injury is associated with significant alterations in substrate utilization. There is enhanced nitrogen loss, indicative of catabolism. Fat remains the primary fuel source under these circumstances. RBC = red blood cell; WBC = white blood cell.
in energy expenditure is mediated in part by sympathetic activation and catecholamine release, which has been replicated by the administration of catecholamines to healthy human subjects. Lipid metabolism after injury is intentionally discussed first because this macronutrient becomes the primary source of energy during stressed states.239

**Lipid Metabolism After Injury**

Lipids are not merely nonprotein, noncarbohydrate fuel sources that minimize protein catabolism in the injured patient. Lipid metabolism potentially influences the structural integrity of cell membranes as well as the immune response during systemic inflammation. Adipose stores within the body (triglycerides) are the predominant energy source (50% to 80%) during critical illness and after injury. Fat mobilization (lipolysis) occurs mainly in response to catecholamine stimulus of the hormone-sensitive triglyceride lipase. Other hormonal influences that potentiate lipolysis include adrenocorticotropic hormone (ACTH), catecholamines, thyroid hormone, cortisol, glucagon, growth hormone release, and reduction in insulin levels.240

**Lipid Absorption.** Although the process is poorly understood, adipose tissue provides fuel for the host in the form of free fatty acids and glycerol during critical illness and injury. Oxidation of 1 g of fat yields approximately 9 kcal of energy. Although the liver is capable of synthesizing triglycerides from carbohydrates and amino acids, dietary and exogenous sources provide the major source of triglycerides. Dietary lipids are not readily absorbable in the gut but require pancreatic lipase and phospholipase within the duodenum to hydrolyze the triglycerides into free fatty acids and monoglycerides. The free fatty acids and monoglycerides are then readily absorbed by gut enterocytes, which resynthesize triglycerides by esterification of the monoglycerides with fatty acyl coenzyme A (acyl-CoA) (Fig. 2-19). Long-chain triglycerides (LCTs), defined as those with 12 carbons or more, generally undergo this process of esterification

---

**Figure 2-18.** Influence of injury severity on resting metabolism (resting energy expenditure, or REE). The shaded area indicates normal REE. (Reproduced with permission from Long CL, Schaffel N, Geiger JW, et al: Metabolic response to injury and illness: estimation of energy and protein needs from indirect calorimetry and nitrogen balance, JPEN J Parenter Enteral Nutr. 1979 Nov-Dec;3(6):452-456.)

**Figure 2-19.** Pancreatic lipase within the small intestinal brush borders hydrolyzes triglycerides into monoglycerides and fatty acids. These components readily diffuse into the gut enterocytes, where they are re-esterified into triglycerides. The resynthesized triglycerides bind carrier proteins to form chylomicrons, which are transported by the lymphatic system. Shorter triglycerides (those with <10 carbon atoms) can bypass this process and directly enter the portal circulation for transport to the liver. CoA = coenzyme A.
and enter the circulation through the lymphatic system as chylomicrons. Shorter fatty acid chains directly enter the portal circulation and are transported to the liver by albumin carriers. Hepatocytes use free fatty acids as a fuel source during stress states but also can synthesize phospholipids or triglycerides (i.e., very-low-density lipoproteins) during fed states. Systemic tissue (e.g., muscle and the heart) can use chylomicrons and triglycerides as fuel by hydrolysis with lipoprotein lipase at the luminal surface of capillary endothelium. Trauma or sepsis suppresses lipoprotein lipase activity in both adipose tissue and muscle, presumably mediated by TNF.

Lipolysis and Fatty Acid Oxidation. Periods of energy demand are accompanied by free fatty acid mobilization from adipose stores. This is mediated by hormonal influences (e.g., catecholamines, ACTH, thyroid hormones, growth hormone, and glucagon) on triglyceride lipase through a cAMP pathway (Fig. 2-20). In adipose tissues, triglyceride lipase hydrolyzes triglycerides into free fatty acids and glycerol. Free fatty acids enter the capillary circulation and are transported by albumin to tissues requiring this fuel source (e.g., heart and skeletal muscle). Insulin inhibits lipolysis and favors triglyceride synthesis by augmenting lipoprotein lipase activity as well as intracellular levels of glycerol-3-phosphate. The use of glycerol for fuel depends on the availability of tissue glycerokinase, which is abundant in the liver and kidneys.

Free fatty acids absorbed by cells conjugate with acyl-CoA within the cytoplasm. The transport of fatty acyl-CoA from the outer mitochondrial membrane across the inner mitochondrial membrane occurs via the carnitine shuttle (Fig. 2-21). Medium-chain triglycerides (MCTs), defined as those 6 to 12 carbons in length, bypass the carnitine shuttle and readily cross the mitochondrial membranes. This accounts in part for the fact that MCTs are more efficiently oxidized than LCTs. Ideally, the rapid oxidation of MCTs makes them less prone to fat deposition, particularly within immune cells and the reticuloendothelial system—a common finding with lipid infusion in parenteral nutrition. However, exclusive use of MCTs as fuel in animal studies has been associated with higher metabolic demands and toxicity, as well as essential fatty acid deficiency.

Within the mitochondria, fatty acyl-CoA undergoes β-oxidation, which produces acetyl-CoA with each pass through the cycle. Each acetyl-CoA molecule subsequently enters the tricarboxylic acid (TCA) cycle for further oxidation to yield 12 adenosine triphosphate (ATP) molecules, carbon dioxide, and water. Excess acetyl-CoA molecules serve as precursors for ketogenesis. Unlike glucose metabolism, oxidation of fatty acids requires proportionally less oxygen and produces less carbon dioxide. This is frequently quantified as the ratio of carbon dioxide produced to oxygen consumed for the reaction and is known as the respiratory quotient (RQ). An RQ of 0.7 would imply greater fatty acid oxidation for fuel, whereas an RQ of 1 indicates greater carbohydrate oxidation (overfeeding). An RQ of 0.85 suggests the oxidation of equal amounts of fatty acids and glucose.

Ketogenesis
Carbohydrate depletion slows the entry of acetyl-CoA into the TCA cycle secondary to depleted TCA intermediates and enzyme activity. Increased lipolysis and reduced systemic carbohydrate availability during starvation diverts excess acetyl-CoA.

**Figure 2-20.** Fat mobilization in adipose tissue. Triglyceride lipase activation by hormonal stimulation of adipose cells occurs through the cyclic adenosine monophosphate (cAMP) pathway. Triglycerides are serially hydrolyzed with resultant free fatty acid (FFA) release at every step. The FFAs diffuse readily into the capillary bed for transport. Tissues with glycerokinase can use glycerol for fuel by forming glycerol-3-phosphate. Glycerol-3-phosphate can esterify with FFAs to form triglycerides or can be used as a precursor for renal and hepatic gluconeogenesis. Skeletal muscle and adipose cells have little glycerokinase and thus do not use glycerol for fuel.
Figure 2-21. Free fatty acids (FFAs) in the cells form fatty acylcoenzyme A (CoA) with CoA. Fatty acyl-CoA cannot enter the inner mitochondrial membrane and requires carnitine as a carrier protein (carnitine shuttle). Once inside the mitochondria, carnitine dissociates, and fatty acyl-CoA is reformed. The carnitine molecule is transported back into the cytosol for reuse. The fatty acyl-CoA undergoes β-oxidation to form acetyl-CoA for entry into the tricarboxylic acid cycle. “R” represents a part of the acyl group of acyl-CoA.

toward hepatic ketogenesis. A number of extrahepatic tissues, but not the liver itself, are capable of using ketones for fuel. Ketosis represents a state in which hepatic ketone production exceeds extrahepatic ketone utilization.

The rate of ketogenesis appears to be inversely related to the severity of injury. Major trauma, severe shock, and sepsis attenuate ketogenesis by increasing insulin levels and by causing rapid tissue oxidation of free fatty acids. Minor injuries and infections are associated with modest elevations in plasma free fatty acid concentrations and ketogenesis. However, in minor stress states ketogenesis does not exceed that in nonstressed starvation.

Carbohydrate Metabolism

Ingested and enteral carbohydrates are primarily digested in the small intestine, where pancreatic and intestinal enzymes reduce the complex carbohydrates to dimeric units. Disaccharidases (e.g., sucrase, lactase, and maltase) within intestinal brush borders dismantle the complex carbohydrates into simple hexose units, which are transported into the intestinal mucosa. Glucose and galactose are primarily absorbed by energy-dependent active transport coupled to the sodium pump. Fructose absorption, however, occurs by concentration-dependent facilitated diffusion. Neither fructose and galactose within the circulation nor exogenous mannitol (for neurologic injury) evokes an insulin response. Intravenous administration of low-dose fructose in fasting humans has been associated with nitrogen conservation, but the clinical utility of fructose administration in human injury remains to be demonstrated.

Discussion of carbohydrate metabolism primarily refers to the utilization of glucose. The oxidation of 1 g of carbohydrate yields 4 kcal, but sugar solutions such as those found in intravenous fluids or parenteral nutrition provide only 3.4 kcal/g of dextrose. In starvation, glucose production occurs at the expense of protein stores (i.e., skeletal muscle). Hence, the primary goal for maintenance glucose administration in surgical patients is to minimize muscle wasting. The exogenous administration of small amounts of glucose (approximately 50 g/d) facilitates fat entry into the TCA cycle and reduces ketosis. Unlike in starvation in healthy subjects, in septic and trauma patients provision of exogenous glucose never has been shown to fully suppress amino acid degradation for gluconeogenesis. This suggests that during periods of stress, other hormonal and proinflammatory mediators have a profound influence on the rate of protein degradation and that some degree of muscle wasting is inevitable. The administration of insulin, however, has been shown to reverse protein catabolism during severe stress by stimulating protein synthesis in skeletal muscles and by inhibiting hepatocyte protein degradation. Insulin also stimulates the incorporation of elemental precursors into nucleic acids in association with RNA synthesis in muscle cells.

In cells, glucose is phosphorylated to form glucose-6-phosphate. Glucose-6-phosphate can be polymerized during glycogenesis or catabolized in glycogenolysis. Glucose catabolism occurs by cleavage to pyruvate or lactate (pyruvic acid pathway) or by decarboxylation to pentoses (pentose shunt) (Fig. 2-22).

Excess glucose from overfeeding, as reflected by RQs >1.0, can result in conditions such as glucosuria, thermogenesis, and conversion to fat (lipogenesis). Excessive glucose administration results in elevated carbon dioxide production, which may be deleterious in patients with suboptimal pulmonary function, as well as hyperglycemia, which may contribute to infectious risk and immune suppression.

Injury and severe infections acutely induce a state of peripheral glucose intolerance, despite ample insulin production at levels several-fold above baseline. This may occur in part due to reduced skeletal muscle pyruvate dehydrogenase activity after injury, which diminishes the conversion of pyruvate to acetyl-CoA and subsequent entry into the TCA cycle. The three-carbon structures (e.g., pyruvate and lactate) that consequently accumulate are shunted to the liver as substrate for gluconeogenesis. Furthermore, regional tissue catheterization and isotope dilution studies have shown an increase in net splanchnic glucose production by 50% to 60% in septic patients and a 50% to 100% increase in burn patients. The increase in plasma glucose levels is proportional to the severity of injury, and this net hepatic gluconeogenic response is believed to be under the influence of glucagon. Unlike in the nonstressed subject, in the hypermetabolic, critically ill patient the hepatic gluconeogenic response to injury or sepsis cannot be suppressed by exogenous or excess glucose administration but rather persists. Hepatic gluconeogenesis, arising primarily from alanine and glutamine catabolism, provides a ready fuel source for tissues such as those of the nervous system, wounds, and erythrocytes, which do not require insulin for glucose transport. The elevated glucose concentrations also provide a necessary energy source for leukocytes in inflamed tissues and in sites of microbial invasions.
The shunting of glucose away from nonessential organs such as skeletal muscle and adipose tissues is mediated by catecholamines. Experiments with infusing catecholamines and glucagon in animals have demonstrated elevated plasma glucose levels as a result of increased hepatic gluconeogenesis and peripheral insulin resistance. Interestingly, although glucocorticoid infusion alone does not increase glucose levels, it does prolong and augment the hyperglycemic effects of catecholamines and glucagon when glucocorticoid is administered concurrently with the latter.

Glycogen stores within skeletal muscles can be mobilized by epinephrine activation of β-adrenergic receptors, GTP-binding proteins (G-proteins), which subsequently activates the second messenger, cAMP. The cAMP activates phosphorylase kinase, which in turn leads to conversion of glycogen to glucose-1-phosphate. Phosphorylase kinase also can be activated by the second messenger, calcium, through the breakdown of phosphatidylinositol phosphate, which is the case in vasopressin-mediated hepatic glycogenolysis.

Protein and Amino Acid Metabolism

The average protein intake in healthy young adults ranges from 80 to 120 g/d, and every 6 g of protein yields approximately 1 g of nitrogen. The degradation of 1 g of protein yields approximately 4 kcal of energy, similar to the yield in carbohydrate metabolism. After injury, the initial systemic proteolysis, mediated primarily by glucocorticoids, increases urinary nitrogen excretion to levels in excess of 30 g/d, which roughly corresponds to a loss in lean body mass of 1.5% per day. An injured individual who does not receive nutrition for 10 days can theoretically lose 15% lean body mass. Therefore, amino acids cannot be considered a long-term fuel reserve, and indeed excessive protein depletion (i.e., 25% to 30% of lean body weight) is not compatible with sustaining life.

Protein catabolism after injury provides substrates for gluconeogenesis and for the synthesis of acute phase proteins. Radiolabeled amino acid incorporation studies and protein analyses confirm that skeletal muscles are preferentially depleted acutely after injury, whereas visceral tissues (e.g., the liver and kidney) remain relatively preserved. The accelerated urea excretion after injury also is associated with the excretion of intracellular elements such as sulfur, phosphorus, potassium, magnesium, and creatinine. Conversely, the rapid utilization of elements such as potassium and magnesium during recovery from major injury may indicate a period of tissue healing.

The net changes in protein catabolism and synthesis correspond to the severity and duration of injury (Fig. 2-23). Elective operations and minor injuries result in lower protein synthesis and moderate protein breakdown. Severe trauma, burns, and sepsis are associated with increased protein catabolism. The rise in urinary nitrogen and negative nitrogen balance can be detected early after injury and peak by 7 days. This state of protein catabolism may persist for as long as 3 to 7 weeks. The patient’s prior physical status and age appear to influence the degree of proteolysis after injury or sepsis. Activation of the ubiquitin-proteosome system in muscle cells is one of the major pathways for protein degradation during acute injury. This response is accentuated by tissue hypoxia, acidosis, insulin resistance, and elevated glucocorticoid levels.

Figure 2-22. Simplified schema of glucose catabolism through the pentose monophosphate pathway or by breakdown into pyruvate. Glucose-6-phosphate becomes an important “crossroad” for glucose metabolism.

7 Nutrition in the Surgical Patient

The goal of nutritional support in the surgical patient is to prevent or reverse the catabolic effects of disease or injury. Although several important biologic parameters have been used to measure the efficacy of nutritional regimens, the ultimate validation for nutritional support in surgical patients should be improvement in clinical outcome and restoration of function.

Estimation of Energy Requirements

All patients admitted to the hospital should have their nutritional status assessed. Overall nutritional assessment is undertaken to
determine the severity of nutrient deficiencies or excess and to aid in predicting nutritional requirements. Pertinent information is obtained by determining the presence of weight loss, chronic illnesses, or dietary habits that influence the quantity and quality of food intake. Social habits predisposing to malnutrition and the use of medications that may influence food intake or urination should also be investigated. Physical examination seeks to assess loss of muscle and adipose tissues, organ dysfunction, and subtle changes in skin, hair, or neuromuscular function reflecting frank or impending nutritional deficiency. Anthropometric data (i.e., weight change, skinfold thickness, and arm circumference muscle area) and biochemical determinations (i.e., creatinine excretion, albumin level, prealbumin level, total lymphocyte count, and transferrin level) may be used to substantiate the patient’s history and physical findings. This information, in conjunction with nutritional risk assessment scoring, can identify patients who may benefit from early nutritional support.

For critically ill and injured patients, validated scoring systems such as the Nutritional Risk Screening (NRS)\textsuperscript{245} or the Nutrition Risk in the Critically Ill (NUTRIC)\textsuperscript{246} score should be employed to make this determination and should be performed in conjunction with assessment of GI tract function and risk of aspiration. Appreciation for the stresses and natural history of the disease process, in combination with nutritional assessment, remains the basis for identifying patients in acute or anticipated need of nutritional support. Currently, specialized enteral nutrition can be avoided in patients who are deemed to be a low nutritional risk with low disease severity for up to one week. However, their nutritional status should be reassessed regularly.\textsuperscript{247}

A fundamental goal of nutritional support is to meet the energy requirements for essential metabolic processes and tissue repair. Failure to provide adequate nonprotein energy sources will lead to consumption of lean tissue stores. The requirement for energy may be measured by indirect calorimetry, which is the gold standard in hospitalized patients and is recommended for the critically ill.\textsuperscript{243} However, the use of indirect calorimetry, particularly in the critically ill patient, may not be available or feasible in this setting. Moreover, it may lead to an overestimation of caloric requirements, which has been associated with increased risk of infectious complications.\textsuperscript{248}

In the absence of indirect calorimetry, resting energy expenditure may also be estimated using a published predictive equation. Adjusted for the type of surgical stress, such equations are suitable for estimating energy requirements in the majority of hospitalized patients. Alternately, a simple weight-based equation of 25 to 30 kcal/kg (using dry or usual body weight) per day is appropriate with a low risk of overfeeding and is consistent with current recommendations from ASPEN (American Society of Parenteral and Enteral Nutrition) in the ICU setting.\textsuperscript{247} After trauma or sepsis, energy substrate demands are increased during the recovery phase and may necessitate greater nonprotein calories beyond calculated energy expenditure (Table 2-9). These additional nonprotein calories provided after injury are usually 1.2 to 2.0 times greater than calculated resting energy expenditure, depending on the type of injury. It is seldom appropriate to exceed this level of nonprotein energy intake during the height of the catabolic phase. Currently, standard enteral nutrition delivers 49% to 53% of calories as carbohydrate and 29% to 30% of calories as fat, which is consistent with current recommendations. For parenteral nutrition, dextrose-containing stock solutions are prepared and available in different concentrations. The percentage of calories that is contributed by dextrose should be determined on a per-patient basis according to the severity of injury/illness and the estimated caloric needs. Lipid emulsions can be included in the total mixture or be administered separately in 10% or 20% solutions with 1.1 kcal/ml and 2 kcal/ml, respectively.

The second objective of nutritional support is to meet the substrate requirements for protein synthesis. Protein nutritional support is especially important for maintaining immune function and lean body mass and is more closely linked to positive outcomes than total caloric intake. Although the mean protein requirement of healthy individuals is defined as 0.8 g/kg per day by the Food and Nutrition Board of the U.S. National Research Council, current recommendations for protein dosing exceed this

![Figure 2-23. The effect of injury severity on nitrogen wasting. (Reproduced with permission from Long CL, Schaffel N, Geiger JW, et al: Metabolic response to injury and illness: estimation of energy and protein needs from indirect calorimetry and nitrogen balance, JPEN J Parenter Enteral Nutr. 1979 Nov-Dec;3(6):452-456.)](image-url)
amount (1.2–2 gm protein/kg per day), especially for the critically ill and injured. Higher protein intake seems to support improved nitrogen balance and high-protein nutritional support is currently recommended for patients with body mass index >30.247

**Vitamins and Minerals**

The requirements for vitamins and essential trace minerals usually can be met easily in the average patient with an uncomplicated postoperative course. Therefore, vitamins usually are not given in the absence of preoperative deficiencies. Patients maintained on elemental diets or parenteral hyperalimentation require complete vitamin and mineral supplementation. Commercial enteral diets contain varying amounts of essential minerals and vitamins. It is necessary to ensure that adequate replacement is available in the diet or by supplementation. Numerous commercial vitamin preparations are available for intravenous or intramuscular use, although most do not contain vitamin K and some do not contain vitamin B12 or folic acid. Supplemental trace minerals may be given intravenously via commercial preparations. Essential fatty acid supplementation also may be necessary, especially in patients with depletion of adipose stores.

**Overfeeding**

Overfeeding usually results from overestimation of caloric needs, as occurs when actual body weight is used to calculate the BEE in patient populations such as the critically ill with significant fluid overload and the obese. Indirect calorimetry can be used to quantify energy requirements but frequently overestimates BEE by 10% to 15% in stressed patients, particularly if they are receiving ventilatory support. In these instances, estimated dry weight should be obtained from preinjury records or family members. Adjusted lean body weight also can be calculated. Overfeeding may contribute to clinical deterioration via increased oxygen consumption, increased carbon dioxide production and prolonged need for ventilatory support, fatty liver, suppression of leukocyte function, hyperglycemia, and increased risk of infection.

**ENTERAL NUTRITION**

**Rationale for Enteral Nutrition**

Enteral nutrition (EN) is preferred over parenteral nutrition (PN) based on the lower cost of enteral feeding and the associated risks of the intravenous route, including vascular access complications.240 Of further consideration are the consequences of gastrointestinal tract disuse, which include diminished soluble IgA production and cytokine production as well as bacterial overgrowth and altered mucosal barrier function and immune defenses. In support of this idea, recent meta-analysis demonstrated a significant reduction in infectious complications in critically ill or injured patients receiving EN when compared to PN as well as ICU length of stay.250 However, no increase in overall survival was noted. While EN is recommended as the first choice for nutritional support in patients who can tolerate it, a recent large trial from Europe comparing early isocaloric EN vs. PN in adult critically ill patients with shock did not reduce mortality or the risk of secondary infections but was associated with a greater risk of digestive complications including intestinal ischemia.251

The benefits of enteral feeding in patients undergoing elective surgery appear to be linked to their preoperative nutritional status. Historical studies comparing postoperative enteral and parenteral nutrition in patients undergoing gastrointestinal surgery have demonstrated reduced infectious complications and acute phase protein production in those fed by the enteral route. Yet prospectively randomized studies of patients with adequate nutritional status (albumin ≥4 g/dL) undergoing gastrointestinal surgery demonstrate no differences in outcome and complications between those administered enteral nutrition and those given maintenance intravenous fluids alone in the initial days after surgery.252

**Early vs. Late Feeding**

Current recommendations support early enteral nutrition (within 48 hours) in critically ill patients, but with a caveat.253 Early “full nutrition” is likely to be harmful and is associated with a higher infection rate. The aim therefore is a caloric target below the actual energy expenditure, with the goal of providing >80% of estimated total energy goals gradually by 3 to 4 days. Early EN may be protective of the enteral epithelial barrier function and help to maintain the diversity of the microbiome. While early caloric limitation seems to benefit the critically ill patient when compared to overfeeding, the restriction likely creates a significant shortfall in protein provision considering the low protein-to-calorie ratio of most enteral products.254

In this regard, it is important to distinguish “permissive underfeeding” in which the total calories provided average 1500 kcal/d with 40 gm/d of protein from hypocaloric nutrition which has the same total calories with 140 gm/d protein. Hypocaloric nutrition is currently recommended for critically ill obese patients, but some investigators argue that this nutritional strategy may also benefit nonobese patients especially during

Caloric adjustments above basal energy expenditure (BEE) in hypermetabolic conditions
the early acute period of critical illness. This recommendation excludes those patients whose pre-ICU weight loss indicate that they are malnourished.

As the patient enters the recovery period of their illness, total protein and caloric requirements are likely to significantly increase. Based on our understanding of starvation, increased extrinsic delivery of both calories and protein are likely to be required during this period.

For patients undergoing elective surgery, healthy patients without malnutrition who are undergoing uncomplicated surgery can tolerate 10 days of partial starvation (i.e., maintenance intravenous fluids only) before any clinically significant protein catabolism occurs. Earlier intervention is likely indicated for patients in whom preoperative protein-calorie malnutrition has been identified. Other clinical scenarios for which the benefits of enteral nutritional support have been substantiated include permanent neurologic impairment, oropharyngeal dysfunction, short-bowel syndrome, and bone marrow transplantation.

Initiation of enteral nutrition should occur as soon as feasible after adequate resuscitation, most readily determined by adequate urine output. The presence of bowel sounds and the passage of flatus or stool are not absolute prerequisites for initiation of enteral nutrition, but in the setting of gastroparesis feedings should be administered distal to the pylorus. Gastric residuals of 200 mL or more in a 4- to 6-hour period or abdominal distention requires cessation of feeding and adjustment of the infusion rate. Concomitant gastric decompression with distal small-bowel feedings may be appropriate in certain patients such as closed-head injury patients with gastroparesis. There is no evidence to support withholding enteral feedings for patients after bowel resection or for those with low-output enterocutaneous fistulas of <500 mL/d. In fact, a recent systematic review of studies of early enteral feeding (within 24 hours of gastrointestinal surgery) showed no effect on anastomotic leak and a reduction in mortality. Early enteral feeding is also associated in reduced incidence of fistula formation in patients with open abdomen. Enteral feeding should also be offered to patients with short-bowel syndrome or clinical malabsorption, but necessary calories, essential minerals, and vitamins should be supplemented using parenteral modalities.

**Intermittent vs. Continuous Enteral Feeding**

Enteral nutrition can be administered either continuously or intermittently; however, the standard choice for critically injured adults is continuous enteral feeding (CEF) due to the lower complication rates. Data also suggest that CEF may promote protein anabolism by inhibiting protein breakdown.

**Enteral Formulas**

For most critically ill patients, the choice of enteral formula will be determined by a number of factors and will include a clinical judgment as to the “best fit” for the patient’s needs. In general, feeding formulas to consider are GI tolerance-promoting, anti-inflammatory, immune-modulating, organ supportive, and standard enteral nutrition. In addition, guidelines from professional nutrition societies identify certain populations of patients who can benefit from formulations with specific pharmaconutrients. For many others, each physician must use his or her own clinical judgment about what formula will best meet the patient’s needs.

The functional status of the gastrointestinal tract determines the type of enteral solutions to be used. Patients with an intact gastrointestinal tract will tolerate complex solutions, but patients who have not been fed via the gastrointestinal tract for prolonged periods are less likely to tolerate complex carbohydrates. In those patients who are having difficulty tolerating standard enteral formulas, peptide- and medium-chain triglyceride-based formulas with probiotics can lessen GI tolerance problems. Additionally, in patients with demonstrated malabsorption issues, such as with inflammatory bowel diseases or short bowel syndrome, current guidelines endorse the provision of hydrolyzed protein formulas to improve absorption. Guidelines have not yet been made with regard to the fiber content of enteral formulas. However, recent evidence indicates that supplementation of enteral formulas with soluble dietary fiber may be beneficial for improving stool consistency in patients suffering from diarrhea.

Factors that influence the choice of enteral formula also include the extent of organ dysfunction (e.g., renal, pulmonary, hepatic, or gastrointestinal), the nutrients needed to restore optimal function and healing, and the cost of specific products. There are still no conclusive data to recommend one category of product over another, and nutritional support committees typically develop the most cost-efficient enteral formulary for the most commonly encountered disease categories within the institution.

As discussed extensively in the first sections of this chapter, surgery and trauma result in a significant “sterile” inflammatory response that impacts for the innate and adaptive immune systems. The provision of immune-modulating nutrients, termed “immunonutrition,” is one mechanism by which the immune response can be supported and an attempt made to lower infectious risk. At present, the best studied of immune-nutrients are glutamine, arginine, and omega-3 PUFAs.

**Immunonutrients.** As discussed extensively in the first sections of this chapter, surgery and trauma result in a significant “sterile” inflammatory response that impacts both the innate and adaptive immune systems. The provision of immune-modulating nutrients, termed “immunonutrition,” is one mechanism by which the immune response can be supported and an attempt made to lower infectious risk. Studies have shown that a variety of nutrients, including amino acids (glutamine and arginine); lipids (omega-3 PUFAs); and micronutrients (e.g., vitamin C and selenium) can provide support to the immune system. While current evidence does not support their use universally, benefit may exist for individual patients. At present, the best studied of immune-nutrients are glutamine, arginine, and omega-3 PUFAs.

**Glutamine** is the most abundant amino acid in the human body, comprising nearly two thirds of the free intracellular amino acid pool. Considered a nonessential amino acid, glutamine is a necessary substrate for nucleotide synthesis in most dividing cells and hence provides a major fuel source for enterocytes. It also serves as an important fuel source for immuneocytes. During stress states, peripheral glutamine stores are rapidly depleted, and the amino acid is preferentially shunted as a fuel source toward the visceral organs and tumors, respectively. These situations create, at least experimentally, a glutamine-depleted environment with potential immune consequences, thus generating interest in both enteral and parenteral glutamine supplementation. However, recently reported data from two large randomized controlled clinical trials in which critically ill patients received glutamine supplementation demonstrated...
Therefore, glutamine supplementation in the critically ill patient is not currently recommended.247

Arginine, also a nonessential amino acid in healthy subjects, first attracted attention for its immunoenhancing properties, wound-healing benefits, and association with improved survival in animal models of sepsis and injury.261 However, arginine can be metabolized to nitric oxide, via nitric oxide synthase (NOS). If NOS is upregulated, with arginine as available substrate, NO production can also increase, which can have a negative impact on the critically ill patient. As with glutamine, the benefits of experimental arginine supplementation during stress states are diverse. In clinical studies involving critically ill and injured patients and patients who have undergone surgery for certain malignancies, enteral administration of arginine has led to net nitrogen retention and protein synthesis, whereas isonitrogenous diets have not. Some of these studies also provide in vitro evidence of enhanced immunocyte function. The clinical utility of arginine supplementation in improving overall patient outcome remains an area of investigation.262

As previously discussed, omega-3 polyunsaturated fatty acids (PUFAs, canola oil, or fish oil) displaces omega-6 fatty acids in cell membranes, which theoretically reduces the pro-inflammatory response from prostaglandin production. Hence, there has been significant interest in reducing the ratio of omega-6 to omega-3. The data regarding supplementation of enteral feedings with fish oil as a source for omega-3 PUFAs has been mixed, however, with no demonstrated improvement in respiratory complications in severe trauma patients and possible benefits in patients with mild sepsis.263

Standard Polymeric Formulas. Most polymeric formulas provide a caloric density from 1 to 2 kcal/mL, and approximately 1500 to 1800 mL are required to meet daily requirements. These compositions provide baseline carbohydrates, protein, electrolytes, water, fat, and fat-soluble vitamins (some do not have vitamin K). These contain no fiber bulk and therefore leave minimum residue. These solutions usually are considered to be the standard or first-line formulas for stable patients with an intact gastrointestinal tract. Normal digestive function is required for this formula.

Fiber-Containing Formulas. Isotonic formulas with fiber contain soluble and insoluble fiber, which is most often soy based. Physiologically, fiber-based solutions delay intestinal transit time and may reduce the incidence of diarrhea compared with nonfiber solutions. It is most beneficial in this regard in patients who have a high number of loose stools.264 Fiber stimulates pancreatic lipase activity and is degraded by gut bacteria into short-chain fatty acids (SCFAs), an important fuel for colonicocytes. Recent data have also demonstrated the expression of SCFA receptors on leukocytes, suggesting that fiber fermentation by the colonic microbiome may indirectly regulate immune cell function. Another potential plus of fiber-containing formulas is the inclusion of prebiotic fibers with the goal of positively impacting bacterial targets in the gut as well as gut barrier function. While there has been limited research in this area to determine the possible impact on clinical outcomes, addition of these fermentable soluble fiber additives is something that should be considered in the ICU patient as a measure that can aid in the maintenance or restoration of a healthy balance of commensal gut bacteria.

Immune-Enhancing Formulas. Immune-enhancing formulas are fortified with special nutrients that are purported to enhance various aspects of immune or solid organ function as previously discussed. Such additives include glutamine, arginine, omega-3 fatty acids, and nucleotides.264 Although several trials have proposed that one or more of these additives reduce surgical complications and improve outcome, these results have not been uniformly corroborated by other trials. The Canadian Clinical Practice Guidelines currently do not recommend the addition of arginine supplements for critically ill patients due to the potential for harm when used in septic patients.265 Omega-3 PUFAs results from the EDEN-Omega study demonstrated that twice-daily enteral supplementation of n-3 fatty acids, γ-linolenic acid, and antioxidants did not improve the primary end point of ventilator-free days or other clinical outcomes in patients with acute lung injury and may be harmful.266 Glutamine supplementation should be strictly guided by the individual patient condition for the reasons discussed previously.

Calorie-Dense Formulas. The primary distinction of calorie-dense formulas is a greater caloric value for the same volume. Most commercial products of this variety provide 1.5 to 2 kcal/mL and therefore are suitable for patients requiring fluid restriction or those unable to tolerate large-volume infusions. As expected, these solutions have higher osmolality than standard formulas and are suitable for intragastric feedings.

High-Protein Formulas/Bariatric Formulas. High-protein formulas are available in isotonic and nonisotonic mixtures and are proposed for critically ill or trauma patients with high protein requirements. These formulas have nonprotein-calorie to nitrogen ratios between 80:1 and 120:1. While some observational studies show improved outcomes with higher protein intakes in critically ill patients, there is limited data from randomized trials that prevents making strong conclusions about the dose of protein in critically ill patients.

As discussed previously, there has been support for high-protein, hypocaloric feeding in obese patients. As such, enteral formulas termed “bariatric formulas” have been developed. As an example, one product has 1 kcal/mL of formula, with 37% of the calories coming from protein. As the evidence for high-protein, hypocaloric feeding is low grade, it is unclear whether clinical outcomes with respect to survival and infectious complications is improved, and more data is required for definitive recommendation.267

Elemental Formulas. Elemental formulas contain predigested nutrients and provide proteins in the form of small peptides. Complex carbohydrates are limited, and fat content, in the form of MCTs and LCTs, is minimal. The primary advantage of such a formula is ease of absorption, but the inherent scarcity of fat, associated vitamins, and trace elements limits its long-term use as a primary source of nutrients. Due to its high osmolality, dilution, or slow infusion rates usually are necessary, particularly in critically ill patients. These formulas have been used frequently in patients with malabsorption, gut impairment, and pancreatitis, but their cost is significantly higher than that of standard formulas. To date, there has been no evidence of their benefit in routine use.

Renal-Failure Formulas. The primary benefits of renal formulas are the lower fluid volume and concentrations of potassium, phosphorus, and magnesium needed to meet daily calorie requirements. This type of formulation almost exclusively
contains essential amino acids and has a high nonprotein-calorie to nitrogen ratio; however, it does not contain trace elements or vitamins. Current guidelines suggest that patients with chronic kidney disease (CKD) who require enteral feeding should be placed on “standard enteral formulations.” Moreover, standard recommendations for both protein and calories support are also recommended.

**Hepatic-Failure Formulas.** Close to 50% of the proteins in hepatic-failure formulas are branched-chain amino acids (e.g., leucine, isoleucine, and valine). The goal of such a formula is to reduce aromatic amino acid levels and increase the levels of branched-chain amino acids, which can potentially reverse encephalopathy in patients with hepatic failure. The use of these formulas is controversial, however, because no clear benefits have been proven by clinical trials. Protein restriction should be avoided in patients with end-stage liver disease because such patients have significant protein energy malnutrition that predisposes them to additional morbidity and mortality. Similar to patients with CKD, standard formulations are recommended initially unless the patient develops hepatic encephalopathy that is refractory to standard treatment. With regard to protein supplementation, data indicate that providing 1.5 gm protein/kg per day improves clinical outcomes in these patients.

**Access for Enteral Nutritional Support**

The available techniques and repertoire for enteral access have provided multiple options for feeding the gut. Presently used methods and preferred indications are summarized in Table 2-10.

**Nasoenteric Tubes.** Nasogastric feeding should be reserved for those with intact mentation and protective laryngeal reflexes to minimize risks of aspiration. Even in intubated patients, nasogastric feedings often can be recovered from tracheal suction. Nasojejunal feedings are associated with fewer pulmonary complications including risk of pneumonia, but access past the pylorus requires greater effort to accomplish. Therefore, routine use of small bowel feedings is preferred in units where small bowel access is readily feasible. Where there may be difficulties obtaining access, small bowel feedings may be considered a priority for those patients at high risk for intolerance to enteral nutrition (e.g., high gastric residuals).

Blind insertion of nasogastric feeding tubes is fraught with misplacement, and air instillation with auscultation is inaccurate for ascertaining proper positioning. Radiographic confirmation is usually required to verify the position of the nasogastric feeding tube.

Several methods have been recommended for the passage of nasoenteric feeding tubes into the small bowel, including use of prokinetic agents, right lateral decubitus positioning, gastric insufflation, tube angulation, and application of clockwise torque. However, the successful placement of feeding tubes by these methods is highly variable and operator dependent. Furthermore, it is time consuming, and success rates for intubation past the duodenum into the jejunum by these methods are <20%. Fluoroscopy-guided intubation past the pylorus has a >90% success rate, and more than half of these intubations result in jejunal placement. Similarly, endoscopy-guided placement past the pylorus has high success rates, but attempts to advance the tube beyond the second portion of the duodenum using a standard gastroduodenoscope is unlikely to be successful.

</tbody>
</table>

Small-bowel feeding is more reliable for delivering nutrition than nasogastric feeding. Furthermore, the risks of aspiration pneumonia can be reduced by 25% with small-bowel feeding compared with nasogastric feeding. The disadvantages of the use of nasoenteric feeding tubes are clogging, kinking, and inadvertent displacement or removal of the tube as well as nasopharyngeal complications. If nasoenteric feeding will be required for longer than 30 days, access should be converted to a percutaneous one.
Percutaneous Endoscopic Gastrostomy. The most common indications for percutaneous endoscopic gastrostomy (PEG) include impaired swallowing mechanisms, oropharyngeal or esophageal obstruction, and major facial trauma. It is frequently used for debilitated patients requiring caloric supplementation, hydration, or frequent medication dosing. It is also appropriate for patients requiring passive gastric decompression. Relative contraindications for PEG placement include ascites, coagulopathy, gastric varices, gastric neoplasm, and lack of a suitable abdominal site. Most tubes are 18F to 28F in size and may be used for 12 to 24 months.

Identification of the PEG site requires endoscopic transillumination of the anterior stomach against the abdominal wall. A 14-gauge angiocatheter is passed through the abdominal wall into the fully insufflated stomach. A guidewire is threaded through the angiocatheter, grasped by snare or forceps, and pulled out through the mouth. The tapered end of the PEG tube is secured to the guidewire and is pulled into position out of the abdominal wall. The PEG tube is secured without tension against the abdominal wall, and many have reported using the tube within hours of placement. It has been the practice of some to connect the PEG tube to a drainage bag for passive decompression for 24 hours before use, allowing more time for the stomach to seal against the peritoneum.

If endoscopy is not available or technical obstacles preclude PEG placement, the interventional radiologist can attempt the procedure percutaneously under fluoroscopic guidance by first insufflating the stomach against the abdominal wall with a nasogastric tube. If this also is unsuccessful, surgical gastrostomy tube placement can be considered, particularly with minimally invasive methods. When surgery is contemplated, it may be wise to consider directly accessing the small bowel for nutrition delivery.

Although PEG tubes enhance nutritional delivery, facilitate nursing care, and are superior to nasogastric tubes, serious complications occur in approximately 3% of patients. These complications include wound infection, necrotizing fasciitis, peritonitis, aspiration, leaks, dislodgment, bowel perforation, enteric fistulas, bleeding, and aspiration pneumonia. For patients with significant gastroparesis or gastric outlet obstruction, feedings through PEG tubes are hazardous. In such cases, the PEG tube can be used for decompression and allow access for converting the PEG tube to a transpyloric feeding tube.

Percutaneous Endoscopic Gastrostomy-Jejunostomy and Direct Percutaneous Endoscopic Jejunostomy. Although gastric bolus feedings are more physiologic, patients who cannot tolerate gastric feedings or who have significant aspiration risks should be fed directly past the pylorus. In the percutaneous endoscopic gastrostomy-jejunostomy (PEG-J) method, a 9F to 12F tube is passed through an existing PEG tube, past the pylorus, and into the duodenum. This can be achieved by endoscopic or fluoroscopic guidance. With weighted catheter tips and guidewires, the tube can be further advanced past the ligament of Treitz. However, the incidence of long-term PEG-J tube malfunction has been reported to be >50% as a result of retrograde tube migration into the stomach, kinking, or clogging.

Direct percutaneous endoscopic jejunostomy (DPEJ) tube placement uses the same techniques as PEG tube placement but requires an enteroscope or colonoscope to reach the jejunum. DPEJ tube malfunctions are probably less frequent than PEG-J tube malfunctions, and kinking or clogging is usually averted by placement of larger-caliber catheters. The success rate of DPEJ tube placement is variable because of the complexity of endoscopic skills required to locate a suitable jejunal site. In such cases where endoscopic means are not feasible, surgical jejunostomy tube placement is more appropriate, especially when minimally invasive techniques are available.

Surgical Gastrostomy and Jejunostomy. For a patient undergoing complex abdominal or trauma surgery, thought should be given during surgery to the possible routes for subsequent nutritional support because laparotomy affords direct access to the stomach or small bowel. The only absolute contraindication to feeding jejunostomy is distal intestinal obstruction. Relative contraindications include severe edema of the intestinal wall, radiation enteritis, inflammatory bowel disease, ascites, severe immunodeficiency, and bowel ischemia. Needle-catheter jejunostomies also can be done with a minimal learning curve. The biggest drawback usually is possible clogging and knotting of the 6F catheter.

Abdominal distention and cramps are common adverse effects of early enteral nutrition. Some have also reported impaired respiratory mechanics as a result of intolerance to enteral feedings. These are mostly correctable by temporarily discontinuing feedings and resuming at a lower infusion rate.

Pneumatosis intestinalis and small-bowel necrosis are infrequent but significant problems in patients receiving jejunal tube feedings. Several contributing factors have been proposed, including the hyperosmolarity of enteral solutions, bacterial overgrowth, fermentation, and accumulation of metabolic breakdown products. The common pathophysiology is believed to be bowel distention and consequent reduction in bowel wall perfusion. Risk factors for these complications include cardiogenic and circulatory shock, vasopressor use, diabetes mellitus, and chronic obstructive pulmonary disease. Therefore, enteral feedings in the critically ill patient should be delayed until adequate resuscitation has been achieved. As alternatives, diluting standard enteral formula, delaying the progression to goal infusion rates, or using monomeric solutions with low osmolality requiring less digestion by the gastrointestinal tract all have been successfully used.

PARENTERAL NUTRITION

Parenteral nutrition is the continuous infusion of a hyperosmolar solution containing carbohydrates, proteins, fat, and other necessary nutrients through an indwelling catheter inserted into the superior vena cava. To obtain the maximum benefit, the calorie to protein ratio must be adequate (at least 100 to 150 kcal/g nitrogen), and both carbohydrates and proteins must be infused simultaneously. When the sources of calories and nitrogen are given at different times, there is a significant decrease in nitrogen utilization. These nutrients can be given in quantities considerably greater than the basic caloric and nitrogen requirements, and this method has proved to be highly successful in achieving growth and development, positive nitrogen balance, and weight gain in a variety of clinical situations. Clinical trials and meta-analysis of studies of parenteral feeding in the perioperative period have suggested that preoperative nutritional support may benefit some surgical patients, particularly those with extensive malnutrition.

Historically, short-term use of parenteral nutrition (PN) in critically ill patients (i.e., duration of <7 days) when enteral
nutrition (EN) may have been instituted was associated with higher rates of infectious complications. It appears, however, that the increased mortality associated with PN may have been associated with excessive caloric delivery. More recent data have shown no mortality difference between EN and PN when caloric delivery was reduced and matched. A recent meta-analysis confirmed this result and noted no increase in infectious complications. That being said, the risk/benefit for PN in the ICU is much smaller and in a patient with low nutritional risk provides little benefit over the first week of hospitalization in the ICU.

**Rationale for Parenteral Nutrition**

The principal indications for parenteral nutrition are malnutrition, sepsis, or surgical or traumatic injury in seriously ill patients for whom use of the gastrointestinal tract for feedings is not possible. Parenteral nutrition should not be used based solely on the medical diagnosis or disease state. Rather, PN use is recommended for those critically ill or injured patients who are at high nutritional risk, when EN is not possible. Alternatively, PN can also be used to supplement EN after 1 week of use if use of EN is unable to meet >60% of energy and protein requirements.

The safe and successful use of parenteral nutrition requires proper selection of patients with specific nutritional needs, experience with the technique, and an awareness of the associated complications. In patients with significant malnutrition, parenteral nutrition can rapidly improve nitrogen balance, which may enhance immune function. Routine postoperative use of parenteral nutrition is not shown to have clinical benefit and may be associated with a significant increase in complication rate. As with enteral nutrition, the fundamental goals are to provide sufficient calories and nitrogen substrate to promote tissue repair and to maintain the integrity or growth of lean tissue mass.

**Total Parenteral Nutrition**

Total parenteral nutrition (TPN), also referred to as central parenteral nutrition, requires access to a large-diameter vein to deliver the entire nutritional requirements of the individual. Dextrose content of the solution is high (15%–25%), and all other macronutrients and micronutrients are deliverable by this route.

**Peripheral Parenteral Nutrition**

The lower osmolarity of the solution used for peripheral parenteral nutrition (PPN), secondary to reduced levels of dextrose (5% to 10%) and protein (3%), allows its administration via peripheral veins. Some nutrients cannot be supplemented because they cannot be concentrated into small volumes. Therefore, PPN is not appropriate for repleting patients with severe malnutrition. It can be considered if central routes are not available or if supplemental nutritional support is required. Typically, PPN is used for short periods (<2 weeks). Beyond this time, TPN should be instituted.

**Initiation of Parenteral Nutrition**

The basic solution for parenteral nutrition contains a final concentration of 15% to 25% dextrose and 3% to 5% crystalline amino acids. The solutions usually are prepared in sterile conditions in the pharmacy from commercially available kits containing the component solutions and transfer apparatus. Preparation in the pharmacy under laminar flow hoods reduces the incidence of bacterial contamination of the solution. Proper preparation with suitable quality control is absolutely essential to avoid septic complications.

The proper provision of electrolytes and amino acids must take into account routes of fluid and electrolyte loss, renal function, metabolic rate, cardiac function, and the underlying disease state.

Intravenous vitamin preparations also should be added to parenteral formulas. Vitamin deficiencies are rare occurrences if such preparations are used. In addition, because vitamin K is not part of any commercially prepared vitamin solution, it should be supplemented on a weekly basis. During prolonged parenteral nutrition with fat-free solutions, essential fatty acid deficiency may become clinically apparent and manifests as dry, scaly dermatitis and loss of hair. The syndrome may be prevented by periodic infusion of a fat emulsion at a rate equivalent to 10% to 15% of total calories. Essential trace minerals may be required after prolonged TPN and may be supplied by direct addition of commercial preparations. The most frequent presentation of trace mineral deficiencies is the eczematoid rash developing both diffusely and at intertriginous areas in zinc-deficient patients. Other rare trace mineral deficiencies include a microcytic anemia associated with copper deficiency, and glucose intolerance presumably related to chromium deficiency. The latter complications are seldom seen except in patients receiving parenteral nutrition for extended periods. The daily administration of commercially available trace mineral supplements will obviate most such problems.

Depending on fluid and nitrogen tolerance, parenteral nutrition solutions generally can be increased over 2 to 3 days toward the desired infusion rate. Current recommendations suggest that hypocaloric nutrition (high protein with lower caloric dosing) be considered in the critically ill or injured over the first week in the ICU. The suggested target dose is <20 kcal/kg per day or <80% of estimated caloric needs with adequate protein (>1.2 g/kg per day). This strategy is suggested to minimize risk of both hyperglycemia and insulin resistance, which may reduce infectious complications. Insulin may be supplemented as necessary to ensure glucose tolerance, with a targeted blood glucose range of 140 or 150 to 180 mg/dL for the general ICU population. Administration of additional intravenous fluids and electrolytes may occasionally be necessary in patients with persistently high fluid losses.

The patient should be carefully monitored for development of electrolyte, volume, acid-base, and septic complications. Vital signs and urinary output should be measured regularly, and the patient should be weighed regularly. Frequent adjustments of the volume and composition of the solutions are necessary during the course of therapy. Samples for measurement of electrolytes are drawn daily until levels are stable and every 2 or 3 days thereafter. Blood counts, blood urea nitrogen level, levels of liver function indicators, and phosphate and magnesium levels are determined at least weekly.

The urine or capillary blood glucose level is checked every 6 hours, and serum glucose concentration is checked at least once daily during the first few days of the infusion and at frequent intervals thereafter. Relative glucose intolerance, which often manifests as glycosuria, may occur after initiation of parenteral nutrition. If blood glucose levels remain elevated or glycosuria persists, the dextrose concentration may be decreased, the infusion rate slowed, or regular insulin added to each bottle. The rise in blood glucose concentration observed after initiating parenteral nutrition may be temporary, as the normal pancreas...
increases its output of insulin in response to the continuous carbohydrate infusion. In patients with diabetes mellitus, additional insulin may be required.

Potassium is essential to achieve positive nitrogen balance and replace depleted intracellular stores. In addition, a significant shift of potassium ion from the extracellular to the intracellular space may take place because of the large glucose infusion, with resultant hypokalemia, metabolic alkalosis, and poor glucose utilization. In some cases, as much as 240 mEq of potassium ion daily may be required. Hypokalemia may cause glycemic increases, which would be treated with potassium, not insulin. Thus, before giving insulin, the serum potassium level must be checked to avoid exacerbating the hypokalemia.

Patients with insulin-dependent diabetes mellitus may exhibit wide fluctuations in blood glucose levels while receiving parenteral nutrition. This may require protocol-driven intravenous insulin therapy. In addition, partial replacement of dextrose calories with lipid emulsions may alleviate these problems in selected patients.

Lipid emulsions derived from soybean or safflower oils are widely used as an adjunctive nutrient to prevent the development of essential fatty acid deficiency, although recent data support reducing the overall omega-6 PUFA load in favor of omega-3 PUFA or MCT. Current recommendations are to limit intravenous fat emulsion infusion over the first week of hospitalization to a maximum of 100 g per week delivered in two divided doses. This is based on standard emulsions that are soy-based. As data is acquired for omega-3 PUFA-based emulsions, including fish-oil or olive-oil based emulsions, these recommendations may alter.

The delivery of parenteral nutrition requires central intravenous access. Temporary or short-term access can be achieved with a 16-gauge percutaneous catheter inserted into a subclavian or internal jugular vein and threaded into the superior vena cava. More permanent access with the intention of providing long-term or home parenteral nutrition can be achieved by placement of a catheter with a subcutaneous port for access by tunneling a catheter with a substantial subcutaneous length or threading a long catheter through the basilic or cephalic vein into the superior vena cava.

Complications of Parenteral Nutrition

Technical Complications. One of the more common and serious complications associated with long-term parenteral feeding is sepsis secondary to contamination of the central venous catheter. Contamination of solutions should also be considered, but it is rare when proper pharmacy protocols have been followed. Central line-associated blood stream infections (CLABSI) occur as a consequence of hematogenous seeding of the catheter with bacteria. One of the earliest signs of systemic sepsis from CVA-BSI may be the sudden development of glucose intolerance (with or without temperature increase) in a patient who previously has been maintained on parenteral alimentation without difficulty. When this occurs, or if high fever (> 38.5°C [101.3°F]) develops without obvious cause, a diligent search for a potential septic focus is indicated. Other causes of fever should also be investigated. If fever persists, the infusion catheter should be removed and submitted for culture. If the catheter is the cause of the fever, removal of the infectious source is usually followed by rapid defervescence. Some centers are now replacing catheters considered at low risk for infection over a guidewire. However, if blood cultures are positive and the catheter tip is also positive, then the catheter should be removed and placed in a new site. Should evidence of infection persist over 24 to 48 hours without a definable source, the catheter should be replaced into the opposite subclavian vein or into one of the internal jugular veins, and the infusion should be restarted.

The use of multilumen catheters may be associated with a slightly increased risk of infection. This is most likely associated with greater catheter manipulation and intensive use. The rate of catheter infection is highest for those placed in the femoral vein, lower for those in the jugular vein, and lowest for those in the subclavian vein. When catheters are indwelling for <3 days, infection risks are negligible. If indwelling time is 3 to 7 days, the infection risk is 3% to 5%. Indwelling times of >7 days are associated with a catheter infection risk of 5% to 10%. Strict adherence to barrier precautions also reduces the rate of infection as can the implementation of procedure checklists to ensure compliance with evidence-based guidelines shown to reduce infectious risk.

Other complications related to catheter placement include the development of pneumothorax, hemothorax, hydrothorax, subclavian artery injury, thoracic duct injury, cardiac arrhythmia, air embolism, catheter embolism, and cardiac perforation with tamponade. All of these complications may be avoided by strict adherence to proper techniques. Further, the use of ultrasonographic guidance during CV line placement has been demonstrated to significantly decrease the failure rate, complication rate, and number of attempts required for successful access.

Metabolic Complications. Hyperglycemia may develop with normal rates of infusion in patients with impaired glucose tolerance or in any patient if the hypertonic solutions are administered too rapidly. This is a particularly common complication in patients with latent diabetes and in patients subjected to severe surgical stress or trauma. Treatment of the condition consists of volume replacement with correction of electrolyte abnormalities and the administration of insulin. This complication can be avoided with careful attention to daily fluid balance and frequent monitoring of blood glucose levels and serum electrolytes.

Increasing experience has emphasized the importance of not overfeeding the parenterally nourished patient. This is particularly true for the depleted patient in whom excess calories infusion may result in carbon dioxide retention and respiratory insufficiency. In addition, excess feeding also has been related to the development of hepatic steatosis or marked glycogen deposition in selected patients. Cholestasis and formation of gallstones are common in patients receiving long-term parenteral nutrition. Mild but transient abnormalities of serum transaminase, alkaline phosphatase, and bilirubin levels occur in many parenterally nourished patients. Failure of the liver enzymes to plateau or return to normal over 7 to 14 days should suggest another etiology.

Intestinal Atrophy. Lack of intestinal stimulation is associated with intestinal mucosal atrophy, diminished villous height, bacterial overgrowth, reduced lymphoid tissue size, reduced immunoglobulin A production, and impaired gut immunity. The full clinical implications of these changes are not well realized, although bacterial translocation has been demonstrated in animal models. The most efficacious method to prevent these changes is to provide at least some nutrients enterally. In patients requiring TPN, it may be feasible to infuse small amounts of feedings via the gastrointestinal tract.

INTRODUCTION
Fluid and electrolyte management is paramount to the care of the surgical patient. Changes in both fluid volume and electrolyte composition occur preoperatively, intraoperatively, and postoperatively, as well as in response to trauma and sepsis. The sections that follow review the normal anatomy of body fluids, electrolyte composition and concentration abnormalities and treatments, common metabolic derangements, and alternative resuscitative fluids. These concepts are then discussed in relationship to management of specific surgical patients and their commonly encountered fluid and electrolyte abnormalities.

BODY FLUIDS

Total Body Water
Water constitutes approximately 50% to 60% of total body weight. The relationship between total body weight and total body water (TBW) is relatively constant for an individual and is primarily a reflection of body fat. Lean tissues such as muscle and solid organs have higher water content than fat and bone. As a result, young, lean males have a higher proportion of body weight as water than elderly or obese individuals. In an average young adult male, TBW accounts for 60% of total body weight, whereas in an average young adult female, it is 50%. The lower percentage of TBW in females correlates with a higher percentage of adipose tissue and lower percentage of muscle mass in most. Estimates of percentage of TBW should be adjusted downward approximately 10% to 20% for obese individuals and upward by 10% for malnourished individuals. The highest percentage of TBW is found in newborns, with approximately 80% of their total body weight comprised of water. This decreases to approximately 65% by 1 year of age and thereafter remains fairly constant.

Preoperative Fluid Therapy / 96
Intraoperative Fluid Therapy / 97

TBW is divided into three functional fluid compartments: plasma, extravascular interstitial fluid, and intracellular fluid (Fig. 3-1). The extracellular fluids (ECF), plasma, and interstitial fluid together compose about one-third of the TBW, and the intracellular compartment composes the remaining two thirds. The extracellular water composes 20% of the total body weight and is divided between plasma (5% of body weight) and interstitial fluid (15% of body weight). Intracellular water makes up approximately 40% of an individual’s total body weight, with the largest proportion in the skeletal muscle mass.

Composition of Fluid Compartments
The normal chemical composition of the body fluid compartments is shown in Fig. 3-2. The ECF compartment is balanced between sodium, the principal cation, and chloride and bicarbonate, the principal anions. The intracellular fluid compartment is composed primarily of the cations potassium and magnesium, the anions phosphate and sulfate, and proteins. The concentration gradient between compartments is maintained by adenosine triphosphate–driven sodium-potassium pumps located within the cell membranes. The composition of the plasma and interstitial fluid differs only slightly in ionic composition. The slightly higher protein content (organic anions) in plasma results in a higher plasma cation composition relative to the interstitial fluid, as explained by the Gibbs-Donnan equilibrium equation. Proteins add to the osmolality of the plasma and contribute to the balance of forces that determine fluid balance across the capillary endothelium. Although the movement of ions and proteins between the various fluid compartments is restricted, water is freely diffusible. Water is distributed evenly throughout all fluid compartments of the body so that a given volume of water increases the volume of any one compartment.
Key Points

1. Proper management of fluid and electrolytes facilitates crucial homeostasis that allows cardiovascular perfusion, organ system function, and cellular mechanisms to respond to surgical illness.

2. Knowledge of the compartmentalization of body fluids forms the basis for understanding pathologic shifts in these fluid spaces in disease states. Although difficult to quantify, a deficiency in the functional extracellular fluid compartment often requires resuscitation with isotonic fluids in surgical and trauma patients.

3. Alterations in the concentration of serum sodium have profound effects on cellular function due to water shifts between the intracellular and extracellular spaces.

4. Different rates of compensation between respiratory and metabolic components of acid-base homeostasis require frequent laboratory reassessment during therapy.

5. Although active investigation continues, alternative resuscitation fluids have limited clinical utility, other than the correction of specific electrolyte abnormalities.

6. Enhanced recovery after surgery (ERAS) protocols have markedly changed perioperative fluid management and are being used more frequently. ERAS minimizes perioperative fluid administration and focuses on early enteral intake to reduce morbidity associated with IV fluid administration.

7. Most acute surgical illnesses are accompanied by some degree of volume loss or redistribution. Consequently, isotonic fluid administration is the most common initial intravenous fluid strategy, while attention is being given to alterations in concentration and composition.

8. Some surgical patients with neurologic illness, malnutrition, acute renal failure, or cancer require special attention to well-defined, disease-specific abnormalities in fluid and electrolyte status.

relatively little. Sodium, however, is confined to the ECF compartment, and because of its osmotic and electrical properties, it remains associated with water. Therefore, sodium-containing fluids are distributed throughout the ECF and add to the volume of both the intravascular and interstitial spaces. Although the administration of sodium-containing fluids expands the intravascular volume, it also expands the interstitial space by approximately three times as much as the plasma.

Osmotic Pressure

The physiologic activity of electrolytes in solution depends on the number of particles per unit volume (millimoles per liter, or mmol/L), the number of electric charges per unit volume (milliequivalents per liter, or mEq/L), and the number of osmotically active ions per unit volume (milliosmoles per liter, or mOsm/L). The concentration of electrolytes usually is expressed in terms of the chemical combining activity, or equivalents. An equivalent of an ion is its atomic weight expressed in grams divided by the valence:

\[
\text{Equivalent} = \frac{\text{atomic weight (g)}}{\text{valence}}
\]

For univalent ions such as sodium, 1 mEq is same as 1 mmol. For divalent ions such as magnesium, 1 mmol equals 2 mEq. The number of milliequivalents of cations must be balanced by the same number of milliequivalents of anions. However, the expression of molar equivalents alone does not allow a physiologic comparison of solutes in a solution.

The movement of water across a cell membrane depends primarily on osmosis. To achieve osmotic equilibrium, water moves across a semipermeable membrane to equalize the concentration on both sides. This movement is determined by the concentration of the solutes on each side of the membrane. Osmotic pressure is measured in units of osmoles (osm) or milliosmoles (mOsm) that refer to the actual number of osmotically active particles. For example, 1 mmol of sodium chloride contributes to 2 mOsm (one from sodium and one from chloride). The principal determinants of osmolality are the concentrations of sodium, glucose, and urea (blood urea nitrogen, or BUN):

\[
\text{Calculated serum osmolality} = 2 \times \text{sodium} + \left( \frac{\text{glucose}}{18} \right) + \left( \frac{\text{BUN}}{2.8} \right)
\]

The osmolality of the intracellular and extracellular fluids is maintained between 290 and 310 mOsm in each compartment. Because cell membranes are permeable to water, any...
change in osmotic pressure in one compartment is accompanied by a redistribution of water until the effective osmotic pressure between compartments is equal. For practical clinical purposes, most significant gains and losses of body fluid are directly from the extracellular compartment.

**BODY FLUID CHANGES**

**Normal Exchange of Fluid and Electrolytes**

The healthy person consumes an average of 2000 mL of water per day, approximately 75% from oral intake and the rest extracted from solid foods. Daily water losses include 800 to 1200 mL in urine, 250 mL in stool, and 600 mL in insensible losses. Insensible losses of water occur through both the skin (75%) and lungs (25%) and can be increased by such factors as fever, hypermetabolism, and hyperventilation. Sensible water losses such as sweating or pathologic loss of gastrointestinal (GI) fluids vary widely, but these include the loss of electrolytes as well as water (Table 3-1). To clear the products of metabolism, the kidneys must excrete a minimum of 500 to 800 mL of urine per day, regardless of the amount of oral intake.

The typical individual consumes 3 to 5 g of dietary salt per day, with the balance maintained by the kidneys. With hypo- or hypovolemia, sodium excretion can be reduced to as little as 1 mEq/d or maximized to as much as 5000 mEq/d to achieve balance except in people with salt-wasting kidneys. Sweat is hypotonic, and sweating usually results in only a small sodium loss. GI losses are isotonic to slightly hypotonic and contribute little to net gain or loss of free water when measured and appropriately replaced by isotonic salt solutions.

**Classification of Body Fluid Changes**

Disorders in fluid balance may be classified into three general categories: disturbances in (a) volume, (b) concentration, and (c) composition. Although each of these may occur simultaneously, each is a separate entity with unique mechanisms demanding individual correction. Isotonic gain or loss of salt solution results in extracellular volume changes, with little impact on intracellular fluid volume. If free water is added or lost from the ECF, water will pass between the ECF and intracellular fluid until solute concentration or osmolarity is equalized between the compartments. Unlike with sodium, the concentration of most other ions in the ECF can be altered without significant change in the total number of osmotically active particles, producing only a compositional change.

**Disturbances in Fluid Balance**

Extracellular volume deficit is the most common fluid disorder in surgical patients and can be either acute or chronic. Acute volume deficit is associated with cardiovascular and central nervous system signs, whereas chronic deficits display tissue signs, such as a decrease in skin turgor and sunken eyes, in addition to cardiovascular and central nervous system signs (Table 3-2). Laboratory examination may reveal an elevated BUN level if the deficit is severe enough to reduce glomerular filtration and hemoconcentration. Urine osmolality usually will be higher than serum osmolality, and urine sodium will be low, typically <20 mEq/L. Serum sodium concentration does not necessarily reflect volume status and therefore may be high, normal, or low when a volume deficit is present. The most common cause of volume deficit in surgical patients is a loss of GI fluids (Table 3-3) from nasogastric suction, vomiting, diarrhea, or...
enterocutaneous fistula. In addition, sequestration secondary to soft tissue injuries, burns, and intra-abdominal processes such as peritonitis, obstruction, or prolonged surgery can also lead to massive volume deficits.

Extracellular volume excess may be iatrogenic or secondary to renal dysfunction, congestive heart failure, or cirrhosis. Both plasma and interstitial volumes usually are increased. Symptoms are primarily pulmonary and cardiovascular (see Table 3-2). In fit patients, edema and hyperdynamic circulation are common and well tolerated. However, the elderly and patients with cardiac disease may quickly develop congestive heart failure and pulmonary edema in response to only a moderate volume excess.

### Volume Control

Volume changes are sensed by both osmoreceptors and baroreceptors. Osmoreceptors are specialized sensors that detect even small changes in fluid osmolality and drive changes in thirst and diuresis through the kidneys. For example, when plasma osmolality is increased, thirst is stimulated and water consumption increases, although the exact cell mechanism is not known. Additionally, the hypothalamus is stimulated to secrete vasopressin, which increases water reabsorption in the kidneys. Together, these two mechanisms return the plasma osmolality to normal. Baroreceptors also modulate volume in response to changes in pressure and circulating volume through specialized pressure sensors located in the aortic arch and carotid sinuses. Baroreceptor responses are both neural, through sympathetic and parasympathetic pathways, and hormonal, through substances including renin-angiotensin, aldosterone, atrial natriuretic peptide, and renal prostaglandins. The net result of alterations in renal sodium excretion and free water reabsorption is restoration of volume to the normal state.

### Concentration Changes

Changes in serum sodium concentration are inversely proportional to TBW. Therefore, abnormalities in TBW are reflected by abnormalities in serum sodium levels.

**Hyponatremia.** A low serum sodium level occurs when there is an excess of extracellular water relative to sodium. Extracellular volume can be high, normal, or low (Fig. 3-3). In most cases of hyponatremia, sodium concentration is decreased as a consequence of either sodium depletion or dilution. Dilutional hyponatremia frequently results from excess extracellular water and therefore is associated with a high extracellular volume status. Excessive oral water intake or iatrogenic intravenous (IV) excess free water administration can cause hyponatremia. Postoperative patients are particularly prone to increased secretion of antidiuretic hormone (ADH), which increases reabsorption of water.
of free water from the kidneys with subsequent volume expansion and hyponatremia. This is usually self-limiting in that both hyponatremia and volume expansion decrease ADH secretion. Additionally, a number of drugs can cause water retention and subsequent hyponatremia, such as antipsychotics and tricyclic antidepressants as well as angiotensin-converting enzyme inhibitors. The elderly are particularly susceptible to drug-induced hyponatremia. Physical signs of volume overload usually are absent, and laboratory evaluation reveals hemodilution. Depletional causes of hyponatremia are associated with either a decreased intake or increased loss of sodium-containing fluids. A concomitant ECF volume deficit is common. Causes include decreased sodium intake, such as consumption of a low-sodium diet or use of enteral feeds, which are typically low in sodium;

Figure 3-3. Evaluation of sodium abnormalities. ADH = antidiuretic hormone; SIADH = syndrome of inappropriate secretion of antidiuretic hormone.
GI losses from vomiting, prolonged nasogastric suctioning, or diarrhea; and renal losses due to diuretic use or primary renal disease.

Hyponatremia also can be seen with an excess of solute relative to free water, such as with untreated hyperglycemia or mannitol administration. When hyponatremia in the presence of hyperglycemia is being evaluated, the corrected sodium concentration should be calculated as follows:

For every 100-mg/dL increment in plasma glucose above normal, the plasma sodium should decrease by 1.6 mEq/L.

Lastly, extreme elevations in plasma lipids and proteins can cause pseudohyponatremia because there is no true decrease in extracellular sodium relative to water.

Signs and symptoms of hyponatremia (Table 3-4) are dependent on the degree of hyponatremia and the rapidity with which it occurred. Clinical manifestations primarily have a central nervous system origin and are related to cellular water intoxication and associated increases in intracranial pressure. Oliguric renal failure also can be a rapid complication in the setting of severe hyponatremia.

A systematic review of the etiology of hyponatremia should reveal its cause in a given instance. Hyperosmolar causes, including hyperglycemia or mannitol infusion and pseudohyponatremia, should be easily excluded. Next, depletional versus dilutional causes of hyponatremia are evaluated. In the absence of renal disease, depletion is associated with low urine sodium levels (<20 mEq/L), whereas renal sodium wasting shows high urine sodium levels (>20 mEq/L). Dilutional causes of hyponatremia usually are associated with hypervolemic circulation. A normal volume status in the setting of hyponatremia should prompt an evaluation for a syndrome of inappropriate secretion of ADH.

**Hyponatremia.** Hyponatremia results from either a loss of free water or a gain of sodium in excess of water. Like hyponatremia, it can be associated with an increased, normal, or decreased extracellular volume (see Fig. 3-3). Hypervolemic hyponatremia usually is caused either by iatrogenic administration of sodium-containing fluids, including excess sodium bicarbonate, or mineralocorticoid as seen in hyperaldosteronism, Cushing’s syndrome, and congenital adrenal hyperplasia. Urine sodium concentration is typically >20 mEq/L, and urine osmolality is >300 mOsm/L. Normovolemic hyponatremia can result from renal causes, including diabetes insipidus, diuretic use, and renal disease, or from nonrenal water loss from the GI tract or skin, although the same conditions can result in hypovolemic hyponatremia. When hypovolemia is present, the urine sodium concentration is <20 mEq/L and urine osmolality is <300 to 400 mOsm/L. Nonrenal water loss can occur secondary to relatively isotonic GI fluid losses such as that caused by diarrhea, to hypotonic skin fluid losses such as loss due to fever, or to losses via tracheotomies during hyperventilation. Additionally, thyrotoxicosis can cause water loss, as can the use of hypertonic glucose solutions for peritoneal dialysis. With nonrenal water loss, the urine sodium concentration is <15 mEq/L, and the urine osmolality is >400 mOsm/L.

Symptomatic hyponatremia usually occurs only in patients with impaired thirst or restricted access to fluid because thirst will result in increased water intake. Symptoms are rare until the serum sodium concentration exceeds 160 mEq/L but, once present, are associated with significant morbidity and mortality. Because symptoms are related to hyperosmolality, central nervous system effects predominate (see Table 3-4). Water shifts from the intracellular to the extracellular space in response to a hyperosmolar extracellular space, which results in cellular dehydration. This can put traction on the cerebral vessels and lead to subarachnoid hemorrhage. Central nervous system symptoms can range from restlessness and irritability to seizures, coma, and death. The classic signs of hypovolemic hyponatremia (tachycardia, orthostasis, and hypotension) may be present, as well as the unique findings of dry, sticky mucous membranes.

### Composition Changes: Etiology and Diagnosis

#### Potassium Abnormalities.** The average dietary intake of potassium is approximately 50 to 100 mEq/d, which in the absence of hypokalemia is excreted primarily in the urine. Extracellular potassium is maintained within a narrow range, principally by renal excretion of potassium, which can range from 10 to 700 mEq/d. Although only 2% of the total body potassium (4.5 mEq/L × 14 L = 63 mEq) is located within the extracellular compartment, this small amount is critical to cardiac and neuromuscular function; thus, even minor changes can have major effects on cardiac activity. The intracellular and extracellular distribution of potassium is influenced by a number of factors, including surgical stress, injury, acidosis, and tissue catabolism.
Hyperkalemia

Hyperkalemia is defined as a serum potassium concentration above the normal range of 3.5 to 5.0 mEq/L. It is caused by excessive potassium intake, increased release of potassium from cells, or impaired potassium excretion by the kidneys (Table 3-5). Increased intake can be either from oral or IV supplementation, or from red cell lysis after transfusion. Hemolysis, rhabdomyolysis, and crush injuries can disrupt cell membranes and release intracellular potassium into the ECF. Acidosis and a rapid rise in extracellular osmolality from hyperglycemia or IV mannitol can raise serum potassium levels by causing a shift of potassium ions to the extracellular compartment. Because 98% of total body potassium is in the intracellular fluid compartment, even small shifts of intracellular potassium out of the intracellular fluid compartment can lead to a significant rise in extracellular potassium. A number of medications can contribute to hyperkalemia, particularly in the presence of renal insufficiency, including potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, and non-steroidal anti-inflammatory drugs (NSAIDs). Spironolactone and angiotensin-converting enzyme inhibitors interfere with aldosterone activity, inhibiting the normal renal mechanism of potassium excretion. Acute and chronic renal insufficiency also impairs potassium excretion.

Symptoms of hyperkalemia are primarily GI, neuromuscular, and cardiovascular (Table 3-6). GI symptoms include nausea, vomiting, intestinal colic, and diarrhea. Neuromuscular symptoms range from weakness to ascending paralysis to respiratory failure. Early cardiovascular signs may be apparent from electrocardiogram (ECG) changes and eventually lead to hemodynamic symptoms of arrhythmia and cardiac arrest. ECG changes that may be seen with hyperkalemia include high peaked T waves (early), widened QRS complex, flattened P wave, prolonged PR interval (first-degree block), sine wave formation, and ventricular fibrillation.

Hypokalemia

Hypokalemia is much more common than hyperkalemia in the surgical patient. It may be caused by inadequate potassium intake; excessive renal potassium excretion; potassium loss in pathologic GI secretions, such as with diarrhea, fistulas, vomiting, or high nasogastric output; or intracellular shifts from metabolic alkalosis or insulin therapy (see Table 3-5).
The change in potassium associated with alkalosis can be calculated by the following formula:

\[
\text{Potassium decreases by 0.3 mEq/L for every 0.1 increase in pH above normal.}
\]

Additionally, drugs such as amphotericin, aminoglycosides, cisplatin, and ifosfamide that induce magnesium depletion cause renal potassium wastage. In cases in which potassium deficiency is due to magnesium depletion, potassium repletion is difficult unless hypomagnesemia is first corrected.

The symptoms of hypokalemia (see Table 3-6), like those of hyperkalemia, are primarily related to failure of normal contractility of GI smooth muscle, skeletal muscle, and cardiac muscle. Findings may include ileus, constipation, weakness, fatigue, diminished tendon reflexes, paralysis, and cardiac arrest. In the setting of ECF depletion, symptoms may be masked initially and then worsened by further dilution during volume repletion. ECG changes suggestive of hypokalemia include U waves, T-wave flattening, ST-segment changes, and arrhythmias (with digitalis therapy).

**Calcium Abnormalities.** The vast majority of the body’s calcium is contained within the bone matrix, with <1% found in the ECF. Serum calcium is distributed among three forms: protein bound (40%), complexed to phosphate and other anions (10%), and ionized (50%). It is the ionized fraction that is responsible for neuromuscular stability and can be measured directly. When total serum calcium levels are measured, the albumin concentration must be taken into consideration:

\[
\text{Adjust total serum calcium down by 0.8 mg/dL for every 1 g/dL decrease in albumin.}
\]

Unlike changes in albumin, changes in pH will affect the ionized calcium concentration. Acidosis decreases protein binding, thereby increasing the ionized fraction of calcium.

Daily calcium intake is 1 to 3 g/d. Most of this is excreted via the bowel, with urinary excretion relatively low. Total body calcium balance is under complex hormonal control, but disturbances in metabolism are relatively long term and less important in the acute surgical setting. However, attention to the critical role of ionized calcium in neuromuscular function often is required.

**Hypercalcemia** Hypercalcemia is defined as a serum calcium level above the normal range of 8.5 to 10.5 mEq/L or an increase in the ionized calcium level above 4.2 to 4.8 mg/dL. Primary hyperparathyroidism in the outpatient setting and malignancy in hospitalized patients, from either bony metastasis or secretion of parathyroid hormone–related protein, account for most cases of symptomatic hypercalcemia. Symptoms of hypercalcemia (see Table 3-6), which vary with the degree of severity, include neurologic impairment, musculoskeletal weakness and pain, renal dysfunction, GI symptoms of nausea, vomiting, and abdominal pain. Cardiac symptoms can be manifested as hypertension, cardiac arrhythmias, and a worsening of digitalis toxicity. ECG changes in hypercalcemia include shortened QT interval, prolonged PR and QRS intervals, increased QRS voltage, T-wave flattening and widening, and atrioventricular block (which can progress to complete heart block and cardiac arrest).

**Hypocalcemia** Hypocalcemia is defined as a serum calcium level below 8.5 mEq/L or a decrease in the ionized calcium level below 4.2 mg/dL. The causes of hypocalcemia include pancreatitis, massive soft tissue infections such as necrotizing fasciitis, renal failure, pancreatic and small bowel fistulas, hypoparathyroidism, toxic shock syndrome, abnormalities in magnesium levels, and tumor lysis syndrome. In addition, transient hypocalcemia commonly occurs after removal of a parathyroid adenoma due to atrophy of the remaining glands and avid bone remineralization, and sometimes requires high-dose calcium supplementation. Additionally, malignancies associated with increased osteoblastic activity, such as breast and prostate cancer, can lead to hypocalcemia from increased bone formation. Calcium precipitation with organic anions is also a cause of hypocalcemia and may occur during hyperphosphatemia from tumor lysis syndrome or rhabdomyolysis. Pancreatitis may sequester calcium via chelation with free fatty acids. Massive blood transfusion with citrate binding is another mechanism. Hypocalcemia rarely results solely from decreased intake because bone reabsorption can maintain normal levels for prolonged periods.

Asymptomatic hypocalcemia may occur when hypophosphatemia results in a normal ionized calcium level. Conversely, symptoms can develop with a normal serum calcium level during alkalosis, which decreases ionized calcium. In general, neuromuscular and cardiac symptoms do not occur until the ionized fraction falls below 2.5 mg/dL (see Table 3-6). Clinical findings may include paresthesias of the face and extremities, muscle cramps, carpopedal spasm, stridor, tetany, and seizures. Patients will demonstrate hyperreflexia and may exhibit positive Chvostek’s sign (spasm resulting from tapping over the facial nerve) and Trousseau’s sign (spasm resulting from pressure applied to the nerves and vessels of the upper extremity with a blood pressure cuff). Hypocalcemia may lead to decreased cardiac contractility and heart failure. ECG changes of hypocalcemia include prolonged QT interval, T-wave inversion, heart block, and ventricular fibrillation.

**Phosphorus Abnormalities.** Phosphorus is the primary intracellular divalent anion and is abundant in metabolically active cells. Phosphorus is involved in energy production during glycolysis and is found in high-energy phosphate products such as adenosine triphosphate. Serum phosphate levels are tightly controlled by renal excretion.

**Hyperphosphatemia** Hyperphosphatemia can be due to decreased urinary excretion, increased intake, or endogenous mobilization of phosphorus. Most cases of hyperphosphatemia are seen in patients with impaired renal function. Hypoparathyroidism or hyperthyroidism also can decrease urinary excretion of phosphorus and thus lead to hyperphosphatemia. Increased release of endogenous phosphorus can be seen in association with any clinical condition that results in cell destruction, including rhabdomyolysis, tumor lysis syndrome, hemolysis, sepsis, severe hyperthermia, and malignant hyperthermia. Excessive phosphate administration from IV hyperalimentation solutions or phosphorus-containing laxatives may also lead to elevated phosphate levels. Most cases of hyperphosphatemia are asymptomatic, but significant prolonged hyperphosphatemia can lead to metastatic deposition of soft tissue calcium-phosphorus complexes.

**Hypophosphatemia** Hypophosphatemia can be due to a decrease in phosphorus intake, an intracellular shift of phosphorus, or an increase in phosphorus excretion. Decreased GI uptake due to malabsorption or administration of phosphate binders and decreased dietary intake from malnutrition are causes of chronic hypophosphatemia. Most acute cases are due to an intracellular
shift of phosphorus in association with respiratory alkalosis, insulin therapy, refeeding syndrome, and hungry bone syndrome. Clinical manifestations of hypophosphatemia usually are absent until levels fall significantly. In general, symptoms are related to adverse effects on the oxygen availability of tissue and to a decrease in high-energy phosphates, and can be manifested as cardiac dysfunction or muscle weakness.

**Magnesium Abnormalities.** Magnesium is the fourth most common mineral in the body and, like potassium, is found primarily in the intracellular compartments. Approximately one-half of the total body content of 2000 mEq is incorporated in bone and is slowly exchangeable. Of the fraction found in the extracellular space, one-third is bound to serum albumin. Therefore, the plasma level of magnesium may be a poor indicator of total body stores in the presence of hypoalbuminemia. Magnesium should be replaced until levels are in the upper limit of normal. The normal dietary intake is approximately 20 mEq/d and is excreted in both the feces and urine. The kidneys have a remarkable ability to conserve magnesium, with renal excretion <1 mEq/d during magnesium deficiency.

**Hypermagnesemia** Hypermagnesemia is rare but can be seen with severe renal insufficiency and parallel changes in potassium excretion. Magnesium-containing antacids and laxatives can produce toxic levels in patients with renal failure. Excess intake in conjunction with total parenteral nutrition (TPN), or, rarely, massive trauma, thermal injury, and severe acidosis, may be associated with symptomatic hypermagnesemia. Clinical examination (see Table 3-6) may find nausea and vomiting; neuromuscular dysfunction with weakness, lethargy, and hyporeflexia; and impaired cardiac conduction leading to hypotension and arrest. ECG changes are similar to those seen with hyperkalemia and include increased PR interval, widened QRS complex, and elevated T waves.

**Hypomagnesemia** Magnesium depletion is a common problem in hospitalized patients, particularly in the critically ill. The kidney is primarily responsible for magnesium homeostasis through regulation by calcium/magnesium receptors on the renal tubular cells that respond to serum magnesium concentrations. Hypomagnesemia may result from alterations of intake, renal excretion, and pathologic losses. Poor intake may occur in cases of starvation, alcoholism, prolonged IV fluid therapy, and TPN with inadequate supplementation of magnesium. Losses are seen in cases of increased renal excretion from alcohol abuse, diuretic use, administration of amphotericin B, and primary aldosteronism, as well as GI losses from diarrhea, malabsorption, and acute pancreatitis. The magnesium ion is essential for proper function of many enzyme systems. Depletion is characterized by neuromuscular and central nervous system hyperactivity. Symptoms are similar to those of calcium deficiency, including hyperactive reflexes, muscle tremors, tetany, and positive Chvostek’s and Trousseau’s signs (see Table 3-6). Severe deficiencies can lead to delirium and seizures. A number of ECG changes also can occur and include prolonged QT and PR intervals, ST-segment depression, flattening or inversion of P waves, torsades de pointes, and arrhythmias. Hypomagnesemia is important not only because of its direct effects on the nervous system but also because it can produce hypocalcemia and lead to persistent hypokalemia. When hypokalemia or hypocalcemia coexists with hypomagnesemia, magnesium should be aggressively replaced to assist in restoring potassium or calcium homeostasis.

**Acid-Base Balance**

**Acid-Base Homeostasis.** The pH of body fluids is maintained within a narrow range despite the ability of the kidneys to generate large amounts of HCO$_3^-$ and the normal large acid load produced as a by-product of metabolism. This endogenous acid load is efficiently neutralized by buffer systems and ultimately excreted by the lungs and kidneys.

Important buffers include intracellular proteins and phosphates and the extracellular bicarbonate–carbonic acid system. Compensation for acid-base derangements can be by respiratory mechanisms (for metabolic derangements) or metabolic mechanisms (for respiratory derangements). Changes in ventilation in response to metabolic abnormalities are mediated by hydrogen-sensitive chemoreceptors found in the carotid body and brain stem. Acidosis stimulates the chemoreceptors to increase ventilation, whereas alkalosis decreases the activity of the chemoreceptors and thus decreases ventilation. The kidneys provide compensation for respiratory abnormalities by either increasing or decreasing bicarbonate reabsorption in response to respiratory acidosis or alkalosis, respectively. Unlike the prompt change in ventilation that occurs with metabolic abnormalities, the compensatory response in the kidneys to respiratory abnormalities is delayed. Significant compensation may not begin for 6 hours and then may continue for several days. Because of this delayed compensatory response, respiratory acid-base derangements before renal compensation are classified as acute, whereas those persisting after renal compensation are categorized as chronic. The predicted compensatory changes in response to metabolic or respiratory derangements are listed in Table 3-7. If the predicted change in pH is exceeded, then a mixed acid-base abnormality may be present (Table 3-8).

**Metabolic Derangements**

**Metabolic Acidosis.** Metabolic acidosis results from an increased intake of acids, an increased generation of acids, or an increased loss of bicarbonate (Table 3-9). The body responds by several mechanisms, including producing buffers (extracellular bicarbonate and intracellular buffers from bone and muscle), increasing ventilation (Kussmaul’s respirations), and increasing renal reabsorption and generation of bicarbonate. The kidney also will increase secretion of hydrogen and thus increase urinary excretion of NH$_4^+$ (H$^+$ + NH$_3$ $\rightarrow$ NH$_4^+$). Evaluation of a patient with a low serum bicarbonate level and metabolic

P$\text{CO}_2$ = partial pressure of carbon dioxide.
acidosis includes determination of the anion gap (AG), an index of unmeasured anions.

\[ \text{AG} = (\text{Na}) - (\text{Cl} + \text{HCO}_3^-) \]

The normal AG is <12 mmol/L and is due primarily to the albumin effect, so that the estimated AG must be adjusted for albumin (hypoaalbuminemia reduces the AG) \(^{19}\).

Corrected AG = actual AG – (2.5[4.5 – albumin])

Metabolic acidosis with an increased AG occurs either from ingestion of exogenous acid such as from ethylene glycol, salicylates, or methanol, or from increased endogenous acid production of the following:

- β-Hydroxybutyrate and acetoacetate in ketoacidosis
- Lactate in lactic acidosis
- Organic acids in renal insufficiency

A common cause of severe metabolic acidosis in surgical patients is lactic acidosis. In circulatory shock, lactate is produced in the presence of hypoxia from inadequate tissue perfusion. The treatment is to restore perfusion with volume resuscitation rather than to attempt to correct the abnormality with exogenous bicarbonate. With adequate perfusion, the lactic acid is rapidly metabolized by the liver, and the pH level returns to normal. In clinical studies of lactic acidosis and ketoacidosis, the administration of bicarbonate has not reduced morbidity or mortality or improved cellular function. \(^{20}\) Administered bicarbonate can combine with the excess hydrogen ions to form carbonic acid; this is then converted to CO\(_2\) and water, which thus raises the partial pressure of CO\(_2\) (Pco\(_2\)). This hypercarbia could compound ventilation abnormalities in patients with underlying acute respiratory distress syndrome. This CO\(_2\) can diffuse into cells, but bicarbonate remains extracellular, which thus worsens intracellular acidosis. Clinically, lactate levels may not be useful in directing resuscitation, although lactate levels may be higher in nonsurvivors of serious injury. \(^{21}\)

Metabolic acidosis with a normal AG results from exogenous acid administration (HCl or NH\(_4\)^+), from loss of bicarbonate due to GI disorders such as diarrhea and fistulas or ureterosigmoidostomy, or from renal losses. In these settings, the bicarbonate loss is accompanied by a gain of chloride; thus, the AG remains unchanged. To determine whether the loss of bicarbonate has a renal cause, the urinary (NH\(_4\)^+) can be measured. A low urinary (NH\(_4\)^+) in the face of hyperchloremic acidosis would indicate that the kidney is the site of loss, and evaluation for renal tubular acidosis should be undertaken. Proximal renal tubular acidosis results from decreased tubular reabsorption of HCO\(_3^-\), whereas distal renal tubular acidosis results from decreased acid excretion. The carbonic anhydrase inhibitor acetazolamide also causes bicarbonate loss from the kidneys.

  - Renal insufficiency

**Normal Anion Gap**
- Acid administration (HCl)
- Loss of bicarbonate
- GI losses (diarrhea, fistulas)
- Ureterosigmoidostomy
- Renal tubular acidosis
- Carbonic anhydrase inhibitor
and intestinal secretions, vomiting with an obstructed pylorus results only in the loss of gastric fluid, which is high in chloride and hydrogen, and therefore results in a hypochloremic alkalosis. Initially, the urinary bicarbonate level is high in compensation for the alkalosis. Hydrogen ion reabsorption also ensues, with an accompanied potassium ion excretion. In response to the associated volume deficit, aldosterone-mediated sodium reabsorption increases potassium excretion. The resulting hypocalemia leads to the excretion of hydrogen ions in the face of alkalosis, a paradoxical aciduria. Treatment includes replacement of the volume deficit with isotonic saline and then potassium replacement once adequate urine output is achieved.

Respiratory Derangements. Under normal circumstances, blood PCO₂ is tightly maintained by alveolar ventilation, controlled by the respiratory centers in the pons and medulla oblongata.

Respiratory Acidosis Respiratory acidosis is associated with the retention of CO₂ secondary to decreased alveolar ventilation. The principal causes are listed in Table 3-11. Because compensation is primarily a renal mechanism, it is a delayed response. Treatment of acute respiratory acidosis is directed at the underlying cause. Measures to ensure adequate ventilation are also initiated. This may entail patient-initiated volume expansion using noninvasive bilevel positive airway pressure or may require endotracheal intubation to increase minute ventilation. In the chronic form of respiratory acidosis, the partial pressure of arterial CO₂ remains elevated, and the bicarbonate concentration rises slowly as renal compensation occurs.

Respiratory Alkalosis In the surgical patient, most cases of respiratory alkalosis are acute and secondary to alveolar hyperventilation. Causes include pain, anxiety, and neurologic disorders, including central nervous system injury and assisted ventilation. Drugs such as salicylates, fever, gram-negative bacteremia, thyrotoxicosis, and hypoxemia are other possibilities. Acute hypocapnia can cause an uptake of potassium and phosphate into cells and increased binding of calcium to albumin, leading to symptomatic hypokalemia, hypophosphatemia, and hypocalcemia with subsequent arrhythmias, paresthesias, muscle cramps, and seizures. Treatment should be directed at the underlying cause, but direct treatment of the hyperventilation using controlled ventilation may also be required.

### FLUID AND ELECTROLYTE THERAPY

#### Parenteral Solutions

A number of commercially available electrolyte solutions are available for parenteral administration. The most commonly used solutions are listed in Table 3-12. The type of fluid administered depends on the patient’s volume status and the type of concentration or compositional abnormality present. Plasma-Lyte, lactated Ringer’s solution, and normal saline are considered isotonic and are useful in replacing GI losses and correcting extracellular volume deficits. Lactated Ringer’s is slightly hypotonic in that it contains 130 mEq of lactate. Lactate is used rather than bicarbonate because it is more stable in IV fluids during storage. It is converted into bicarbonate by the liver after infusion, even in the face of hemorrhagic shock.

Sodium chloride is mildly hypertonic, containing 154 mEq of sodium that is balanced by 154 mEq of chloride. The high chloride concentration imposes a significant chloride load on the kidneys and may lead to a hyperchloremic metabolic acidos.

Sodium chloride is an ideal solution, however, for correcting volume deficits associated with hypernatremia, hypochloremia, and metabolic alkalosis.

Plasma-Lyte is the crystalloid preparation that most closely resembles the electrolyte composition of human plasma. In addition to the favorable, isotonic electrolyte composition, Plasma-Lyte contains a number of additional buffers that create a favorable profile for addressing acidosis. These characteristics have resulted in Plasma-Lyte emerging as one of the most popular isotonic fluids for use in surgery. It should be noted that Plasma-Lyte contains small quantities of potassium; although the likelihood of inducing hyperkalemia is very low, care should be taken when using Plasma-Lyte in patients at risk for renal impairment.

The less concentrated sodium solutions, such as 0.45% sodium chloride, are useful for replacement of ongoing GI losses as well as for maintenance fluid therapy in the postoperative period. This solution provides sufficient free water for insensible losses and enough sodium to aid the kidneys in adjustment of serum sodium levels. The addition of 5% dextrose...
BASIC CONSIDERATIONS

PART I

(50 g of dextrose per liter) supplies 200 kcal/L, and dextrose is always added to solutions containing <0.45% sodium chloride to maintain osmolality and thus prevent the lysis of red blood cells that may occur with rapid infusion of hypotonic fluids. The addition of potassium is useful once adequate renal function and urine output are established.

Alternative Resuscitative Fluids

A number of alternative solutions for volume expansion and resuscitation are available (Table 3-13). Hypertonic saline solutions (3.5% and 5%) are used for correction of severe sodium deficits and are discussed elsewhere in this chapter. Hypertonic saline (7.5%) has been used as a treatment modality in patients with closed head injuries. It has been shown to increase cerebral perfusion and decrease intracranial pressure, thus decreasing brain edema. However, there have also been concerns about increased bleeding because hypertonic saline is an arteriolar vasodilator. A recent meta-analysis of hypertonic saline in severe traumatic brain injury revealed that, in a total of 11 eligible studies, there was no mortality benefit associated with hypertonic saline compared to other solutions. Colloids also are used in surgical patients, and their effectiveness as volume expanders compared with isotonic crystalloids has long been debated. Due to their molecular weight, they are confined to the intravascular space, and their infusion results in more efficient transient plasma volume expansion. However, under conditions of severe hemorrhagic shock, capillary membrane permeability increases; this permeability permits colloids to enter the interstitial space, which can worsen edema and impair tissue oxygenation. Four major types of colloids are available—albumin, dextrans, hetastarch, and gelatins—and are described by their molecular weight and size in Table 3-13. In a large randomized trial of patients admitted to an intensive care unit with hypovolemic shock, administration of colloid showed no improvement in mortality at 30 days as compared to crystalloid resuscitation. Interestingly, there was a suggestion of improvement of 90-day mortality and more days alive without mechanical ventilation in patients receiving colloid; however, these were not trial primary endpoints and were considered exploratory. Furthermore, a Cochrane Database systematic review on the topic concluded that there is no available evidence from randomized trials to support colloid use over crystalloid to reduce the risk of death following trauma, burns, or surgery. Colloids are markedly more expensive than crystalloids, and certain colloids, such as hydroxyethyl starch, have been associated with increased morbidity including the need for renal replacement therapy. Taken together, the use of colloid for resuscitation of critically ill and surgical patients has limited application.

Correction of Life-Threatening Electrolyte Abnormalities

Sodium

**Hypernatremia** Treatment of hypernatremia usually consists of treatment of the associated water deficit. In hypovolemic patients, volume should be restored with normal saline before the concentration abnormality is addressed. Once adequate volume has been achieved, the water deficit is replaced using a hypertonic fluid such as 5% dextrose, 5% dextrose in one-quarter normal saline, or enterally administered water. The formula used to estimate the amount of water required to correct hypernatremia is as follows:

$$\text{Water deficit (L)} = \frac{\text{serum sodium} - 140}{140} \times \text{TBW}$$

Estimate TBW as 50% of lean body mass in men and 40% in women.
The rate of fluid administration should be titrated to achieve a decrease in serum sodium concentration of no more than 1 mEq/h and 12 mEq/d for the treatment of acute symptomatic hypernatremia. Even slower correction should be undertaken for chronic hypernatremia (0.7 mEq/h) because overly rapid correction can lead to cerebral edema and herniation. The type of fluid used depends on the severity and ease of correction. Oral or enteral replacement is acceptable in most cases, or IV replacement with half- or quarter-normal saline can be used. Caution also should be exercised when using 5% dextrose in water to avoid overly rapid correction. Frequent neurologic evaluation as well as frequent evaluation of serum sodium levels also should be performed. Hypernatremia is less common than hyponatremia, but has a worse prognosis, and is an independent predictor of mortality in critical illness.29

Hyponatremia Most cases of hyponatremia can be treated by free water restriction and, if severe, the administration of sodium. In patients with normal renal function, symptomatic hyponatremia usually does not occur until the serum sodium level is ≤120 mEq/L. If neurologic symptoms are present, 3% normal saline should be used to increase the sodium by no more than 1 mEq/L per hour until the serum sodium level reaches 130 mEq/L or neurologic symptoms are improved. Correction of asymptomatic hyponatremia should increase the sodium level by no more than 0.5 mEq/L per hour to a maximum increase of 12 mEq/L per day, and even more slowly in chronic hyponatremia. The rapid correction of hyponatremia can lead to pontine myelinolysis,30 with seizures, weakness, paresis, akinetic movements, and unresponsiveness, and may result in permanent brain damage and death. Serial magnetic resonance imaging may be necessary to confirm the diagnosis.31

Potassium

Hyperkalemia Treatment options for symptomatic hyperkalemia are listed in Table 3-14. The goals of therapy include reducing the total body potassium, shifting potassium from the extracellular to the intracellular space, and protecting the cells from the effects of increased potassium. For all patients, exogenous sources of potassium should be removed, including potassium supplementation in IV fluids and enteral and parenteral solutions. Potassium can be removed from the body using a cation-exchange resin such as Kayexalate that binds potassium in exchange for sodium. It can be administered either orally, in alert patients, or rectally. Immediate measures also should include attempts to shift potassium intracellularly with glucose and bicarbonate infusion. Nebulized albuterol (10 to 20 mg) may also be used. Use of glucose alone will cause a rise in insulin secretion, but in the acutely ill, this response may be blunted, and therefore both glucose and insulin may be necessary. Circulatory overload and hypernatremia may result from the administration of Kayexalate and bicarbonate, so care should be exercised when administering these agents to patients with fragile cardiac function. When ECG changes are present, calcium chloride or calcium gluconate (5 to 10 mL of 10% solution) should be administered immediately to counteract the myocardial effects of hyperkalemia. Calcium infusion should be used cautiously in patients receiving digitalis because digitalis toxicity may be precipitated. All of the aforementioned measures are temporary, lasting from 1 to approximately 4 hours. Dialysis should be considered in severe hyperkalemia when conservative measures fail.

Hypokalemia Treatment for hypokalemia consists of potassium repletion, the rate of which is determined by the symptoms (Table 3-15). Oral repletion is adequate for mild, asymptomatic hypokalemia. If IV repletion is required, usually no more than 10 mEq/h is advisable in an unmonitored setting. This amount can be increased to 40 mEq/h when accompanied by continuous ECG monitoring, and even more in the case of imminent cardiac arrest from a malignant arrhythmia-associated hypokalemia. Caution should be exercised when oliguria or impaired renal function is coexistent.

Calcium

Hypercalcemia Treatment is required when hypercalcemia is symptomatic, which usually occurs when the serum level exceeds 12 mg/dL. The critical level for serum calcium is 15 mg/dL, when symptoms noted earlier may rapidly progress to death. The initial treatment is aimed at repleting the associated volume deficit and then inducing a brisk diuresis with normal saline. Treatment of hypercalcemia associated with malignancies is discussed later in this chapter.

Hypocalcemia Asymptomatic hypocalcemia can be treated with oral or IV calcium (see Table 3-15). Acute symptomatic hypocalcemia should be treated with IV 10% calcium gluconate to achieve a serum concentration of 7 to 9 mg/dL. Associated deficits in magnesium, potassium, and pH must also be corrected. Hypocalcemia will be refractory to treatment if coexisting hypomagnesemia is not corrected first. Routine calcium supplementation is no longer recommended in association with massive blood transfusions.32

Phosphorus

Hyperphosphatemia Phosphate binders such as sucralfate or aluminum-containing antacids can be used to lower serum phosphorus levels. Calcium acetate tablets also are useful when hypocalcemia is simultaneously present. Dialysis usually is reserved for patients with renal failure.

Hypophosphatemia Depending on the level of depletion and tolerance to oral supplementation, a number of enteral and parenteral repletion strategies are effective for the treatment of hypophosphatemia (see Table 3-15).

Magnesium

Hypermagnesemia Treatment for hypermagnesemia consists of measures to eliminate exogenous sources of magnesium,
Table 3-15
Electrolyte replacement therapy protocol

**Potassium**
Serum potassium level <4.0 mEq/L:
- Asymptomatic, tolerating enteral nutrition: KCl 40 mEq per enteral access × 1 dose
- Asymptomatic, not tolerating enteral nutrition: KCl 20 mEq IV q2h × 2 doses
- Symptomatic: KCl 20 mEq IV q1h × 4 doses
Recheck potassium level 2 h after end of infusion; if <3.5 mEq/L and asymptomatic, replace as per above protocol

**Magnesium**
Magnesium level 1.0–1.8 mEq/L:
- Magnesium sulfate 0.5 mEq/kg in normal saline 250 mL infused IV over 24 h × 3 d
Recheck magnesium level in 3 d
Magnesium level <1.0 mEq/L:
- Magnesium sulfate 1 mEq/kg in normal saline 250 mL infused IV over 24 h × 1 d, then 0.5 mEq/kg in normal saline 250 mL infused IV over 24 h × 2 d
Recheck magnesium level in 3 d
If patient has gastric access and needs a bowel regimen:
- Milk of magnesia 15 mL (approximately 49 mEq magnesium) q24h per gastric tube; hold for diarrhea

**Calcium**
Ionized calcium level <4.0 mg/dL:
- With gastric access and tolerating enteral nutrition: Calcium carbonate suspension 1250 mg/5 mL q6h per gastric access; recheck ionized calcium level in 3 d
- Without gastric access or not tolerating enteral nutrition: Calcium gluconate 2 g IV over 1 h × 1 dose; recheck ionized calcium level in 3 d

**Phosphate**
Phosphate level 1.0–2.5 mg/dL:
- Tolerating enteral nutrition: Neutra-Phos 2 packets q6h per gastric tube or feeding tube
- No enteral nutrition: KPHO₄ or NaPO₄ 0.15 mmol/kg IV over 6 h × 1 dose
Recheck phosphate level in 3 d
Phosphate level <1.0 mg/dL:
- Tolerating enteral nutrition: KPHO₄ or NaPO₄ 0.25 mmol/kg over 6 h × 1 dose
Recheck phosphate level 4 h after end of infusion; if <2.5 mg/dL, begin Neutra-Phos 2 packets q6h
- Not tolering enteral nutrition: KPHO₄ or NaPO₄ 0.25 mmol/kg (LBW) over 6 h × 1 dose; recheck phosphate level 4 h after end of infusion; if <2.5 mg/dL, then KPHO₄ or NaPO₄ 0.15 mmol/kg (LBW) IV over 6 h × 1 dose

3 mmol KPHO₄ = 3 mmol Phos and 4.4 mEq K⁺ = 1 mL
3 mmol NaPO₄ = 3 mmol Phos and 4 mEq Na⁺ = 1 mL
Neutra-Phos 1 packet = 8 mmol Phos, 7 mEq K⁺, 7 mEq Na⁺
Use patient’s lean body weight (LBW) in kilograms for all calculations.
Disregard protocol if patient has renal failure, is on dialysis, or has a creatinine clearance <30 mL/min.

Correct concurrent volume deficits, and correct acidosis if present. To manage acute symptoms, calcium chloride (5 to 10 mL) should be administered to immediately antagonize the cardiovascular effects. If elevated levels or symptoms persist, hemodialysis may be necessary.

**Hypomagnesemia**
Correction of magnesium depletion can be oral if asymptomatic and mild. Otherwise, IV repletion is indicated and depends on severity (see Table 3-15) and clinical symptoms. For those with severe deficits (<1.0 mEq/L) or those who are symptomatic, 1 to 2 g of magnesium sulfate may be administered IV over 15 minutes. Under ECG monitoring, it may be given over 2 minutes if necessary to correct torsades de pointes (irregular ventricular rhythm). Caution should be taken when giving large amounts of magnesium because magnesium toxicity may develop. The simultaneous administration of calcium gluconate will counteract the adverse side effects of a rapidly rising magnesium level and correct hypocalcemia, which is frequently associated with hypomagnesemia.

**Preoperative Fluid Therapy**
The administration of maintenance fluids should be all that is required in an otherwise healthy individual who may be under orders to receive nothing by mouth for some period before the time of surgery. This does not, however, include replenishment of a preexisting deficit or ongoing fluid losses. The following is a frequently used formula for calculating the volume of maintenance fluids in the absence of preexisting abnormalities:

<table>
<thead>
<tr>
<th>Weight Range</th>
<th>Fluid Requirement</th>
</tr>
</thead>
<tbody>
<tr>
<td>For the first 0–10 kg</td>
<td>Give 100 mL/kg per day</td>
</tr>
<tr>
<td>For the next 10–20 kg</td>
<td>Give an additional 50 mL/kg per day</td>
</tr>
<tr>
<td>For weight &gt;20 kg</td>
<td>Give an additional 20 mL/kg per day</td>
</tr>
</tbody>
</table>

For example, a 60-kg female would receive a total of 2300 mL of fluid daily: 1000 mL for the first 10 kg of body
weight (10 kg × 100 mL/kg per day), 500 mL for the next 20 kg (10 kg × 50 mL/kg per day), and 800 mL for the last 40 kg (40 kg × 20 mL/kg per day).

An alternative approach is to replace the calculated daily water losses in urine, stool, and insensible loss with a hypotonic saline solution rather than water alone, which allows the kidney some sodium excess to adjust for concentration. Although there should be no “routine” maintenance fluid orders, both of these methods would yield an appropriate choice of 5% dextrose in 0.45% sodium chloride at 100 mL/h as initial therapy, with potassium added for patients with normal renal function. However, many surgical patients have volume and/or electrolyte abnormalities associated with their surgical disease. Preoperative evaluation of a patient’s volume status and preexisting electrolyte abnormalities is an important part of overall preoperative assessment and care. Volume deficits should be considered in patients who have obvious GI losses, such as through emesis or diarrhea, as well as in patients with poor oral intake secondary to their disease. Less obvious are those fluid losses known as third-space or nonfunctional ECF losses that occur with GI obstruction, peritoneal or bowel inflammation, ascites, crush injuries, burns, and severe soft tissue infections such as necrotizing fasciitis. The diagnosis of an acute volume deficit is primarily clinical (see Table 3-2), although the physical signs may vary with the duration of the deficit. Cardiovascular signs of tachycardia and orthostasis predominate with acute volume loss, usually accompanied by oliguria and hemoconcentration. Acute volume deficits should be corrected as much as possible before the time of operation.

Once a volume deficit is diagnosed, prompt fluid replacement should be instituted, usually with an isotonic crystalloid, depending on the measured serum electrolyte values. Patients with cardiovascular signs of volume deficit should receive a bolus of 1 to 2 L of isotonic fluid followed by a continuous infusion. Close monitoring during this period is imperative. Resuscitation should be guided by the reversal of the signs of volume deficit, such as restoration of acceptable values for vital signs, maintenance of adequate urine output (0.5 to 1 mL/kg per hour in an adult), and correction of base deficit. Patients whose volume deficit is not corrected after this initial volume challenge and those with impaired renal function and the elderly should be considered for more intensive monitoring in an intensive care unit setting. In these patients, early invasive monitoring of central venous pressure or cardiac output may be necessary.

If symptomatic electrolyte abnormalities accompany volume deficit, the abnormality should be corrected to the point that the acute symptom is relieved before surgical intervention. For correction of severe hypernatremia associated with a volume deficit, an unsafe rapid fall in extracellular osmolarity from 5% dextrose infusion is avoided by slowly correcting the hypernatremia with 0.45% saline or even lactated Ringer’s solution rather than 5% dextrose alone. This will safely and slowly correct the hypernatremia while also correcting the associated volume deficit.

Intraoperative Fluid Therapy

With the induction of anesthesia, compensatory mechanisms are lost, and hypotension will develop if volume deficits are not appropriately corrected before the time of surgery. Hemodynamic instability during anesthesia is best avoided by correcting known fluid losses, replacing ongoing losses, and providing adequate maintenance fluid therapy preoperatively. In addition to measured blood loss, major open abdominal surgeries are associated with continued extracellular losses in the form of bowel wall edema, peritoneal fluid, and the wound edema during surgery. Large soft tissue wounds, complex fractures with associated soft tissue injury, and burns are all associated with additional third-space losses that must be considered in the operating room. These represent distributional shifts, in that the functional volume of ECF is reduced but fluid is not externally lost from the body. These functional losses have been referred to as parasitic losses, sequestration, or third-space edema because the lost volume no longer participates in the normal functions of the ECF.

Until the 1960s saline solutions were withheld during surgery. Administered saline was retained and was felt to be an inappropriate challenge to a physiologic response of intraoperative salt intolerance. Basic and clinical research began to change this concept, eventually leading to the current concept that saline administration is necessary to restore the obligate ECF losses noted earlier. Although no accurate formula can predict intraoperative fluid needs, replacement of ECF during surgery often requires 500 to 1000 mL/h of a balanced salt solution to support homeostasis. The addition of albumin or other colloid-containing solutions to intraoperative fluid therapy is not necessary. Manipulation of colloidal oncotic forces by albumin infusion during major vascular surgery showed no advantage in supporting cardiac function or avoiding the accumulation of extravascular lung water.

Postoperative Fluid Therapy

Postoperative fluid therapy should be based on the patient’s current estimated volume status and projected ongoing fluid losses. Any deficits from either preoperative or intraoperative losses should be corrected, and ongoing requirements should be included along with maintenance fluids. Third-space losses, although difficult to measure, should be included in fluid replacement strategies. In the initial postoperative period, an isotonic solution should be administered. The adequacy of resuscitation should be guided by the restoration of acceptable values for vital signs and urine output and, in more complicated cases, by the correction of base deficit or lactate. Adjuncts to assessing volume status in the postoperative patient include such tools as a straight leg raise, point-of-care ultrasound, and assessment of respiratory variation via use of an arterial catheter in a mechanically ventilated patient. After the initial 24 to 48 hours, fluids can be changed to 5% dextrose in 0.45% saline in patients unable to tolerate enteral nutrition. If normal renal function and adequate urine output are present, potassium may be added to the IV fluids. Daily fluid orders should begin with assessment of the patient’s volume status and assessment of electrolyte abnormalities. There is rarely a need to check electrolyte levels in the first few days of an uncomplicated postoperative course. However, postoperative diuresis may require attention to replacement of urinary potassium loss. All measured losses, including losses through vomiting, nasogastric suctioning, drains, and urine output, as well as insensible losses, are replaced with the appropriate parenteral solutions as previously reviewed.

Fluid Management in Enhanced Recovery After Surgery (ERAS) Pathways

As pioneered by the Danish surgeon Henrik Kehlet, ERAS pathways have been designed to guide the perioperative management
of various types of surgical procedures. ERAS consists of a multimodal strategy to maximize and maintain preoperative organ function, and implementation of ERAS protocols has resulted in a decrease in length of stay, improved patient satisfaction, cost savings, and a reduction in complications. A full discussion of ERAS is outside the scope of this chapter; however, it is important to note that perioperative fluid management is a major tenet of ERAS protocols. The 2011 European Society of Anaesthesiology guidelines were among the first formal recommendations to alter standard recommendations for preoperative enteral intake. These recommendations include allowance of clear liquids up to 2 hours prior to surgery. Many ERAS protocols include the use of carbohydrate and electrolyte-rich fluids to enhance hydration and metabolic response to surgery. In addition to preoperative enteral hydration, a major focus of ERAS protocols is the restriction of intra- and postoperative sodium and intravenous fluids. Fluid overload has been associated with prolonged ileus and coagulation abnormalities. Goal-directed fluid therapy has been shown to reduce postoperative morbidity and length of stay independent of the other multimodal components of ERAS, making minimizing fluids a major target of intervention. Postoperatively, early enteral intake is advised, with prompt discontinuation of intravenous fluids. These strategies targeting euvolemia have been shown to be safe and improve outcomes, making ERAS a rapidly evolving strategy that will continue to influence the perioperative fluid and electrolyte management of surgical patients.

Special Considerations for the Postoperative Patient

Volume excess is a common disorder in the postoperative period. The administration of isotonic fluids in excess of actual needs may result in excess volume expansion. This may be due to the overestimation of third-space losses or to ongoing GI losses that are difficult to measure accurately. The earliest sign of volume overload is weight gain. The average postoperative patient who is not receiving nutritional support should lose approximately 0.25 to 0.5 lb/d (0.11 to 0.23 kg/d) from catabolism. Additional signs of volume excess may also be present as listed in Table 3-2. Peripheral edema may not necessarily be associated with intravascular volume overload because overexpansion of total ECF may exist in association with a deficit in the circulating plasma volume.

Volume deficits also can be encountered in surgical patients if preoperative losses were not completely corrected, intraoperative losses were underestimated, or postoperative losses were greater than appreciated. The clinical manifestations are described in Table 3-2 and include tachycardia, orthostasis, and oliguria. Hemoconcentration also may be present. Treatment will depend on the amount and composition of fluid lost. In most cases of volume depletion, replacement with an isotonic fluid will be sufficient while alterations in concentration and composition are being evaluated.

ELECTROLYTE ABNORMALITIES IN SPECIFIC SURGICAL PATIENTS

Neurologic Patients

Syndrome of Inappropriate Secretion of Antidiuretic Hormone. The syndrome of inappropriate secretion of antidiuretic hormone (SIADH) can occur after head injury or surgery to the central nervous system, but it also is seen in association with administration of drugs such as morphine, nonsteroidals, and oxytocin, and in a number of pulmonary and endocrine diseases, including hypothyroidism and glucocorticoid deficiency. Additionally, it can be seen in association with a number of malignancies, most often small cell cancer of the lung but also pancreatic carcinoma, thymoma, and Hodgkin’s disease.

SIADH should be considered in patients who are euvoletic and hyponatremic with elevated urine sodium levels and urine osmolality. ADH secretion is considered inappropriate when it is not in response to osmotic or volume-related conditions. Correction of the underlying problem should be attempted when possible. In most cases, restriction of free water will improve the hyponatremia. The goal is to achieve net water balance while avoiding volume depletion that may compromise renal function. Furosemide also can be used to induce free water loss. If hyponatremia persists after fluid restriction, the addition of isotonic or hypertonic fluids may be effective. The administration of isotonic saline may sometimes worsen the problem if the urinary sodium concentration is higher than the infused sodium concentration. The use of loop diuretics may be helpful in this situation by preventing further urine concentration. In chronic SIADH, when long-term fluid restriction is difficult to maintain or is ineffective, demeclocycline and lithium can be used to induce free water loss.

Diabetes Insipidus. Diabetes insipidus (DI) is a disorder of ADH stimulation and is manifested by dilute urine in the case of hypernatremia. Central DI results from a defect in ADH secretion, and nephrogenic DI results from a defect in end-organ responsiveness to ADH. Central DI is frequently seen in association with pituitary surgery, closed head injury, and anoxic encephalopathy. Nephrogenic DI occurs in association with hypokalemia, administration of radiocontrast dye, and use of certain drugs such as aminoglycosides and amphotericin B. In patients tolerating oral intake, volume status usually is normal because thirst stimulates increased intake. However, volume depletion can occur rapidly in patients who are incapable of oral intake. The diagnosis can be confirmed by documenting a paradoxical increase in urine osmolality in response to a period of water deprivation. In mild cases, free water replacement may be adequate therapy. In more severe cases, vasopressin can be added. The usual dosage of vasopressin is 5 U subcutaneously every 6 to 8 hours. However, serum electrolytes and osmolality should be monitored to avoid excess vasopressin administration with resulting iatrogenic SIADH.

Cerebral Salt Wasting. Cerebral salt wasting is a diagnosis of exclusion that occurs in patients with a cerebral lesion and renal wasting of sodium and chloride with no other identifiable cause. Natriuresis in a patient with a contracted extracellular volume should prompt the possible diagnosis of cerebral salt wasting. Hyponatremia is frequently observed but is nonspecific and occurs as a secondary event, which differentiates it from SIADH.

Malnourished Patients: Refeeding Syndrome

Refeeding syndrome is a potentially lethal condition that can occur with rapid and excessive feeding of patients with severe underlying malnutrition due to starvation, alcoholism, delayed nutritional support, anorexia nervosa, or massive weight loss in obese patients. With refeeding, a shift in metabolism from fat to carbohydrate substrate stimulates insulin release, which
results in the cellular uptake of electrolytes, particularly phosphate, magnesium, potassium, and calcium. However, severe hyperglycemia may result from blunted basal insulin secretion. The refeeding syndrome can be associated with enteral or parenteral refeeding, and symptoms from electrolyte abnormalities include cardiac arrhythmias, confusion, respiratory failure, and even death. To prevent the development of refeeding syndrome, underlying electrolyte and volume deficits should be corrected. Additionally, thiamine should be administered before the initiation of feeding. Caloric repletion should be instituted slowly and should gradually increase over the first week. Vital signs, fluid balance, and electrolytes should be closely monitored and any deficits corrected as they evolve.

**Acute Renal Failure Patients**

A number of fluid and electrolyte abnormalities are specific to patients with acute renal failure. With the onset of renal failure, an accurate assessment of volume status must be made. If prerenal azotemia is present, prompt correction of the underlying volume deficit is mandatory. Once acute tubular necrosis is established, measures should be taken to restrict daily fluid intake to match urine output and insensible and GI losses. Oliguric renal failure requires close monitoring of serum potassium levels. Measures to correct hyperkalemia as reviewed in Table 3-14 should be instituted early, including consideration of early hemodialysis. Hyponatremia is common in established renal failure as a result of the breakdown of proteins, carbohydrates, and fats, as well as the administration of free water. Dialysis may be required for severe hyponatremia. Hypocalcemia, hypomagnesemia, and hyperphosphatemia also are associated with acute renal failure. Hypocalcemia should be verified by measuring ionized calcium, because many patients also are hypoalbuminemic. Phosphate binders can be used to control hyperphosphatemia, but dialysis may be required in more severe cases. Metabolic acidosis is commonly seen with renal failure, as the kidneys lose their ability to clear acid by-products. Bicarbonate can be useful, but dialysis often is needed. Although dialysis may be either intermittent or continuous, renal recovery may be improved by continuous renal replacement.

**Cancer Patients**

Fluid and electrolyte abnormalities are common in patients with cancer. The causes may be common to all patient populations or may be specific to cancer patients and their treatment. Hypotension is frequently hypovolemic due to renal loss of sodium caused by diuretics or salt-wasting nephropathy as seen with some chemotherapeutic agents such as cisplatin. Cerebral salt wasting also can occur in patients with intracerebral lesions. Normovolemic hyponatremia may occur in association with SIADH from cervical cancer, lymphoma, and leukemia, or from certain chemotherapeutic agents. Hypernatremia in cancer patients most often is due to poor oral intake or GI volume losses, which are common side effects of chemotherapy. Central DI also can lead to hypernatremia in patients with central nervous system lesions.

Hypokalemia can develop from GI losses associated with diarrhea caused by radiation enteritis or chemotherapy, or from tumors such as villous adenomas of the colon. Tumor lysis syndrome can precipitate severe hyperkalemia from massive tumor cell destruction.

Hypocalcemia can be seen after removal of a thyroid or parathyroid tumor or after a central neck dissection, which can damage the parathyroid glands. Hungry bone syndrome produces acute and profound hypocalcemia after parathyroid surgery for secondary or tertiary hyperparathyroidism because calcium is rapidly taken up by bones. Prostate and breast cancer can result in increased osteoblastic activity, which decreases serum calcium by increasing bone formation. Acute hypocalcemia also can occur with hyperphosphatemia because phosphorus complexes with calcium. Hypomagnesemia is a side effect of ifosfamide and cisplatin therapy. Hyperphosphatemia can be seen in hyperparathyroidism, due to decreased phosphorus reabsorption, and in oncogenic osteomalacia, which increases the urinary excretion of phosphorus. Other causes of hyperphosphatemia in cancer patients include renal tubular dysfunction from multiple myeloma, Bence Jones proteins, and certain chemotherapeutic agents. Acute hyperphosphatemia can occur as rapidly proliferating malignant cells take up phosphorus in acute leukemia. Tumor lysis syndrome or the use of bisphosphonates to treat hypercalcemia also can result in hyperphosphatemia.

Malignancy is the most common cause of hypercalcemia in hospitalized patients and is due to increased bone resorption or decreased renal excretion. Bone destruction occurs from bony metastasis as seen in breast or renal cell cancer but also can occur in multiple myeloma. With Hodgkin’s and non-Hodgkin’s lymphoma, hypercalcemia results from increased calcitriol formation, which increases both absorption of calcium from the GI tract and mobilization from bone. Humoral hypercalcemia of malignancy is a common cause of hypercalcemia in cancer patients. As in primary hyperparathyroidism, a parathyroid-related protein is secreted that binds to parathyroid receptors, stimulating calcium resorption from bone and decreasing renal excretion of calcium. The treatment of hypercalcemia of malignancy should begin with saline volume expansion, which will decrease renal reabsorption of calcium as the associated volume deficit is corrected. Once an adequate volume status has been achieved, a loop diuretic may be added. Unfortunately, these measures are only temporary, and additional treatment is often necessary. A variety of drugs are available with varying times of onset, durations of action, and side effects. The bisphosphonates etidronate and pamidronate inhibit bone resorption and osteoclastic activity. They have a slow onset of action, but effects can last for 2 weeks. Calcitonin also is effective, inhibiting bone resorption and increasing renal excretion of calcium. It acts quickly, within 2 to 4 hours, but its use is limited by the development of tachyphylaxis. Corticosteroids may decrease tachyphylaxis in response to calcitonin and can be used alone to treat hypercalcemia. Gallium nitrates are potent inhibitors of bone resorption. They display a long duration of action but can cause nephrotoxicity. Mitomycin is an antibiotic that blocks osteoclastic activity, but it can be associated with liver, renal, and hematologic abnormalities, which limits its use to the treatment of Paget’s disease of bone. For patients with severe, refractory hypercalcemia who are unable to tolerate volume expansion due to pulmonary edema or congestive heart failure, dialysis is an option.

Tumor lysis syndrome results when the release of intracellular metabolites overwhelms the kidneys’ excretory capacity. This rapid release of uric acid, potassium, and phosphorus can result in marked hyperuricemia, hyperkalemia, hyperphosphatemia, hypocalcemia, and acute renal failure. It is typically seen with poorly differentiated lymphomas and leukemias but also can occur with a number of solid tumor malignancies. Tumor lysis syndrome most commonly develops during treatment.
with chemotherapy or radiotherapy. Once it develops, volume expansion should be undertaken and any associated electrolyte abnormalities corrected. In this setting, hypocalcaemia should not be treated unless it is symptomatic to avoid metastatic calcifications. Dialysis may be required for management of impaired renal function or correction of electrolyte abnormalities.

REFERENCES

Entries highlighted in bright blue are key references.

This meta-analysis demonstrated no mortality benefit or effect on intracranial pressure control utilizing hypertonic saline and was a key summary of eleven major trials in the field.

This multi-center randomized trial found no difference in mortality at 28 days in a mixed ICU population of patients with hypovolemia when comparing colloid to crystalloid resuscitation. The authors observed a reduction in 90-day mortality in the group receiving colloids; however, they cautioned that this observation was exploratory and required further analysis.

This Cochrane review of 70 trials including mortality data found no benefit to colloid resuscitation for reduction of risk of mortality, while the use of hydroxystethyl starch (HES) was found to have a possible association with increased mortality. The recommendation of the review was that colloid use in the ICU could not be supported due to increased cost and no mortality benefit.

In a randomized trial designed to address a primary outcome of 90-day mortality, the use of HES revealed no mortality benefit over saline with a statistically significant increase in the rate of renal replacement therapy after HES use.

This early paper by Shires and colleagues produced important early observations of fluid shifts and resuscitation strategies following surgery and shaped some of the early questions in the field of resuscitation science after surgery.

Index guidelines published by the European Society of Anaesthesiology were among the first to support the use of ERAS principles and provided a template for the design of the rapidly evolving practice of ERAS worldwide.

Meta-analysis of randomized controlled trials demonstrated a marked reduction in morbidity, hospital length of stay (LOS),
ICU LOS, and time to passage of feces utilizing goal-directed fluid therapy (GDFT) for intraoperative fluid management. Of note, in those studies where a multimodal ERAS pathway was utilized, the benefits of GDFT were reduced, although reduction in major morbidities remained. These data suggest that the multimodal benefits of ERAS may extend beyond just fluid management.

Hemostasis, Surgical Bleeding, and Transfusion

Ronald Chang, John B. Holcomb, Evan Leibner, Matthew Pommerening, and Rosemary A. Kozar

**BIOLOGY OF HEMOSTASIS**

Hemostasis is a complex process whose function is to limit blood loss from an injured vessel. Four major physiologic events participate in the hemostatic process: vascular constriction, platelet plug formation, fibrin formation, and fibrinolysis. Although each tends to be activated in order, the four processes are interrelated so that there is a continuum and multiple reinforcements. The process is shown schematically in Fig. 4-1.

**Vascular Constriction**

Vascular constriction is the initial response to vessel injury. It is more pronounced in vessels with medial smooth muscles and is dependent on local contraction of smooth muscle. Vasoconstriction is subsequently linked to platelet plug formation. Thromboxane A₂ (TXA₂) is produced locally at the site of injury via the release of arachidonic acid from platelet membranes and is a potent constrictor of smooth muscle. Similarly, endothelin synthesized by injured endothelium and serotonin (5-hydroxytryptamine [5-HT]) released during platelet aggregation are potent vasoconstrictors. Lastly, bradykinin and fibrinopeptides, which are involved in the coagulation schema, are also capable of contracting vascular smooth muscle.

The extent of vasoconstriction varies with the degree of vessel injury. A small artery with a lateral incision may remain open due to physical forces, whereas a similarly sized vessel that is completely transected may contract to the extent that bleeding ceases spontaneously.

**Platelet Function**

Platelets are anucleate fragments of megakaryocytes. The normal circulating number of platelets ranges between 150,000 and 400,000/μL. Up to 30% of circulating platelets may be sequestered in the spleen. If not consumed in a clotting reaction, platelets are normally removed by the spleen and have an average life span of 7 to 10 days.

Platelets play an integral role in hemostasis by forming a hemostatic plug and by contributing to thrombin formation (Fig. 4-2). Platelets do not normally adhere to each other or to the vessel wall but can form a plug that aids in cessation of bleeding when vascular disruption occurs. Injury to the intimal layer in the vascular wall exposes subendothelial collagen to which platelets adhere. This process requires von Willebrand factor (vWF), a protein in the subendothelium that is lacking in patients with von Willebrand’s disease. vWF binds to glycoprotein (GP) I/IX/V on the platelet membrane. Following adhesion, platelets initiate a release reaction that recruits other platelets from the circulating blood to seal the disrupted vessel. Up to this point, this process is known as primary hemostasis. Platelet aggregation is reversible and is not associated with secretion. Additionally, heparin does not interfere with this reaction, and thus, hemostasis can occur in the heparinized patient. Adenosine diphosphate (ADP) and serotonin are the principal mediators in platelet aggregation.

Arachidonic acid released from the platelet membranes is converted by cyclooxygenase to prostaglandin G₂ (PGG₂) and then to prostaglandin H₂ (PGH₂), which, in turn, is converted to TXA₂. TXA₂ has potent vasoconstriction and platelet aggregation effects. Arachidonic acid may also be shuttled to adjacent endothelial cells and converted to prostacyclin (PGL₂), which is a vasodilator and acts to inhibit platelet aggregation. Platelet cyclooxygenase is irreversibly inhibited by aspirin and reversibly blocked by nonsteroidal anti-inflammatory agents but is not affected by cyclooxygenase-2 (COX-2) inhibitors.

In the second wave of platelet aggregation, a release reaction occurs in which several substances including ADP, Ca²⁺, serotonin, TXA₂, and α-granule proteins are discharged.
The life span of platelets ranges from 7 to 10 days. Drugs that interfere with platelet function include aspirin, clopidogrel, prasugrel, dipyridamole, and the glycoprotein IIb/IIIa (GP IIb/IIIa) inhibitors. Approximately 5 to 7 days should pass from the time the drug is stopped until an elective procedure is performed.

Laboratory evidence of trauma-induced coagulopathy is found in up to one-third of severely injured patients at admission. It is distinct from disseminated intravascular coagulopathy and iatrogenic causes of coagulopathy such as hemodilution. Several non–mutually exclusive mechanisms have been proposed. However, the relationship between laboratory coagulation abnormalities and clinically evident coagulopathic bleeding is unclear.

Direct oral anticoagulants have no readily available method for monitoring anticoagulation. A new monoclonal antibody has been approved to reverse coagulopathy due to dabigatran, and agents are currently in clinical trials for the reversal of direct factor Xa oral anticoagulants.

When determining the need for bridging of therapeutic anticoagulation in the preoperative and postoperative setting, the patient’s risk of bleeding should be carefully considered against the risk of thromboembolism and used to guide the need for reversal of anticoagulation therapy preoperatively and the timing of its reinstatement postoperatively.

Damage control resuscitation has three basic components: permissive hypotension, minimizing crystalloid-based resuscitation, and the administration of balanced ratios of blood products.

The need for massive transfusion should be anticipated, and guidelines should be in place to provide early and balanced amounts of red blood cells, plasma, and platelets.

Fibrinogen is a required cofactor for this process, acting as a bridge for the GP IIb/IIIa receptor on the activated platelets. The release reaction results in compaction of the platelets into a plug, a process that is no longer reversible. Thrombospondin, another protein secreted by the α-granule, stabilizes fibrinogen binding to the activated platelet surface and strengthens the platelet-platelet interactions. Platelet factor 4 (PF4) and α-thromboglobulin are also secreted during the release reaction. PF4 is a potent heparin antagonist. The second wave of platelet aggregation is inhibited by aspirin and nonsteroidal anti-inflammatory drugs, by cyclic adenosine monophosphate (cAMP), and by nitric oxide. As a consequence of the release reaction, alterations occur in the phospholipids of the platelet membrane that allow calcium and clotting factors to bind to the platelet surface, forming enzymatically active complexes. The altered lipoprotein surface (sometimes referred to as platelet factor 3) catalyzes reactions that are involved in the conversion of prothrombin (factor II) to thrombin (factor IIa) by activated factor X (Xa) in the presence of factor V and calcium, and it is involved in the reaction by which activated factor IX (IXa), factor VIII, and calcium activated factor X. Platelets may also play a role in the initial activation of factors XI and XII.

Coagulation

Hemostasis involves a complex interplay and combination of interactions between platelets, the endothelium, and multiple circulating or membrane-bound coagulation factors. While overly simplistic and not reflective of the depth or complexity of these interactions, the coagulation cascade has traditionally been depicted as two possible pathways converging into a single
common pathway (Fig. 4-3). While this pathway reflects the basic process and sequences that lead to the formation of a clot, the numerous feedback loops, endothelial interplay, and platelet functions are not included. The intrinsic pathway begins with the activation of factor XII that subsequently activates factors XI, IX, and VIII. In this pathway, each of the primary factors is “intrinsic” to the circulating plasma, whereby no surface is required to initiate the process. In the extrinsic pathway, tissue factor (TF) is released or exposed on the surface of the endothelium, binding to circulating factor VII, facilitating its activation to VIIa. Each of these pathways continues on to a common sequence that begins with the activation of factor X to Xa (in the presence of VIIIa). Subsequently, Xa (with the help of factor Va) converts factor II (prothrombin) to thrombin and then factor I (fibrinogen) to fibrin. Clot formation occurs after fibrin monomers are cross-linked to polymers with the assistance of factor XIII.

One convenient feature of depicting the coagulation cascade with two merging arms is that commonly used laboratory tests segregate abnormalities of clotting to one of the two arms. An elevated activated partial thromboplastin time (aPTT) is associated with abnormal function of the intrinsic arm of the cascade (II, IX, X, XI, XII), while the prothrombin time (PT) is associated with the extrinsic arm (II, VII, X). Vitamin K deficiency or warfarin use affects factors II, VII, IX, and X.

Expanding from the basic concept of Fig. 4-3, the cell-based model of hemostasis, divided into the initiation, amplification, and propagation phases, provides a more complete picture of clot formation. During initiation, the primary pathway for coagulation is initiated by TF exposure following subendothelial injury. TF binds to VIIa, and this complex catalyzes the activation of factor X to Xa and IX to IXa, which in turn activates factor V to Va. This “prothrombinase” complex generates small amounts of thrombin from prothrombin in a calcium-dependent process. During amplification, platelets adhere to extracellular matrix components at the site of injury and become activated upon exposure to thrombin and other stimuli. Finally, during the propagation phase, “tenase” (factor VIIIa/IXa) and prothrombinase (factor Va/Xa) complexes are assembled on the surfaces of activated platelets. This results in large-scale generation of thrombin (“thrombin burst”) and fibrin.

In building on the redundancy inherent in the coagulation system, factor VIIIa combines with IXa to form the intrinsic factor complex. Factor IXa is responsible for the bulk of the conversion of factor X to Xa. This complex (VIIIa-IXa) is 50 times more effective at catalyzing factor X activation than is the extrinsic (TF-VIIa) complex and five to six orders of magnitude more effective than factor IXa alone.

Once formed, thrombin leaves the membrane surface and converts fibrinogen by two cleavage steps into fibrin and two small peptides termed fibrinopeptides A and B. Removal of fibrinopeptide A permits end-to-end polymerization of the fibrin molecules, whereas cleavage of fibrinopeptide B allows side-to-side polymerization of the fibrin clot. This latter step is
facilitated by thrombin-activatable fibrinolysis inhibitor (TAFI), which acts to stabilize the resultant clot.

In seeking to balance profound bleeding with overwhelming clot burden, several related processes exist to prevent propagation of the clot beyond the site of injury. First, feedback inhibition on the coagulation cascade deactivates the enzyme complexes leading to thrombin formation. Thrombomodulin (TM) presented by the endothelium serves as a “thrombin sink” by forming a complex with thrombin, rendering it no longer available to cleave fibrinogen. This then activates protein C (APC) and reduces further thrombin generation by inhibiting factors V and VIII. Second, tissue plasminogen activator (tPA) is released from the endothelium following injury, cleaving plasminogen to initiate fibrinolysis. APC then consumes plasminogen activator inhibitor-1 (PAI-1), leading to increased tPA activity and fibrinolysis. Building on the anticoagulant response to inhibit thrombin formation, tissue factor pathway inhibitor (TFPI) is released, blocking the TF-VIIa complex and reducing the production of factors Xa and IXa. Antithrombin III (AT-III) then neutralizes all of the procoagulant serine proteases and also inhibits the TF-VIIa complex. The most potent mechanism of thrombin inhibition involves the APC system. APC forms a complex with its cofactor, protein S, on a phospholipid surface. This complex then cleaves factors Va and VIIIa so that they are no longer able to participate in the formation of TF-VIIa or prothrombinase complexes. This is of interest clinically in the form of a genetic mutation, called factor V Leiden. In this setting, factor V is resistant to cleavage by APC, thereby remaining active as a procoagulant. Patients with factor V Leiden are predisposed to venous thromboembolic events.

Degradation of fibrin clot is accomplished by plasmin, a serine protease derived from the proenzyme plasminogen. Plasmin formation occurs as a result of one of several plasminogen activators. tPA is made by the endothelium and other cells of the vascular wall and is the main circulating form of this family of enzymes. tPA is selective for fibrin-bound plasminogen so that endogenous fibrinolytic activity occurs predominately at the site of clot formation. The other major plasminogen activator, urokinase plasminogen activator (uPA), is also produced by endothelial cells as well as by urothelium, is not selective for fibrin-bound plasminogen. Of note, the thrombin-TM complex activates TAFI, leading to a mixed effect on clot stability. In addition to inhibiting fibrinolysis directly, removal of the terminal lysine on the fibrin molecule by TAFI renders the clot more susceptible to lysis by plasmin.

**Fibrinolysis**

Fibrin clot breakdown (lysis) allows restoration of blood flow during the healing process following injury and begins at the same time clot formation is initiated. Fibrin polymers are degraded by plasmin, a serine protease derived from the proenzyme plasminogen. Plasminogen is converted to plasmin by one of several plasminogen activators, including tPA. Plasmin then degrades the fibrin mesh at various places, leading to the production of circulating fragments, termed fibrin degradation products (FDPs), cleared by other proteases or by the kidney and liver (Fig. 4-4). Fibrinolysis is directed by circulating kinases, tissue activators, and kallikrein present in vascular endothelium. tPA is synthesized by endothelial cells and released by the cells on thrombin stimulation. Bradykinin, a potent endothelial-dependent vasodilator, is cleaved from high molecular weight kininogen by kallikrein and enhances the release of tPA. Both tPA and plasminogen bind to fibrin as it forms, and this trimeric complex cleaves fibrin very efficiently. After plasmin is generated, however, it cleaves fibrin somewhat less efficiently.

As with clot formation, fibrinolysis is also kept in check through several robust mechanisms. tPA activates plasminogen more efficiently when it is bound to fibrin, so that plasmin is formed selectively on the clot. Plasmin is inhibited by α2-antiplasmin, a protein that is cross-linked to fibrin by factor XIII, which helps to ensure that clot lysis does not occur too quickly. Any circulating plasmin is also inhibited by α2-antiplasmin and circulating tPA or urokinase. Clot lysis yields FDPs including E-nodules and D-dimers. These smaller fragments interfere with normal platelet aggregation, and the larger fragments may be incorporated into the clot in lieu of normal fibrin monomers. This may result in an unstable clot as seen in cases of severe coagulopathy such as hyperfibrinolysis associated with trauma-induced coagulopathy or disseminated intravascular coagulopathy. The presence of D-dimers in the circulation may serve as a marker of thrombosis or other conditions in which a significant activation of the fibrinolytic system is present. Another inhibitor of the fibrinolytic system is TAFI, which removes lysine residues from fibrin that are essential for binding plasminogen.

**CONGENITAL FACTOR DEFICIENCIES**

**Coagulation Factor Deficiencies**

Inherited deficiencies of all of the coagulation factors are seen. However, the three most frequent are factor VIII deficiency (hemophilia A or von Willebrand’s disease), factor IX deficiency (hemophilia B or Christmas disease), and factor XI deficiency. Hemophilia A and hemophilia B are inherited as sex-linked recessive disorders with males being affected almost exclusively. The clinical severity of hemophilia A and hemophilia B depends on the measurable level of factor VIII or factor IX in the patient’s plasma. Plasma factor levels less than 1% of normal are considered severe disease, factor levels between 1% and 5% moderately severe disease, and levels between 5% and 30% mild disease. Patients with severe hemophilia have spontaneous bleeds, frequently into joints, leading to crippling arthropathies. Intracranial bleeding, intramuscular hematomas, retroperitoneal hematomas, and gastrointestinal, genitourinary, and retropharyngeal bleeding are added clinical sequelae seen with severe disease. Patients with moderately severe hemophilia have less spontaneous bleeding but are likely to bleed severely...
HEMOSTASIS, SURGICAL BLEEDING, AND TRANSFUSION

CHAPTER 4

after trauma or surgery. Mild hemophiliacs do not bleed spontaneously and have only minor bleeding after major trauma or surgery. Since platelet function is normal in hemophiliacs, patients may not bleed immediately after an injury or minor surgery as they have a normal response with platelet activation and formation of a platelet plug. At times, the diagnosis of hemophilia is not made in these patients until after their first minor procedure (e.g., tooth extraction or tonsillectomy).

Patients with hemophilia A or B are treated with factor VIII or factor IX concentrate, respectively. Recombinant factor VIII is strongly recommended for patients not treated previously and is generally recommended for patients who are both human immunodeficiency virus (HIV) and hepatitis C virus (HCV) seronegative. For factor IX replacement, the preferred products are recombinant or high-purity factor IX. In general, activity levels should be restored to 30% to 40% for mild hemorrhage, 50% for severe bleeding, and 80% to 100% for life-threatening bleeding. Up to 20% of hemophiliacs with factor VIII deficiency develop inhibitors that can neutralize FVIII. For patients with low titers, inhibitors can be overcome with higher doses of factor VIII. For patients with high inhibitor titers, alternate treatments should be used and may include porcine factor VIII, prothrombin complex concentrates, activated prothrombin complex concentrates, or recombinant factor VIIIa. For patients undergoing elective surgical procedures, a multidisciplinary approach with preoperative planning and replacement is recommended.2

von Willebrand’s Disease. von Willebrand’s disease (vWD), the most common congenital bleeding disorder, is characterized by a quantitative or qualitative defect in vWF, a large glycoprotein responsible for carrying factor VIII and platelet adhesion. The latter is important for normal platelet adhesion to exposed subendothelium and for aggregation under high shear conditions. Patients with vWD have bleeding that is characteristic of platelet disorders such as easy bruising and mucosal bleeding. Menorrhagia is common in women. vWD is classified into three types. Type I is a partial quantitative deficiency; type II is a qualitative defect; type III is total deficiency. For bleeding, type I patients usually respond well to desmopressin (DDAVP). Type II patients may respond, depending on the particular defect. Type III patients are usually unresponsive. These patients may require vWF concentrates.3

Factor XI Deficiency. Factor XI deficiency, an autosomal recessive inherited condition sometimes referred to as hemophilia C, is more prevalent in the Ashkenazi Jewish population but found in all races. Spontaneous bleeding is rare, but bleeding may occur after surgery, trauma, or invasive procedures. Treatment of patients with factor XI deficiency who present with bleeding or in whom surgery is planned and who are known to have bled previously is with fresh frozen plasma (FFP). Each milliliter of plasma contains 1 unit of factor XI activity, so the volume needed depends on the patient’s baseline level, the desired level, and the plasma volume. Antifibrinolitics may be useful in patients with menorrhagia. Factor VIIa is recommended for patients with anti-factor XI antibodies, although thrombosis has been reported.4 There has been renewed interest in factor XI inhibitors as antithrombotic agents because patients with factor XI deficiency generally have only minimal bleeding risk unless a severe deficiency is present and seem to be protected from thrombosis.5

Deficiency of Factors II (Prothrombin), V, and X. Inherited deficiencies of factors II, V, and X are rare. These deficiencies are inherited as autosomal recessive. Significant bleeding in homozygotes with less than 1% of normal activity is encountered. Bleeding with any of these deficiencies is treated with FFP. Similar to factor XI, FFP contains one unit of activity of each per milliliter. However, factor V activity is decreased because of its inherent instability. The half-life of prothrombin (factor II) is long (approximately 72 hours), and only about 25% of a normal level is needed for hemostasis. Prothrombin complex concentrates can be used to treat deficiencies of prothrombin or factor X. Daily infusions of FFP are used to treat bleeding in factor V deficiency, with a goal of 20% to 25% activity. Factor V deficiency may be co-inherited with factor VIII deficiency. Treatment of bleeding in individuals with the combined deficiency requires factor VIII concentrate and FFP. Some patients with factor V deficiency are also lacking the factor V normally present in platelets and may need platelet transfusions as well as FFP.

Factor VII Deficiency. Inherited factor VII deficiency is a rare autosomal recessive disorder. Clinical bleeding can vary widely and does not always correlate with the level of FVII coagulant activity in plasma. Bleeding is uncommon unless the level is less than 3%. The most common bleeding manifestations involve easy bruising and mucosal bleeding, particularly epistaxis or oral mucosal bleeding. Postoperative bleeding is also common, reported in 30% of surgical procedures.6 Treatment is with FFP or recombinant factor VIIa. The half-life of recombinant factor VIIa is only approximately 2 hours, but excellent hemostasis can be achieved with frequent infusions. The half-life of factor VII in FFP is up to 4 hours.

Factor XIII Deficiency. Congenital factor XIII (FXIII) deficiency, originally recognized by Duckert in 1960, is a rare autosomal recessive disease usually associated with a severe bleeding diathesis.7 The male-to-female ratio is 1:1. Although acquired FXIII deficiency has been described in association with hepatic failure, inflammatory bowel disease, and myeloid leukemia, the only significant association with bleeding in children is the inherited deficiency.8 Bleeding is typically delayed because clots form normally but are susceptible to fibrinolysis. Umbilical stump bleeding is characteristic, and there is a high risk of intracranial bleeding. Spontaneous abortion is usual in women with factor XIII deficiency unless they receive replacement therapy. Replacement can be accomplished with FFP, cryoprecipitate, or a factor XIII concentrate. Levels of 1% to 2% are usually adequate for hemostasis.

Platelet Functional Defects

Inherited platelet functional defects include abnormalities of platelet surface proteins, abnormalities of platelet granules, and enzyme defects. The major surface protein abnormalities are thrombasthenia and Bernard-Soulier syndrome. Thrombasthe-nia, or Glanzmann thrombasthenia, is a rare genetic platelet disorder, inherited in an autosomal recessive pattern, in which the platelet glycoprotein Ib/IIa (GP Ib/IIa) complex is either lacking or present but dysfunctional. This defect leads to faulty platelet aggregation and subsequent bleeding. The disorder was first described by Dr. Eduard Glanzmann in 1918.8 Bleeding in thrombasthenic patients must be treated with platelet transfusions. Bernard-Soulier syndrome is caused by a defect in the GP Ib/IX/V receptor for vWF, which is necessary for platelet adhesion to the subendothelium. Transfusion of normal platelets is required for bleeding in these patients.
The most common intrinsic platelet defect is storage pool disease. It involves loss of dense granules (storage sites for ADP, adenosine triphosphate [ATP], Ca²⁺, and inorganic phosphate) and α-granules. Dense granule deficiency is the most prevalent of these. It may be an isolated defect or occur with partial albinism in Hermansky-Pudlak syndrome. Bleeding is variable, depending on the severity of the granule defect. Bleeding is caused by the decreased release of ADP from these platelets. A few patients have been reported who have decreased numbers of both dense and α-granules. They have a more severe bleeding disorder. Patients with mild bleeding as a consequence of a form of storage pool disease can be treated with DDAVP. It is likely that the high levels of vWF in the plasma after DDAVP somehow compensate for the intrinsic platelet defect. With more severe bleeding, platelet transfusion is required.

**ACQUIRED HEMOSTATIC DEFECTS**

**Platelet Abnormalities**

Acquired congenital abnormalities of platelets are much more common than acquired defects and may be quantitative or qualitative, although some patients have both types of defects. Quantitative defects may be a result of failure of production, shortened survival, or sequestration. Failure of production is generally a result of bone marrow disorders such as leukemia, myelodysplastic syndrome, severe vitamin B₁₂ or folate deficiency, chemotherapy drugs, radiation, acute ethanol intoxication, or viral infection. If a quantitative abnormality exists and treatment is indicated either due to symptoms or the need for an invasive procedure, platelet transfusion is utilized. The etiologies of both qualitative and quantitative defects are reviewed in Table 4-1.

**Quantitative Defects.** Shortened platelet survival is seen in immune thrombocytopenia, disseminated intravascular coagulation, or disorders characterized by platelet thrombi such as thrombotic thrombocytopenic purpura and hemolytic uremic syndrome. Immune thrombocytopenia may be idiopathic or associated with other autoimmune disorders or low-grade B-cell malignancies, and it may also be secondary to viral infections (including HIV) or drugs. Secondary immune thrombocytopenia often presents with a very low platelet count, petechiae and purpura, and epistaxis. Large platelets are seen on peripheral smear. Initial treatment consists of corticosteroids, intravenous gamma globulin, or anti-D immunoglobulin in patients who are Rh positive. Both gamma globulin and anti-D immunoglobulin are rapid in onset. Platelet transfusions are not usually needed unless central nervous system bleeding or active bleeding from other sites occurs. Survival of the transfused platelets is usually short.

Primary immune thrombocytopenia is also known as idiopathic thrombocytopenic purpura (ITP). In children, it is usually acute in onset, short lived, and typically follows a viral illness. In contrast, ITP in adults is gradual in onset, chronic in nature, and has no identifiable cause. Because the circulating platelets in ITP are young and functional, bleeding is less for a given platelet count than when there is failure of platelet production. The pathophysiology of ITP is believed to involve both impaired platelet production and T cell–mediated platelet destruction.¹⁰ Management options are summarized in Table 4-2.¹¹ Treatment of drug-induced immune thrombocytopenia may simply entail withdrawal of the offending drug, but corticosteroids, gamma globulin, and anti-D immunoglobulin may hasten recovery of the count.¹²,¹³

Heparin-induced thrombocytopenia (HIT) is a form of drug-induced immune thrombocytopenia. It is an immunologic event during which antibodies against platelet factor 4 (PF4) formed during exposure to heparin affect platelet activation and endothelial function with resultant thrombocytopenia and intravascular thrombosis. The platelet count typically begins to fall 5 to 7 days after heparin has been started, but if it is a reexposure, the decrease in count may occur within 1 to 2 days. HIT should be suspected if the platelet count falls to less than 100,000 or if it drops by 50% from baseline in a patient receiving heparin. While HIT is more common with full-dose unfractionated heparin (1% to 3%), it can also occur with prophylactic doses or with low molecular weight heparins. Interestingly, approximately 17% of patients receiving unfractionated heparin and 8% receiving low molecular weight heparin develop antibodies against PF4, yet a much smaller percentage develop thrombocytopenia, and even fewer develop clinical HIT. In addition to mild to moderate thrombocytopenia, this disorder is characterized by a high incidence of thrombosis that may be arterial or venous. Importantly, the absence of thrombocytopenia in these patients does not preclude the diagnosis of HIT. The 4Ts scoring system by Lo et al can be used to assess the pretest probability of HIT and incorporates the timing and magnitude of the platelet count fall, new thrombosis, and the likelihood of other reasons for thrombocytopenia. A low probability 4Ts score is quite accurate in excluding HIT, but patients with intermediate or high probability scores require further evaluation.

Laboratory testing should include an anti–platelet factor 4–heparin enzyme-linked immunosorbent assay (ELISA). Unfortunately, this test, like the 4Ts, has a high negative predictive value but a low positive predictive value. While a negative ELISA essentially rules out HIT, a positive ELISA does not confirm HIT. To increase the specificity of this assay, it can be restricted to IgG antibodies or obtained in conjunction with a functional assay such as the serotonin release assay and the heparin-induced platelet activation test. Both of these are available only at specialized laboratories and should only be used as second-line diagnostic assays.

The initial treatment of suspected HIT is to stop heparin and begin an alternative anticoagulant. Stopping heparin without addition of another anticoagulant is not adequate to prevent thrombosis in this setting. Alternative anticoagulants are primarily thrombin inhibitors. The most recent guideline by the American College of Chest Physicians recommends lepirudin, argatroban, or danaparoid for patients with normal renal function and argatroban for patients with renal insufficiency. Because of warfarin’s early induction of a hypercoagulable state, warfarin should be instituted only once full anticoagulation with an alternative agent has been accomplished and the platelet count has begun to recover.

These are also disorders in which thrombocytopenia is a result of platelet activation and formation of platelet thrombi. In thrombotic thrombocytopenic purpura (TTP), large vWF molecules interact with platelets, leading to activation. These large molecules result from inhibition of a metalloproteinase enzyme, ADAM-S13, which cleaves the large vWF molecules. TTP is classically characterized by thrombocytopenia, microangiopathic hemolytic anemia, fever, and renal and neurologic signs or symptoms. The finding of schistocytes on a peripheral blood smear aids in the diagnosis. Plasma exchange with replacement of FFP is the treatment for acute TTP. Additionally, rituximab, a monoclonal antibody against the CD20 protein on B lymphocytes, is indicated in relapsing and/or refractory TTP.

Hemolytic uremic syndrome (HUS) often occurs secondary to infection by Escherichia coli O157:H7 or other Shiga toxin-producing bacteria. The metalloproteinase is normal in these cases. HUS is usually associated with some degree of renal failure, with many patients requiring renal replacement therapy. Neurologic symptoms are less frequent. A number of patients develop features of both TTP and HUS. This may occur with autoimmune diseases, especially systemic lupus erythematosus and HIV infection, or in association with certain drugs (such as ticlopidine, mitomycin C, gemcitabine) or immunosuppressive agents (such as cyclosporine and tacrolimus). Discontinuation of the involved drug is the mainstay of therapy. Plasmapheresis is frequently used, but it is not clear what etiologic factor is being removed by the pheresis.

Sequestration is another important cause of thrombocytopenia and usually involves trapping of platelets in an enlarged spleen typically related to portal hypertension, sarcoid, lymphoma, or Gaucher’s disease. The total body platelet mass is essentially normal in patients with hypersplenism, but a much larger fraction of the platelets are in the enlarged spleen. Platelet survival is mildly decreased. Bleeding is less than anticipated from the count because sequestered platelets can be mobilized to some extent and enter the circulation. Platelet transfusion does not increase the platelet count as much as it would in a normal person because the transfused platelets are similarly sequestered in the spleen. Spleenectomy is not indicated to correct the thrombocytopenia of hypersplenism caused by portal hypertension.

Thrombocytopenia and platelet dysfunction are the most common abnormalities of hemostasis that result in bleeding in the surgical patient. The patient may have a reduced platelet count as a result of a variety of disease processes, as discussed earlier. In these circumstances, the marrow usually demonstrates a normal or increased number of megakaryocytes. By contrast, when thrombocytopenia occurs in patients with leukemia or uremia and in patients on cytotoxic therapy, there are generally a reduced number of megakaryocytes in the marrow. Thrombocytopenia also occurs in surgical patients as a result of massive blood loss with product replacement deficient in platelets. Thrombocytopenia may also be induced by heparin administration during cardiac and vascular cases, as in the case of HIT, or may be associated with thrombotic and hemorrhagic complications. When thrombocytopenia is present in a patient for whom an elective operation is being considered, management is contingent upon the extent and cause of platelet reduction and extent of platelet dysfunction.

Early platelet administration has now become part of massive transfusion protocols. Platelets are also administered preoperatively to rapidly increase the platelet count in surgical patients with underlying thrombocytopenia or platelet dysfunction. One unit of platelet concentrate contains approximately 5.5 \times 10^{10} platelets and would be expected to increase the circulating platelet count by about 10,000/μL in the average 70-kg person. Fever, infection, hepatosplenomegaly, and the presence of antiplatelet alloantibodies decrease the effectiveness of platelet transfusions. In patients who are refractory to standard platelet transfusion, the use of human leukocyte antigen (HLA)-compatible platelets coupled with special processors has proved effective.
Qualitative Platelet Defects. Impaired platelet function often accompanies thrombocytopenia but may also occur in the presence of a normal platelet count. The importance of this is obvious when one considers that 80% of overall clot strength is related to platelet function. The life span of platelets ranges from 7 to 10 days, placing them at increased risk for impairment by medical disorders and prescription and over-the-counter medications. Impairment of ADP-stimulated aggregation occurs with massive transfusion of blood products. Uremia may be associated with increased bleeding time and impaired aggregation. Defective aggregation and platelet dysfunction are also seen in patients with severe trauma, thrombocytopenia, polycythemia vera, and myelofibrosis.

Drugs that interfere with platelet function include aspirin, clopidogrel, prasugrel, dipyridamole, and GP IIb/IIIa inhibitors. Aspirin, clopidogrel, and prasugrel all irreversibly inhibit platelet function. Clopidogrel and prasugrel do so through selective irreversible inhibition of ADP-induced platelet aggregation. Aspirin works through irreversible acetylation of platelet prostaglandin synthase.

There are no prospective randomized trials in general surgical patients to guide the timing of surgery in patients on aspirin, clopidogrel, or prasugrel. The general recommendation is that approximately 5 to 7 days should pass from the time the drug is stopped until an elective procedure is performed. Timing of urgent and emergent surgeries is even more unclear. Preoperative platelet transfusions may be beneficial, but there are no good data to guide their administration. However, functional tests such as thromboelastography (TEG) with platelet mapping are becoming available that may better demonstrate defects in platelet function and may serve to guide the timing of operation or when platelet transfusions might be indicated.

Other disorders associated with abnormal platelet function include uremia, myeloproliferative disorders, monoclonal gammopathies, and liver disease. In the surgical patient, platelet dysfunction of uremia can often be corrected by dialysis or the administration of DDAVP. Platelet transfusion may not be helpful if the patient is uremic when the platelets are given and only serve to increase antibodies. Platelet dysfunction in myeloproliferative disorders is intrinsic to the platelets and usually improves if the platelet count can be reduced to normal with chemotherapy. If possible, surgery should be delayed until the count has been decreased. These patients are at risk for both bleeding and thrombosis. Platelet dysfunction in patients with monoclonal gammopathies is a result of interaction of the monoclonal protein with platelets. Treatment with chemotherapy or, occasionally, plasmapheresis to lower the amount of monoclonal protein improves hemostasis.

Acquired Hypofibrinogenemia

Disseminated Intravascular Coagulation (DIC). DIC is an acquired syndrome characterized by systemic activation of coagulation pathways that result in excessive thrombin generation and the diffuse formation of microthrombi. This disturbance ultimately leads to consumption and depletion of platelets and coagulation factors with the resultant classic picture of diffuse bleeding. Fibrin thrombi developing in the microcirculation may cause microvascular ischemia and subsequent end-organ failure if severe. There are many different conditions that predispose a patient to DIC, and the presence of an underlying condition is required for the diagnosis. For example, injuries resulting in embolization of materials such as brain matter, bone marrow, or amniotic fluid can act as potent thromboplastins that activate the DIC cascade. Additional etiologies include malignancy, organ injury (such as severe pancreatitis), liver failure, certain vascular abnormalities (such as large aneurysms), snake bites, illicit drugs, transfusion reactions, transplant rejection, and sepsis. In fact, DIC frequently accompanies sepsis and may be associated with multiple organ failure. The important interplay between sepsis and coagulation abnormalities was demonstrated by Dhainaut et al who showed that activated protein C was effective in septic patients with DIC, though this has subsequently been disproven. The diagnosis of DIC is made based on an inciting etiology with associated thrombocytopenia, prolongation of the prothrombin time, a low fibrinogen level, and elevated fibrin markers (FPDs, D-dimer, soluble fibrin monomers). A scoring system developed by the International Society for Thrombosis and Hemostasis has been shown to have high sensitivity and specificity for diagnosing DIC as well as a strong correlation between an increasing DIC score and mortality, especially in patients with infections.

The most important facets of treatment are relieving the patient’s causative primary medical or surgical problem and maintaining adequate perfusion. If there is active bleeding, hemostatic factors should be replaced with FFP, which is usually sufficient to correct the hypofibrinogenemia, although cryoprecipitate, fibrinogen concentrates, or platelet concentrates may also be needed. Given the formation of microthrombi in DIC, heparin therapy has also been proposed. Heparin may be indicated in cases where thrombosis predominates, such as arterial or venous thromboembolism and severe purpura fulminans.

Primary Fibrinolysis. Other than due to trauma, an acquired hypofibrinogenic state in the surgical patient can be a result of pathologic fibrinolysis. This may occur in patients following prostate resection when urokinase is released during surgical manipulation of the prostate or in patients undergoing extracorporeal bypass. The severity of fibrinolytic bleeding is dependent on the concentration of breakdown products in the circulation. Antifibrinolytic agents, such as ε-aminocaproic acid and tranexamic acid, interfere with fibrinolysis by inhibiting plasminogen activation.

Myeloproliferative Diseases

Polycythemia, or an excess of red blood cells, places surgical patients at risk. Spontaneous thrombosis is a complication of polycythemia vera, a myeloproliferative neoplasm, and can be explained in part by increased blood viscosity, increased platelet count, and an increased tendency toward stasis. Paradoxically, a significant tendency toward spontaneous hemorrhage also is noted in these patients. Thrombocytosis can be reduced by the administration of low-dose aspirin, phlebotomy, and hydroxyurea.
thrombotic risk. The most common coagulation abnormalities associated with liver dysfunction are thrombocytopenia and impaired humoral coagulation function manifested as prolongation of the prothrombin time and international normalized ratio (INR). The etiology of thrombocytopenia in patients with liver disease is typically related to hypersplenism, reduced production of thrombopoietin, and immune-mediated destruction of platelets. The total body platelet mass is often normal in patients with hypersplenism, but a much larger fraction of the platelets is sequestered in the enlarged spleen. Bleeding may be less than anticipated because sequestered platelets can be mobilized to some extent and enter the circulation. Thrombopoietin, the primary stimulus for thrombopoiesis, may be responsible for some cases of thrombocytopenia in cirrhotic patients, although its role is not well delineated. Finally, immune-mediated thrombocytopenia may also occur in cirrhotics, especially those with hepatitis C and primary biliary cirrhosis. In addition to thrombocytopenia, these patients also exhibit platelet dysfunction via defective interactions between platelets and the endothelium, and possibly due to uremia and changes in endothelial function in the setting of concomitant renal insufficiency. Hypocoagulopathy is further exacerbated with low platelet counts because platelets help facilitate thrombin generation by assembling coagulation factors on their surfaces. In conditions mimicking intravascular flow, low hematocrit and low platelet counts contributed to decreased adhesion of platelets to endothelial cells, although increased vWF, a common finding in cirrhotic patients, may offset this change in patients with cirrhosis. Hypercoagulability of liver disease has recently gained increased attention, with more evidence demonstrating the increased incidence of thromboembolism despite thrombocytopenia and a hypocoagulable state on conventional blood tests. This is attributed to decreased production of liver-synthesized proteins C and S, antithrombin, and plasminogen levels, as well as elevated levels of endothelial-derived vWF and factor VIII, a potent driver of thrombin generation. Given the concomitant hypo- and hypercoagulable features seen in patients with liver disease, conventional coagulation tests may be difficult to interpret, and whole blood functional tests such as thromboelastography (TEG) or ROTEM may be more informative of the status of clot formation and stability in cirrhotic patients. Small studies have indicated that TEG provides a better assessment of bleeding risk than standard tests of hemostasis in patients with liver disease; however, no large studies have directly tested this, and future larger trials are needed.

Before instituting any therapy to ameliorate thrombocytopenia, the actual need for correction should be strongly considered. In general, correction based solely on a low platelet count should be discouraged. Most often, treatment should be withheld for invasive procedures and surgery. When required, platelet transfusions are the mainstay of therapy; however, the effect typically lasts only several hours. Risks associated with transfusions in general and the development of antplatelet antibodies in a patient population likely to need recurrent correction should be considered. A less well-accepted option is splenectomy or splenic embolization to reduce hypersplenism. In addition to the risks associated with these techniques, reduced splenic blood flow can reduce portal vein flow with subsequent portal vein thrombosis. Results are mixed following insertion of a transjugular intrahepatic portosystemic shunt (TIPS). Therefore, treatment of thrombocytopenia should not be the primary indication for a TIPS procedure.

Decreased production or increased destruction of coagulation factors as well as vitamin K deficiency can all contribute to a prolonged PT and INR in patients with liver disease. As liver dysfunction worsens, so does the liver’s synthetic function, which results in decreased production of coagulation factors. Additionally, laboratory abnormalities may mimic those of DIC. Elevated D-dimers have been reported to increase the risk of variceal bleeding. The absorption of vitamin K is dependent on bile production. Therefore, liver patients with impaired bile production and cholestatic disease may be at risk for vitamin K deficiency.

Similar to thrombocytopenia, correction of coagulopathy should be reserved for treatment of active bleeding and prophylaxis for invasive procedures and surgery. Treatment of coagulopathy caused by liver disease is usually done with FFP, but because the coagulopathy is usually not a result of decreased levels of factor V, complete correction is not usually possible. If the fibrinogen is less than 200 mg/dL, administration of cryoprecipitate may be helpful. Cryoprecipitate is also a source of factor VIII for the rare patient with a low factor VIII level.

### Coagulopathy of Trauma

Traditional teaching regarding trauma-related coagulopathy attributed its development to acidosis, hypothermia, and dilution of coagulation factors. Recent data, however, have shown that over one-third of severely injured patients have laboratory-based evidence of coagulopathy at the time of admission, a phenotype called trauma-induced coagulopathy (TIC). TIC is independent of traditional (iatrogenic) causes of posttraumatic coagulopathy such as hemodilution, is precipitated by tissue injury and/or hemorrhagic shock, and is associated with significantly higher risk of mortality, especially in the first 24 hours after injury. Furthermore, TIC is a separate and distinct process from disseminated intravascular coagulopathy with its own specific components of hemostatic failure.

As shown in Fig. 4-5, several non–mutually exclusive mechanisms have been proposed as the etiology of TIC, including activated protein C-mediated clotting factor deactivation, endothelial injury and “auto-heparinization” due to shedding of endothelial heparin sulfate and chondroitin sulfate into the circulation, platelet dysfunction, and hyperfibrinolysis. Hemorrhagic shock was previously thought to be an essential component of TIC, but isolated traumatic brain injury and pulmonary contusions have been shown to induce laboratory-defined TIC in the absence of shock, possibly due to a high proportion of endothelium in these organs. Traumatic brain injury may also induce TIC via a consumptive mechanism by the release of large amounts of tissue factor into the circulation.
However, the relationship between laboratory-based coagulation abnormalities and true clinically evident coagulopathic bleeding is unclear. With the widespread application of damage control resuscitation, the frequency of clinical coagulopathy has decreased.

Interestingly, the converse of hyperfibrinolysis, known as fibrinolytic shutdown, has also been associated with increased mortality after trauma. In a multicenter study of 2540 trauma patients, those with intermediate fibrinolytic activity (“physiologic,” 0.8% to 2.9% lysis) had the lowest mortality (14%). Shutdown (<0.8% lysis) patients had increased mortality (22%), often due to late causes such as multiple organ failure, while patients with hyperfibrinolysis (≥3% lysis) had the greatest mortality (34%) and most often died due to hemorrhage.

**Acquired Coagulation Inhibitors**

Among the most common acquired coagulation inhibitors is the antiphospholipid syndrome (APLS), which includes the lupus anticoagulant and anticardiolipin antibodies. These antibodies may be associated with either venous or arterial thrombosis, or both. In fact, patients presenting with recurrent thrombosis should be evaluated for APLS. Antiphospholipid antibodies are very common in patients with systemic lupus but may also be seen in association with rheumatoid arthritis and Sjögren’s syndrome. There are also individuals who will have no autoimmune disorders but develop transient antibodies in response to infections or those who develop drug-induced APLS. The hallmark of APLS is a prolonged aPTT in vitro but an increased risk of thrombosis in vivo.

**Anticoagulation and Bleeding**

Spontaneous bleeding can be a complication of any anticoagulant therapy whether it is heparin, low molecular weight heparins, warfarin, factor Xa inhibitors, or new direct thrombin inhibitors. The risk of spontaneous bleeding related to heparin is reduced with a continuous infusion technique. Therapeutic anticoagulation is more reliably achieved with a low molecular weight heparin. However, laboratory testing is more challenging with these medications, as they are not detected with conventional coagulation testing. However, their more reliable therapeutic levels (compared to heparin) make them an attractive option for outpatient anticoagulation and more cost-effective for the inpatient setting. If monitoring is required (e.g., in the presence of renal insufficiency or severe obesity), the drug effect should be determined with an assay for anti-Xa activity.

Warfarin is used for long-term anticoagulation in various clinical conditions, including deep vein thrombosis, pulmonary embolism, valvular heart disease, atrial fibrillation, recurrent systemic emboli, recurrent myocardial infarction, prosthetic heart valves, and prosthetic implants. Due to the interaction of the P450 system, the anticoagulant effect of the warfarin is reduced (e.g., increased dose required) in patients receiving barbiturates as well as in patients with diets low in vitamin K. Increased warfarin requirements may also be needed in patients taking contraceptives or estrogen-containing compounds, corticosteroids, and adrenocorticotropic hormone (ACTH). Medications that can alter warfarin requirements are shown in Table 4-4.

Although warfarin use is often associated with a significant increase in morbidity and mortality in acutely injured and emergency surgery patients, with rapid reversal, these complications can be reduced. There are several reversal options that include vitamin K administration, plasma, cryoprecipitate, recombinant factor VIIa, and factor concentrates. The 2012 CHEST guidelines for the Management of Anticoagulant Therapy Antithrombotic Therapy and Prevention of Thrombosis recommends patients with major life-threatening bleeding

due to warfarin receive reversal with vitamin K and a rapid reversal agent such as plasma or prothrombin complex concentrate (PCC). Vitamin K is given to sustain the effects of the plasma or PCC due to their short half-lives. In major bleeds, vitamin K 10 mg given as a slow IV infusion is utilized for more rapid onset compared to the oral form. Studies have shown that PCC is superior to plasma for speed of reversal and has decreased risk of fluid overload, but it is equivalent in adverse and thromboembolic events and costlier. Prothrombin complex concentrate is available in two forms: three-factor PCC (factors II, IX, and X) and four-factor PCC (factors II, VII, IX, and X). Four-factor PCCs have shown to have a more reliable correction of INR compared to three-factor PCCs.

Direct oral anticoagulants (DOACs) include direct thrombin inhibitors and factor Xa inhibitors and have no readily available method of detection of the degree of anticoagulation. More concerning is the difficulty in the reversal of these new anticoagulants. Recently, idarucizumab, a humanized monoclonal antibody fragment that binds dabigatran, has been approved for use for reversal of the thrombin inhibitor, dabigatran, and dabigatran-related coagulopathy. Clinical studies have demonstrated normalization of laboratory tests.

Factor Xa inhibitors such as rivaroxaban, apixaban, and edoxaban currently lack a specific antidote. Two novel anticoagulants, andexanet alfa and ciraparantag (PER977), are currently undergoing clinical trials. Andexanet alfa is a recombinant human FXa variant, and ciraparantag is a cationic small molecule. These are both being evaluated for reversal of the factor Xa inhibitors. Until these agents are approved, attempts to reverse Factor Xa inhibitors should include four factor PCCs. In less urgent states, these drugs can be held for 36 to 48 hours prior to surgery without increased risk of bleeding in those with normal renal function. Alternatively, activated clotting time (stand alone or with rapid TEG) or ecarin clotting time can be obtained in those on dabigatran, and anti-factor Xa assays can be obtained in those taking rivaroxaban.

Bleeding complications in patients on anticoagulants include hematuria, soft tissue bleeding, intracerebral bleeding, skin necrosis, and abdominal bleeding. Bleeding secondary to anticoagulation therapy is also a common cause of rectus sheath hematomas.

Surgical intervention may prove necessary in patients receiving anticoagulation therapy. Increasing experience suggests that surgical treatment can be undertaken without full reversal of the anticoagulant, depending on the procedure being performed. When the aPTT is less than 1.3 times control in a heparinized patient, or when the INR is less than 1.5 in a patient on warfarin, reversal of anticoagulation therapy may not be necessary. However, meticulous surgical technique is mandatory, and the patient must be observed closely throughout the postoperative period.

Certain surgical procedures should not be performed in concert with anticoagulation. In particular, cases where even minor bleeding can cause great morbidity, such as the central nervous system and the eye, surgery should be avoided. Emergency operations are occasionally necessary in patients who have been heparinized. The first step in these patients is to discontinue heparin. For more rapid reversal, protamine sulfate is effective. However, significant adverse reactions, especially in patients with severe fish allergies, may be encountered when administering protamine. Symptoms include hypotension, flushing, bradycardia, nausea, and vomiting. Prolongation of the aPTT after heparin neutralization with protamine may also be a result of the anticoagulant effect of protamine. In the elective surgical patient who is receiving warfarin-derivative therapy sufficient to effect anticoagulation, the drug can be discontinued several days before operation and the prothrombin concentration then checked. Rapid reversal of anticoagulation can be accomplished with plasma or prothrombin complex concentrates in the emergent situation. An example of a warfarin reversal guideline using four-factor prothrombin complex concentrate for patients with major or life-threatening bleeding or intracranial bleeding is shown in Fig. 4-6. Parenteral administration of vitamin K also is indicated in elective surgical treatment of patients with biliary obstruction or malabsorption who may be vitamin K deficient. However, if low levels of factors II, VII, IX, and X (vitamin K–dependent factors) exist as a result of hepatocellular dysfunction, vitamin K administration is ineffective.

Cardiopulmonary Bypass. Under normal conditions, homeostasis of the coagulation system is maintained by complex interactions between the endothelium, platelets, and coagulation factors. In patients undergoing cardiopulmonary bypass (CPB), contact with circuit tubing and membranes results in abnormal platelet and clotting factor activation, as well as activation of inflammatory cascades, that ultimately results in excessive fibrinolysis and a combination of both quantitative and qualitative platelet defects. Platelets undergo reversible alterations in morphology and their ability to aggregate, which causes sequestration in the filter, partially degranulated platelets, and platelet fragments. This multifactorial coagulopathy is compounded by the effects of shear stress in the system, induced hypothermia, hemoïdilution, and anticoagulation. While on pump, activated clotting time measurements are obtained along with blood gas measurements; however, conventional coagulation assays and platelet counts are not normally performed until rewarming and after a standard dose of protamine has been given. TEG may give a better estimate of the extent of coagulopathy and may also be used to anticipate transfusion requirements if bleeding is present. Empiric treatment with FFP and cryoprecipitate is often used for bleeding patients; however, there are no universally accepted transfusion thresholds. Platelet concentrates are given for bleeding patients in the immediate postoperative period; however, studies have shown that indiscriminate platelet therapy conferred no therapeutic advantage. It is in these
patients where rapid coagulation testing is required to assist with directed transfusion therapy. Many institutions now use antifibrinolytics, such as ε-aminocaproic acid and tranexamic acid, at the time of anesthesia induction after several studies have shown that such treatment reduced postoperative bleeding and reoperation. Aprotinin, a protease inhibitor that acts as an antifibrinolytic agent, has been shown to reduce transfusion requirements associated with cardiac surgery. Desmopressin acetate stimulates release of factor VIII from endothelial cells and may also be effective in reducing blood loss during cardiac surgery.

**Local Hemostasis.** Significant surgical bleeding is usually caused by ineffective local hemostasis. The goal is therefore to prevent further blood loss from a disrupted vessel that has been incised or transected. Hemostasis may be accomplished by interrupting the flow of blood to the involved area or by direct closure of the blood vessel wall defect.

**Mechanical Procedures.** The oldest mechanical method of bleeding cessation is application of direct digital pressure, either at the site of bleeding or proximally to permit more definitive action. An extremity tourniquet that occludes a major vessel proximal to the bleeding site or the Pringle maneuver for liver bleeding are good examples. Direct digital pressure is very effective and has the advantage of being less traumatic than hemostatic or even “atraumatic” clamps.

When a small vessel is transected, a simple ligature is usually sufficient. However, for larger pulsating arteries, a transfixion suture to prevent slipping is indicated. All sutures represent foreign material, and selection should be based on their intrinsic characteristics and the state of the wound. Direct pressure applied by “packing” a wound with gauze or laparotomy pads affords the best method of controlling diffuse bleeding from large areas, such as in the trauma situation. Packing bone wax on the raw surface to effect pressure can control bleeding from cut bone.

**Thermal Agents.** Heat achieves hemostasis by denaturation of protein that results in coagulation of large areas of tissue. Electrocautery generates heat by induction from an alternating current source, which is then transmitted via conduction from the instrument directly to the tissue. The amplitude setting should be high enough to produce prompt coagulation, but not so high as to set up an arc between the tissue and the cautery tip. This avoids thermal injury outside of the operative field and also prevents exit of current through electrocardiographic leads, other monitoring devices, or permanent pacemakers or defibrillators. A negative grounding plate should be placed beneath the patient to avoid severe skin burns, and caution should be used with certain

**Figure 4-6.** Example of a warfarin reversal guideline using four-factor prothrombin complex concentrate for patients with major or life-threatening bleeding or intracranial bleeding.
anesthetic agents (diethyl ether, divinyl ether, ethyl chloride, ethylene, and cyclopropane) because of the hazard of explosion.

A direct current also can result in hemostasis. Because the protein moieties and cellular elements of blood have a negative surface charge, they are attracted to a positive pole where a thrombus is formed. Direct currents in the 20- to 100-mA range have successfully controlled diffuse bleeding from raw surfaces, as has argon gas.

**Topical Hemostatic Agents**

Topical hemostatic agents can play an important role in helping to facilitate surgical hemostasis. These agents are classified based on their mechanism of action, and many act at specific stages in the coagulation cascade and take advantage of natural physiologic responses to bleeding. The ideal topical hemostatic agent has significant hemostatic action, minimal tissue reactivity, nonantigenicity, in vivo biodegradability, ease of sterilization, low cost, and can be tailored to specific needs.

Achneck et al have published a comprehensive overview of absorbable, biologic, and synthetic agents. Absorbable agents include gelatin foams (Gelfoam), oxidized cellulose (Surgicel), and microfibrillar collagens (Avitene). Both gelatin foam and oxidized cellulose provide a physical matrix for clotting initiation, while microfibrillar collagens facilitate platelet adherence and activation. Biologic agents include topical thrombin, fibrin sealants (FloSeal), and platelet sealants (Vitargel). Human or recombinant thrombin derivatives, which facilitate the formation of fibrin clots and subsequent activation of several clotting factors, take advantage of natural physiologic processes, thereby avoiding foreign body or inflammatory reactions. Caution must be taken in judging vessel caliber in the wound because thrombin entry into larger caliber vessels can result in systemic exposure to thrombin with a risk of disseminated intravascular clotting or death. They are particularly effective in controlling capillary bed bleeding when pressure or ligation is insufficient; however, the bovine derivatives should be used with caution due to the potential immunologic response and worsened coagulopathy. Fibrin sealants are prepared from cryoprecipitate (homologous or synthetic) and have the advantage of not promoting inflammation or tissue necrosis. A recent study by Koea et al demonstrated in a prospective multicenter randomized trial that a fibrin sealant patch was safe and highly effective in controlling parenchymal bleeding following hepatectomy regardless of the type of resection. Platelet sealants are a mixture of collagen and thrombin combined with plasma-derived fibrinogen and platelets from the patient, which requires the additional need for centrifugation and processing.

Topical agents are not a substitute for meticulous surgical technique and only function as adjuncts to help facilitate surgical hemostasis. The advantages and disadvantages of each agent must be considered, and use should be limited to the minimum amount necessary to minimize toxicity, adverse reactions, interference with wound healing, and procedural costs.

**Replacement Therapy**

**Typing and Crossmatching.** Serologic compatibility for A, B, O, and Rh groups is established routinely. Crossmatching between the donors’ red blood cells and the recipients’ sera (the major crossmatch) is performed. Rh-negative recipients should be transfused only with Rh-negative red blood cells. However, this group represents only 15% of the population. Therefore, the administration of Rh-positive red blood cells is acceptable if Rh-negative red blood cells blood is not available. However, Rh-positive red blood cells should not be transfused to Rh-negative females who are of childbearing age.

In emergency situations, universal donor type O-negative red blood cells and type AB plasma may be transfused to all recipients. Platelets do not require crossmatching. Due to a shortage of type AB plasma, low anti-B titer type A plasma has become widely adopted for emergency (uncrossmatched) transfusion. In the United States, 85% of individuals are type A or type O, making type AB plasma compatible with the vast majority of potential recipients. Uncrossmatched plasma is routinely transfused as part of platelet transfusions, with major transfusion reactions reported rarely, and type AB plasma currently carries a higher risk of TRALI compared to other plasma types. Many centers have transitioned to low titer type A plasma for emergency transfusions, with no increase in adverse events. O negative and type-specific red blood cells are equally safe for emergency transfusion. In patients known to have clinically significant cold agglutinins, blood should be administered through a blood warmer. If these antibodies are present in high titer, hypothermia is contraindicated.

In patients who have been multiply transfused and who have developed alloantibodies or who have autoimmune hemolytic anemia with pan-red blood cell antibodies, typing and crossmatching is often difficult, and sufficient time should be allotted preoperatively to accumulate blood that might be required during the operation. Crossmatching should always be performed before the administration of dextran because it interferes with the typing procedure.

**Banked Whole Blood.** Interest in whole blood as an ideal therapy for acute traumatic hemorrhagic shock has increased in the last several years with multiple reports of successful use in military and civilian trauma patients. However, there is still limited access in most civilian centers.

**Red Blood Cells and Frozen Red Blood Cells.** Red blood cells are the traditional product of choice for most clinical
situations requiring resuscitation, although deficits in oxygen delivery are rarely related to inadequate red cells. Concentrated suspensions of red blood cells can be prepared by removing most of the supernatant plasma after centrifugation. The preparation reduces but does not eliminate reactions caused by plasma components. With sequential changes in storage solutions, the shelf life of red blood cells is now 42 days. However, recent evidence has demonstrated that the age of red cells may play a significant role in the inflammatory response and incidence of multiple organ failure. The changes in the red blood cells that occur during storage include reduction of intracellular ADP and 2,3-diphosphoglycerate (2,3-DPG), which alters the oxygen dissociation curve of hemoglobin, resulting in a decrease in oxygen transport. Stored RBCs progressively become acidic with elevated levels of lactate, potassium, and ammonia. Additionally, the in vitro hemostatic potential of plasma and platelet products also decrease with storage.

The morphologic and biochemical changes that occur over time in red cells may contribute to worsened outcomes. This limits the ability to bank large amounts of blood, particularly rarer blood types, for use in times of high demand and blood supply shortage, such as on the battlefield and after mass casualty events. Storage solutions, however, do not fully suppress the metabolic and physical changes associated with aging RBCs. Newer evidence suggests that cryopreservation of red blood cells may provide a safe alternative means of storage. Cryopreservation uses the beneficial effects of ultra-low temperatures to suppress molecular motion and arrest metabolic and biochemical reactions. Frozen (cryopreserved) red blood cells have a shelf life of ten years at −80°C with improved cellular viability and maintenance of ATP and 2,3 DPG concentrations. A trial of stable trauma patients randomized to old (>14 storage days) red blood cells, young (≤14 storage days) red blood cells, and cryopreserved red blood cells found that cryopreserved red blood cells were as safe and effective as standard red blood cells. Cryopreserved red blood cells required a thawing and preparation period of about 90 minutes, limiting immediate availability for emergency use. A recent study suggests that the post-thaw characteristics of cryopreserved units may not, however, be comparable to fresh red cells. Additional research needs to be done to optimize the process, but frozen cells likely represent a viable option for storage in the future.

**Leukocyte-Reduced and Leukocyte-Reduced/Washed Red Blood Cells.** These products are prepared by filtration that removes about 99.9% of the white blood cells and most of the platelets (leukocyte-reduced red blood cells) and, if necessary, by additional saline washing (leukocyte-reduced/washed red blood cells). Leukocyte reduction prevents almost all febrile, nonhemolytic transfusion reactions (fever and/or rigors), alloimmunization to HLA class I antigens, and platelet transfusion refractoriness and cytomegalovirus transmission. In most Western nations, it is the standard red blood cell transfusion product. Supporters of universal leukocyte reduction argue that allogenic transfusion of white cells predisposes to postoperative bacterial infection and multiorgan failure. Reviews of randomized trials and meta-analyses have not provided convincing evidence either way, although a large Canadian retrospective study suggests a decrease in mortality and infections.

**Platelet Concentrates.** The indications for platelet transfusion include thrombocytopenia caused by massive blood loss and replacement with platelet-poor products, thrombocytopenia caused by inadequate production, and qualitative platelet disorders. Platelets are stored at room temperature under constant agitation to prevent clumping and have a shelf life of 5 days from time of donation due to risk of bacterial overgrowth. One unit of platelet concentrate has a volume of approximately 50 mL. Platelet preparations are capable of transmitting infectious diseases and can account for allergic reactions similar to those caused by red blood cell transfusion. A therapeutic level of platelets is in the range of 50,000 to 100,000/μL, but is very dependent on the clinical situation. Recent evidence suggests that earlier use of platelets may improve outcomes in bleeding patients.

In rare cases, in patients who become alloimmunized through previous transfusion or patients who are refractory from sensitization through prior pregnancies, HLA-matched platelets can be used.

**Plasma.** Plasma is the usual source of the vitamin K–dependent factors, the only source of factor V, and carries similar infectious risks as other component therapies. Several plasma products are available. Fresh frozen plasma (FFP) is frozen within hours of donation and can be stored for up to two years at −18°C, but requires 20 to 30 minutes to thaw prior to use, limiting immediate availability. Thawed FFP can be relabeled as thawed plasma, which is immediately transfusable and can be stored for up to 5 days at 2°C to 4°C. Liquid plasma is never frozen and can be stored for up to 26 days at 2°C to 4°C. In vitro studies demonstrate that liquid plasma has a better hemostatic profile than thawed plasma. Freeze-dried (lyophilized) plasma (FDP) has been recently “rediscovered” as an ideal resuscitation product for patients in remote and austere environments. FDP is distributed as a powder that is shelf-stable for up to 2 years at room temperature and relatively stable at temperature extremes. It was used extensively as a primary resuscitation fluid during World War II, but production was stopped due to risk of disease transmission. FDP is currently manufactured by updated processes in France, Germany, and South Africa. Several noncomparative studies in the literature have documented its ease of use, rapid reconstitution within minutes, clinical efficacy similar to other plasma products, and lack of apparent adverse events. The Israeli Defense Force has reported successful use of FDP at the point of injury, just as it was used in World War II. Beside limited use by U.S. Special Forces under the U.S. Federal Drug Administration’s (FDA) Investigational New Drug (IND) program, no FDP product is currently approved for general use in the United States. These products have the advantage of being pathogen reduced, have expanded storage capabilities, and can be quickly reconstituted.

**Tranexamic Acid.** Tranexamic acid (TXA; trade name: Cyclokapron) is an antifibrinolytic that inhibits both plasminogen activation and plasmin activity, thus preventing clot breakdown rather than promoting new clot formation. It occupies the lysine-binding sites on plasminogen, thus preventing its binding to lysine residues on fibrin. This reduces plasminogen activation to plasmin. Similarly, blockade of lysine-binding sites on circulating plasmin prevents binding to fibrin and thus prevents clot breakdown. TXA is 10 times more potent in vitro than aminocaproic acid. At therapeutically relevant concentrations, TXA does not affect platelet count or aggregation or coagulation parameters. It is excreted largely unchanged in urine and has a half-life of about 2 hours in circulation. It has been used to decrease bleeding and the need for blood transfusions in coronary artery
bypass grafting (CABG), orthotopic liver transplantation, hip and knee arthroplasty, and other surgical settings. TXA has been used to treat injured patients in both civilian and military settings. A recent practice guideline by the Eastern Association for the Surgery of Trauma (EAST) conditionally recommended the use of tranexamic acid as a hemostatic adjunct in severely injured patients when used early after injury. There is some controversy if its use should be empiric in patients with hemorrhage or based on documented hyperfibrinolysis. Results of prehospital studies with TXA are not yet available, but there are five ongoing trials. The true risk of venous thrombotic events is also not well established. Therefore, tranexamic acid should not be used with active intravascular clotting and should not be given with activated prothrombin complex concentrate or factor IX complex concentrates.

Indications for Replacement of Blood and Its Elements

Improvement in Oxygen-Carrying Capacity. Oxygen-carrying capacity is primarily a function of the red blood cells. Thus, transfusion of red blood cells should augment oxygen-carrying capacity. Additionally, hemoglobin is fundamental to arterial oxygen content and thus oxygen delivery. Despite this obvious association, there is little evidence that actually supports the premise that transfusion of red blood cells equates with enhanced cellular delivery and utilization. The reasons for this apparent discrepancy are related to changes that occur with storage of blood. The decrease in 2,3-DPG and P50 impair oxygen offloading, and deformation of the red cells impairs microcirculatory perfusion.

Treatment of Anemia: Transfusion Triggers. The concept of transfusion triggers refers primarily to the nonactively bleeding ICU patient. A 1988 National Institutes of Health Consensus Report challenged the dictum that a hemoglobin value of less than 10 g/dL or a hematocrit level less than 30% indicates a need for preoperative red blood cell transfusion. This was verified in a prospective randomized controlled trial in critically ill patients that compared a restrictive transfusion threshold to a more liberal strategy and demonstrated that maintaining hemoglobin levels between 7 and 9 g/dL had no adverse effect on mortality. In fact, patients with APACHE II scores of ≤20 or patients age <55 years actually had a lower mortality.

One unresolved issue related to transfusion triggers is the safety of maintaining a hemoglobin of 7 g/dL in a patient with ischemic heart disease. Data on this subject are mixed, and many studies have significant design flaws, including their retrospective nature. However, the majority of the published data favors a restrictive transfusion trigger for patients with non-ST-elevation acute coronary syndrome, with many reporting worse outcomes in those patients receiving transfusions. Recent guidelines from the American Association of Blood Banks (AABB) recommend a minimum threshold of 7 g/dL for hemodynamically stable patients and 8 g/dL for patients undergoing cardiac surgery, orthopedic surgery, and those with pre-existing cardiovascular disease. However, both the SCCM/EAST and AABB guidelines recommend taking into account patient-specific characteristics and the overall clinical context when considering RBC transfusions in non-acuteley hemorrhaging patients. Patients with symptomatic anemia should be transfused one RBC unit at a time, and isolated asymptomatic anemia in and of itself is rarely an indication for RBC transfusion.

Volume Replacement

The most common indication for blood transfusion in surgical patients is the replenishment of the blood volume; however, the quantification of actual intravascular volume deficit is often difficult to accurately and quickly determine. Measurements of hemoglobin or hematocrit levels are frequently used to assess blood loss, but can be occasionally misleading in the face of acute loss. Both the amount and the rate of bleeding are factors in the development of signs and symptoms of blood loss.

Loss of blood in the operating room can be roughly evaluated by estimating the amount of blood in the wound and on the drapes, weighing the sponges, and quantifying blood suctioned from the operative field. Significant blood loss will require a balanced resuscitation including red blood cells, FFP, and platelets (detailed later in this chapter) (Table 4-5).

New Concepts in Resuscitation

Traditional resuscitation algorithms were sequentially based on crystalloid followed by red blood cells and then plasma and platelet transfusions, and they have been in widespread use since the 1970s. No quality clinical data supported this concept. Recently the damage control resuscitation (DCR) strategy, with simultaneous measures to acquire mechanical hemorrhage control, has become the standard for treatment of substantial traumatic hemorrhage. DCR emphasizes rapid maneuvers that promote hemostasis (balanced resuscitation with early delivery of plasma and platelets) while limiting iatrogenic insults that exacerbate bleeding (i.e., minimization of crystalloid and artificial colloid, permissive hypotension), combined with multiple adjuncts for hemorrhage control.

Rationale. In urban civilian trauma systems, nearly half of all deaths happen before a patient reaches the hospital. Patients who survive to an emergency center have a high incidence of truncal hemorrhage, and deaths in this group of patients may be potentially preventable. Truncal hemorrhage patients in shock often present with the early coagulopathy of trauma in the emergency department and are at significant risk of dying. Many of these patients have suffered substantial bleeding, generally defined as requiring the administration of ≥3 units of red blood cells within any hour of admission, and may have received a massive transfusion (MT), traditionally defined as ≥10 units of red blood cells in 24 hours. The traditional definition is admittedly arbitrary and fails to identify many patients who truly receive large volume transfusions in a short period of time, further promoting survival bias. Newer definitions evaluating massive transfusion do so by taking into account both volume transfused as well as the rate at which transfusions are given. The critical administration threshold (CAT) has been prospectively validated and shown to be a superior predictor of mortality when compared to the conventional definition of MT. By this measure, CAT-positive status is defined by transfusion of 3 units of red blood cells within a 60-minute period, and this is additive for each additional time this measure is reached. CAT-positive status is associated with a two-fold increase in risk of mortality. CAT is more sensitive than traditional definitions of bleeding and allows for both earlier and more accurate identification of injured patients at greatest risk of death.

Although 25% of all severely injured trauma admissions receive a unit of blood early after admission, only a small

percentage of patients receive a massive transfusion. In the military setting, the percentage of massive transfusion patients almost doubles.111

**Damage Control Resuscitation.** Prior to DCR, resuscitation guidelines advocated volume replacement with crystalloid, followed by packed red blood cell and only later plasma or platelets.112 This conventional massive transfusion practice was based on a several small uncontrolled retrospective studies that used blood products containing increased amounts of plasma, which are no longer available.113 Because of the known early coagulopathy of trauma, the current approach to managing the exsanguinating patient involves early implementation of DCR.

Although most of the attention to hemorrhagic shock resuscitation has centered on higher ratios of plasma and platelets, DCR is actually composed of four basic components: permissive hypotension, minimizing crystalloid-based resuscitation, the immediate release and administration of predefined balanced blood products (red blood cells, plasma, and platelets) in ratios similar to those of whole blood, and the use of hemostatic adjuncts.

The shift to DCR began in earnest in 2007 when a retrospective study of 246 military casualties reported that patients with high plasma:RBC ratio (median 1:1.4) had substantially reduced mortality (19% vs. 65%) compared to patients with low plasma:RBC ratio (median 1:8).114 Subsequent observational studies among civilian and military trauma patients corroborated these findings.115-118 In particular, the prospective, observational, multicenter, major trauma transfusion (PROMMTT) study119 found that hemorrhagic death occurred rapidly (median of 2 to 3 hours after hospital arrival) and that plasma:RBC and platelet:RBC ratios significantly varied during massive transfusion. Increased plasma:RBC (adjusted hazard ratio [HR] 0.31, 95% confidence interval [CI] 0.16-0.58) and increased platelet:RBC (adjusted HR 0.55, 95% CI 0.31-0.98) were associated with reduced 6-hour mortality, when risk of hemorrhagic death was highest. After 6 hours, however, increasing plasma:RBC and platelet:RBC were no longer associated with reduced mortality due to increasing competing risk for non-hemorrhagic death (e.g., traumatic brain injury). The Pragmatic Randomized Optimal Platelet and Plasma Ratios (PROPR) trial120 randomized 680 bleeding trauma patients across 12 highest-level trauma centers to resuscitation with 1:1:1 vs. 1:1:2 plasma to platelets to RBCs. Although there was no significant difference in mortality at 24 hours (13% vs. 17%) or 30 days (22% vs. 26%), the 1:1:1 group had significantly decreased mortality due to hemorrhage at 24 hours (9% vs. 15%) and more patients achieving hemostasis (86% vs. 78%). Despite fears that resuscitation with increased plasma volumes would lead to more inflammatory complications, there were no between-group differences in 23 prespecified secondary outcomes, including acute respiratory distress syndrome, sepsis, multiple organ failure, and venous thromboembolism. A recent systematic review/meta-analysis and practice management guideline from EAST reported reduced mortality (31% vs. 38%) in 5292 patients receiving high (≥1:1) versus low (<1:2) plasma to RBC, and reduced mortality (28% vs. 43%) in 1607 patients receiving high versus low platelet to RBC.121 The authors therefore recommend high and balanced ratio (≥1:1) of plasma and platelet to RBC for resuscitation of severely injured trauma patients.

The mechanism for these benefits are unclear. While correction of hypovolemia as well as augmentation of the patient’s hemostatic potential with clotting factors and platelets are important, other plasma proteins likely play key roles as well. Recently, plasma resuscitation has been shown to reverse endothelial injury in animal models of hemorrhagic shock, particularly by repair of the endothelial glycocalyx layer (EGL).122,123 The EGL is the primary determinant of vascular permeability.122 Hemorrhage results in shedding of EGL components and vascular permeability. Crystalloid and artificial colloid-based resuscitation increases the hydrostatic pressure without repairing the EGL, which likely contributes to the myriad of edema-related complications seen in the pre-DCR era. Plasma, on the other hand, repairs the EGL, limiting extravascular leakage and edema. However, the exact protein moieties that mediate these benefits have yet to be identified and remain an area of investigation. Nevertheless, several studies have reported decreased inflammatory and edema-related complications with increased plasma and decreased crystalloid utilization. In trauma patients, there are strong correlations between increasing circulating levels of glycocalyx components such as syndecan-1 and trauma severity, coagulopathy, and mortality,124-126 although it remains unclear if these relationships are causative or merely associative. Finally, the use of DCR principles to guide transfusion of substantial nontraumatic hemorrhage is intuitive, although there is little evidence in the literature to support this practice.

It is essential that the trauma center has an established mechanism to deliver these products quickly and in the correct amounts to these critically injured patients.99 An example of an adult massive transfusion clinical guideline specifying the early use of component therapy is shown in Table 4-6. Specific recommendations for the administration of component therapy during a massive transfusion are shown in Table 4-7.

Because only a small percentage of trauma patients require a massive transfusion and because blood products in general are in short supply, there is a need for early prediction models.127 A comparison of results from existing models in both civilian and military studies is shown in Table 4-8.128-132 While compelling, many of these models require laboratory data, complicated injury severity scores, or calculated values that are not readily available or feasible to obtain in the urgent setting of bleeding. The Assessment of Blood Consumption (ABC) score is a simplified score to predict massive transfusion after trauma using immediately available data (heart rate, blood pressure, FAST exam, mechanism of injury).128 The ABC score has been validated across multiple trauma centers; however, it may be limited in some centers by the variable use of and operator-dependent FAST examination. In using the ABC score as it was intended, less than 5% of patients who will require massive transfusion will be missed; and 85% of all major trauma patients will be correctly identified.

**Prehospital Transfusion**

In bleeding patients, earlier initiation of appropriate therapy improves outcomes. For example, decreased overall blood product use and increased 30-day survival was observed after moving four units of universal donor, ready-to-transfuse plasma from the blood bank to the emergency department and using the plasma as a primary resuscitation fluid.133 A prehospital retrospective study that analyzed 1677 severely injured trauma patients who were transported by helicopter found that in-flight plasma transfusion was associated with less deranged physiology on admission and reduced early mortality in the most critically ill patients.134 Prehospital RBC transfusion has also been...
A. Initial Transfusion of Red Blood Cells (RBCs):
1. Notify blood bank immediately of urgent need for RBCs.
   - O negative uncrossmatched (available immediately).
   - As soon as possible, switch to O negative for females and O positive for males.
   - Type-specific uncrossmatched (available in approximately 5–10 min).
   - Completely crossmatched (available in approximately 40 min).
2. A blood sample must be sent to blood bank for a type and cross.
3. The Emergency Release of Blood form must be completed. If the blood type is not known and blood is needed immediately, O-negative RBCs should be issued.
4. RBCs will be transfused in the standard fashion. All patients must be identified (name and number) prior to transfusion.
5. Patients who are unstable or receive 1–2 RBCs and do not rapidly respond should be considered candidates for the massive transfusion (MT) guideline.

B. Adult Massive Transfusion Guideline:
1. The Massive Transfusion Guideline (MTG) should be initiated as soon as it is anticipated that a patient will require massive transfusion. The blood bank should strive to deliver plasma, platelets, and RBCs in a 1:1:1 ratio. To be effective and minimize further dilutional coagulopathy, the 1:1:1 ratio must be initiated early, ideally with the first 2 units of transfused RBCs. Crystalloid infusion should be minimized.
2. Once the MTG is activated, the blood bank will have 6 RBCs, 6 FFP, and a 6-pack of platelets packed in a cooler available for rapid transport. If 6 units of thawed FFP are not immediately available, the blood bank will issue units that are ready and notify appropriate personnel when the remainder is thawed. Every attempt should be made to obtain a 1:1:1 ratio of plasma:platelets:RBCs.
3. Once initiated, the MT will continue until stopped by the attending physician. MT should be terminated once the patient is no longer actively bleeding.
4. No blood components will be issued without a pickup slip with the recipient’s medical record number and name.
5. Basic laboratory tests should be drawn immediately on ED arrival and optimally performed on point-of-care devices, facilitating timely delivery of relevant information to the attending clinicians. These tests should be repeated as clinically indicated (e.g., after each cooler of products has been transfused). Suggested laboratory values are:
   - CBC
   - INR, fibrinogen
   - pH and/or base deficit
   - TEG, where available

CBC = complete blood count; ED = emergency department; FFP = fresh frozen plasma; INR = international normalized ratio; TEG = thromboelastography.

associated with similar findings. In the military setting, implementation of prehospital transfusion protocols in conjunction with other measures, including more rapid transport times, was also associated with reduced mortality.

Whole Blood Resuscitation
Military experience with whole blood for the resuscitation of traumatic hemorrhage is extensive, going back to the American Civil War. In the modern era, more than 10,000 whole blood units were transfused during Operations Enduring Freedom and Iraqi Freedom. One key advantage of whole blood versus component therapy is that platelets are often unavailable in the remote and austere settings. Two retrospective studies of military casualties treated at a combat support hospital and forward surgical teams found that whole blood was associated with improved survival compared to component (plasma and RBC) therapy. Whole blood has higher hematocrit, clotting factor activity, and platelet count compared to 1:1:1 component therapy due to relatively less diluent volume in whole blood. During the Vietnam War, low anti-A and anti-B titer whole blood was transfused universally with a low incidence of hemolytic reactions (1 per 9600 units). An in vitro study found that the hemostatic potential of whole blood was preserved for up to 14 days with cold storage. Pilot trials have reported successful use of crossmatched modified whole blood (leukoreduced and platelet-poor) and uncrossmatched low-titer whole blood (leukoreduced, containing platelets) in the initial resuscitation of civilian trauma patients. In the future, whole blood may return as the therapy of choice for the initial resuscitation of substantial hemorrhage.

Fibrinogen Replacement
Fibrinogen is the first coagulation factor to fall to critically low levels during major hemorrhage, and low systemic concentrations of fibrinogen are associated with increased severity of injury and coagulopathy and are independently predictive of mortality. Additionally, fibrinogen levels drop in the prehospital phase of injury, suggesting early administration by fibrinogen concentrate (not FDA-approved) or cryoprecipitate is needed. Fibrinogen concentrate is stored as a lyophilized powder at room temperature and can be reconstituted quickly allowing for rapid administration without delays for thawing or crossmatching. In contrast to plasma, viral inactivation steps are routinely included in the manufacturing process for fibrinogen concentrate, thus minimizing the risk of viral transmission. A pilot trial of massively transfused trauma patients randomized to a massive transfusion protocol or a massive transfusion protocol with early cryoprecipitate found that early cryoprecipitate delivery was feasible and that these patients had higher fibrinogen levels at all time points during resuscitation, although there was no mortality difference. A randomized control trial in Austria of prehospital fibrinogen concentrate versus placebo has been completed with publication of results pending.

Complications of Transfusion (Table 4-9)
Transfusion-related complications are primarily related to blood-induced proinflammatory responses. Transfusion-related events are estimated to occur in approximately 10% of all transfusions, but less than 0.5% are serious in nature. Transfusion-related deaths, although exceedingly rare, do occur and are related primarily to transfusion-related acute lung injury (TRALI), ABO hemolytic transfusion reactions, and bacterial contamination of platelets.

Nonhemolytic Reactions. Febrile, nonhemolytic reactions are defined as an increase in temperature (>1°C) associated with a transfusion and are fairly common (approximately 1% of all transfusions). Preformed cytokines in donated blood and recipient antibodies reacting with donated antibodies are postulated etiologies. The incidence of febrile reactions can be greatly reduced by the use of leukocyte-reduced blood products. Pretreatment with acetaminophen reduces the severity of the reaction. Bacterial contamination of infused blood is rare. Gram-negative organisms, which are capable of growth at 4°C, are the most common cause. Most cases, however, are associated with the administration of platelets that are stored at 20°C or, even more commonly, with apheresis platelets stored at room temperature. Cases from FFP thawed in contaminated water baths have also been reported. Bacterial contamination can result in sepsis and death in up 25% of patients. Clinical manifestations include systemic signs such as fever and chills, tachycardia and hypotension, and gastrointestinal symptoms (abdominal cramps, vomiting, and diarrhea). If the diagnosis is suspected, the transfusion should be discontinued and the blood cultured. Emergency treatment includes oxygen, adrenergic blocking agents, and antibiotics.

Allergic Reactions. Allergic reactions are relatively frequent, occurring in about 1% of all transfusions. Reactions are usually mild and consist of rash, urticaria, and flushing. In rare instances, anaphylactic shock develops. Allergic reactions are caused by the transfusion of antibodies from hypersensitive donors or the transfusion of antigens to which the recipient is hypersensitive. Allergic reactions can occur after the administration of any blood product but are commonly associated with FFP and platelets. Treatment and prophylaxis consist of the administration of antihistamines. In more serious cases, epinephrine or steroids may be indicated.

Respiratory Complications. Respiratory compromise may be associated with transfusion-associated circulatory overload (TACO), which is an avoidable complication. It can occur with rapid infusion of blood, plasma expanders, and crystalloids, particularly in older patients with underlying heart disease. Central venous pressure monitoring should be considered whenever large amounts of fluid are administered. Overload is manifested by a rise in venous pressure, dyspnea, and cough. Rales can generally be heard at the lung bases. Treatment consists of diuresis, slowing the rate of blood administration, and minimizing fluids while blood products are being transfused.

The syndrome of TRALI is defined as noncardiogenic pulmonary edema related to transfusion. It can occur with the administration of any plasma-containing blood product. Symptoms are similar to circulatory overload with dyspnea and associated hypoxemia. However, TRALI is characterized as noncardiogenic and is often accompanied by fever, rigors, and bilateral pulmonary infiltrates on chest X-ray. It most commonly occurs within 1 to 2 hours after the onset of transfusion but virtually always before 6 hours. Toy et al reported a decrease in the incidence of TRALI with the reduction transfusion of plasma from female donors, due to a combination of reduced transfusion of strong cognate HLA class II antibodies and HNA antibodies in patients with risk factors for acute lung injury. TRALI now occurs less than 1 in 10,000 units transfused and is usually self-limited with supportive therapy. Treatment of TRALI entails discontinuation of any transfusion, notification of the transfusion service, and pulmonary support, which may vary from supplemental oxygen to mechanical ventilation.
Hemolytic Reactions. Hemolytic reactions can be classified as either acute or delayed. Acute hemolytic reactions occur with the administration of ABO-incompatible blood and can be fatal in up to 6% of cases. Contributing factors include errors in the laboratory of a technical or clerical nature or the administration of the wrong blood type. Immediate hemolytic reactions are characterized by intravascular destruction of red blood cells and consequent hemoglobinemia and hemoglobinuria. DIC can be initiated by antibody-antigen complexes activating factor XII and complement, leading to activation of the coagulation cascade. Finally, acute renal insufficiency results from the toxicity associated with free hemoglobin in the plasma, resulting in tubular necrosis and precipitation of hemoglobin within the tubules.

Delayed hemolytic transfusion reactions occur 2 to 10 days after transfusion and are characterized by extravascular hemolysis, mild anemia, and indirect (unconjugated) hyperbilirubinemia. They occur when an individual has a low antibody titer at the time of transfusion, but the titer increases after transfusion as a result of an anamnestic response. Reactions to non-ABO antigens involve immunoglobulin G-mediated clearance by the reticuloendothelial system.

If the patient is awake, the most common symptoms of acute transfusion reactions are pain at the site of transfusion, facial flushing, and back and chest pain. Associated symptoms include fever, respiratory distress, hypotension, and tachycardia. In anesthetized patients, diffuse bleeding and hypotension are the hallmarks. A high index of suspicion is needed to make the diagnosis. The laboratory criteria for a transfusion reaction are hemoglobinuria and serologic criteria that show incompatibility of the donor and recipient blood. A positive Coombs’ test indicates
transfused cells coated with patient antibody and is diagnostic. Delayed hemolytic transfusions may also be manifested by fever and recurrent anemia. Jaundice and decreased haptoglobin usually occur, and low-grade hemoglobinemia and hemoglobinuria may be seen. The Coombs’ test is usually positive, and the blood bank must identify the antigen to prevent subsequent reactions.

If an immediate hemolytic transfusion reaction is suspected, the transfusion should be stopped immediately, and a sample of the recipient’s blood drawn and sent along with the suspected unit to the blood bank for comparison with the pretransfusion samples. Urine output should be monitored and adequate hydration maintained to prevent precipitation of hemoglobin within the tubules. Delayed hemolytic transfusion reactions do not usually require specific intervention.

**Transmission of Disease.** Malaria, Chagas’ disease, brucellosis, and, very rarely, syphilis are among the diseases that have been transmitted by transfusion. Malaria can be transmitted by all blood components. The species most commonly implicated is *Plasmodium malariae*. The incubation period ranges from 8 to 100 days; the initial manifestations are shaking chills and spiking fever. Cytomegalovirus (CMV) infection resembling infectious mononucleosis also has occurred.

Transmission of hepatitis C and HIV-1 has been dramatically minimized by the introduction of better antibody and nucleic acid screening for these pathogens. The residual risk among allogeneic donations is now estimated to be less than 1 per 1,000,000 donations. The residual risk of hepatitis B is approximately 1 per 300,000 donations. Hepatitis A is very rarely transmitted because there is no asymptomatic carrier state. Improved donor selection and testing are responsible for the decreased rates of transmission. Recent concerns about the rare transmission of these and other pathogens, such as West Nile virus, are being addressed by current trials of “pathogen inactivation systems” that reduce infectious levels of all viruses and bacteria known to be transmittable by transfusion. Prion disorders (e.g., Creutzfeldt-Jakob disease) also are transmissible by transfusion, but there is currently no information on inactivation of prions in blood products for transfusion.

Recently, there is heightened concern of transmission of Zika virus by blood product transfusion. Studies in endemic areas have shown rates of Zika infection detected in donor blood as high as 2.8%. Although no such cases have been reported in the United States, transmission of Zika virus via platelet products have been reported in Brazil. Zika virus may result in serious birth defects including microcephaly when infection occurs in pregnant women. Because the majority of cases in adults produce nonspecific or no symptoms, Zika screening cannot be accomplished by questionnaires. The Centers for Disease Control and Prevention has issued guidelines for screening of Zika virus in donated blood. Although no tests have been FDA-approved, laboratory testing is currently being performed under the FDA’s IND program.

**Tests of Hemostasis and Blood Coagulation**

The initial approach to assessing hemostatic function is a careful review of the patient’s clinical history (including previous abnormal bleeding or bruising), drug use, and basic laboratory testing.

**Conventional Coagulation Tests.** Common screening laboratory testing includes platelet count, PT or INR, and aPTT. Platelet dysfunction can occur at either extreme of platelet count. The normal platelet count ranges from 150,000 to 400,000/μL. Whereas a platelet count greater than 1,000,000/μL may be associated with bleeding or thrombotic complications, increased bleeding complications may be observed with major surgical procedures when the platelets are below 50,000/μL and with minor surgical procedures when counts are below 30,000/μL, and spontaneous hemorrhage can occur when the counts fall below 20,000/μL. Despite a lack of evidence supporting their use, platelet transfusions are still recommended in ophthalmologic and neurosurgical procedures when the platelet count is less than 100,000/μL.

The PT and aPTT are variations of plasma recalcification times initiated by the addition of a thromboplastin agent. The PT reagent contains thromboplastin and calcium that, when added to plasma, leads to the formation of a fibrin clot. The PT test measures the function of factors I, II, V, VII, and X. Factor VII is part of the extrinsic pathway, and the remaining factors are part of the common pathway. Factor VII has the shortest half-life of the coagulation factors, and its synthesis is vitamin K dependent. The PT test is best suited to detect abnormal coagulation caused by vitamin K deficiencies and warfarin therapy.

Due to variations in thromboplastin activity, it can be difficult to accurately assess the degree of anticoagulation on the basis of PT alone. To account for these variations, the INR is now the method of choice for reporting PT values. The International Sensitivity Index (ISI) is unique to each batch of thromboplastin and is furnished by the manufacturer to the hematology laboratory. Human brain thromboplastin has an ISI of 1, and the optimal reagent has an ISI between 1.3 and 1.5.

The INR is a calculated number derived from the following equation:

\[
\text{INR} = \frac{\text{measured PT}}{\text{normal PT}}^{\text{ISI}}
\]

The aPTT reagent contains a phospholipid substitute, activator, and calcium, which in the presence of plasma leads to fibrin clot formation. The aPTT measures function of factors I, II, and V of the common pathway and factors VIII, IX, X, and XII of the intrinsic pathway. Heparin therapy is often monitored by following aPTT values with a therapeutic target range of 1.5 to 2.5 times the control value (approximately 50 to 80 seconds). Low molecular weight heparins are selective Xa inhibitors that may mildly elevate the aPTT, but therapeutic monitoring is not routinely recommended.

Additional medications may significantly impair hemostatic function, such as antiplatelet agents (clopidogrel and GP IIb/IIIa inhibitors), anticoagulant agents (hirudin, chondroitin sulfate, dextran sulfate), and thrombolytic agents (streptokinase, tPA). If abnormalities in any of the coagulation studies cannot be explained by known medications, congenital abnormalities of coagulation or comorbid disease should be considered.

Unfortunately, while conventional coagulation tests (PT, aPTT) capture the classic intrinsic and extrinsic coagulation cascade, they do not reflect the complexity of in vivo coagulation. Although they are useful to follow warfarin and heparin therapies, they poorly reflect the status of actively bleeding patients. This is not surprising given that these tests use only plasma and not whole blood to provide their assessment of the patient’s clotting status. To better assess the complex and rapidly changing hemostatic function of an actively bleeding patient, many centers have moved to whole blood viscoelastic testing.
Viscoelastic Assays. Viscoelastic assays, such as TEG or rotational thromboelastometry (ROTEM), monitor hemostasis as a dynamic process rather than revealing information from isolated conventional coagulation screen.

**PART I** Viscoelastic Assays. Viscoelastic assays, such as TEG or rotational thromboelastometry (ROTEM), monitor hemostasis as a dynamic process rather than revealing information from isolated conventional coagulation screen.

Both tests measure the viscoelastic properties of blood as clotting is induced under a low-shear environment. The patterns of change in shear elasticity enable determination of the kinetics of clot formation and growth as well as the strength and stability of the formed clot. The strength and stability provide information about the ability of the clot to perform the work of hemostasis, while the kinetics determines the adequacy of quantitative factors available for clot formation.

Continuous improvements in this technique have made this test a valuable tool for medical personnel interested in coagulation. A sample of celite-activated whole blood is placed into a prewarmed cuvette, and the clotting process is activated with reagents, such as kaolin for standard TEG, and kaolin plus tissue factor for rapid TEG. Both TEG and ROTEM employ a vertical pin which is lowered into the activated blood sample. In TEG, the cuvette oscillates in an arc around the stationary pin. As the blood clots, fibrin strands and platelet aggregates form between the pin and inner walls of the cuvette. The resulting torque on the pin is measured and converted to an electrical signal. In ROTEM, the cuvette is stationary while the pin oscillates within the sample. The extent to which the pin can oscillate is reduced as the blood clots, and this is measured by the angle of deflection of a beam of light directed at the pin.

In TEGs, the strength of a clot is graphically represented over time as a characteristic cigar-shaped figure (Fig. 4-7).

Several parameters are generated from the TEG tracing. The r-value (reaction time) represents the time between the start of the assay and initial clot formation. This reflects clotting factor activity and initial fibrin formation and is increased with factor deficiency or severe hemodilution. The k-time (clot kinetics) is the time needed to reach specified clot strength and represents the interactions of clotting factors and platelets. As such, the k-time is prolonged with hypofibrinogenemia and significant factor deficiency. Prolonged r-value and k-time are commonly addressed with plasma transfusions. The alpha or angle ($\alpha$) is the slope of the tracing and reflects clot acceleration. The angle reflects the interactions of clotting factors and platelets. The slope is decreased with hypofibrinogenemia and platelet dysfunction. Decreased angles are treated with cryoprecipitate transfusion or fibrinogen administration. The maximal amplitude (mA) is the greatest height of the tracing and represents clot strength. Its height is reduced with dysfunction or deficiencies in platelets or fibrinogen. Decreased mA is addressed with platelet transfusion and, in cases where the angle is also decreased, with cryoprecipitate (or fibrinogen) as well. The G-value is a parametric measure derived from the mA value and reflects overall clot strength or firmness. An increased G-value is associated with hypercoagulability, whereas a decrease is seen with hypo-coagulable states. Finally, the LY30 is the amount of lysis occurring in the clot, and the value is the percentage of amplitude reduction at 30 minutes after mA is achieved. The LY30 represents clot stability and when increased fibrinolysis is present.

TEG and ROTEM are the only tests measuring all dynamic steps of clot formation until eventual clot lysis or retraction. TEG has also been shown to identify on admission those patients likely to develop thromboembolic complications after injury and postoperatively.

Recent trauma data have shown TEG to be useful in predicting early transfusion of red blood cells, plasma, platelets, and cryoprecipitate. TEG can also predict the need for lifesaving interventions shortly after arrival, 24-hour and 30-day mortality, and can be used to guide administration of TXA to injured patients with hyperfibrinolysis. Lastly, some centers have demonstrated that the graphic display options allow for more rapid return of results and may be less expensive than standard coagulation panels. Given the strong association of viscoelastic tests with clinical outcomes, some centers now use TEG rather than conventional coagulation tests to evaluate injured patients in the emergency department.

**EVALUATION OF EXCESSIVE INTRAOPERATIVE OR POSTOPERATIVE BLEEDING**

Excessive bleeding during or after a surgical procedure may be the result of ineffective hemostasis, blood transfusion, undetected hemostatic defect, consumptive coagulopathy, and/or fibrinolysis. Excessive bleeding from the operative field associated with bleeding from other sites usually suggests inadequate mechanical hemostasis.

Massive blood transfusion is a well-known cause of thrombocytopenia. Bleeding following massive transfusion can occur because of hypothermia, dilutional coagulopathy, platelet dysfunction, fibrinolysis, or hypofibrinogenemia. Another cause of hemostatic failure related to the administration of blood is a hemolytic transfusion reaction. The first sign of a transfusion reaction may be diffuse bleeding. The pathogenesis of this bleeding is thought to be related to the release of ADP from hemolyzed red blood cells, resulting in diffuse platelet aggregation, after which the platelet clumps are removed out of the circulation.

Transfusion purpura occurs when the donor platelets are of the uncommon HPA-1 group. This is an uncommon cause of thrombocytopenia and associated bleeding after transfusion. The platelets sensitize the recipient, who makes antibody to the foreign platelet antigen. The foreign platelet antigen does not completely disappear from the recipient circulation but attaches to the recipient’s own platelets. The antibody then destroys the recipient’s own platelets. The resultant thrombocytopenia and bleeding may continue for several weeks. This uncommon cause of thrombocytopenia should be considered if bleeding follows transfusion by 5 or 6 days. Platelet transfusions are of little help in the management of this syndrome because the new donor platelets usually are subject to the binding of antigen and damage from the antibody. Corticosteroids may be of some help in reducing the bleeding tendency. Posttransfusion purpura is self-limited, and the passage of several weeks inevitably leads to subsidence of the problem.

DIC is characterized by systemic activation of the coagulation system, which results in the deposition of fibrin clots and microvascular ischemia and may contribute to the development of this syndrome.
of multiorgan failure. Consumption and subsequent exhaustion of coagulation proteins and platelets due to the ongoing activation of the coagulation system may induce severe bleeding complications.

Lastly, severe hemorrhagic disorders due to thrombocytopenia have occurred as a result of gram-negative sepsis. Defibrination and hemostatic failure also may occur with meningococcemia, Clostridium perfringens sepsis, and staphylococcal sepsis. Hemolysis appears to be one mechanism in sepsis leading to defibrination.

“Shock is the manifestation of the rude unhinging of the machinery of life.”

—Samuel V. Gross, 1872

EVOLUTION IN UNDERSTANDING SHOCK

Overview

Shock, at its most rudimentary definition and regardless of its etiology, is the failure to meet the metabolic needs of the cell and the consequences that ensue. The initial cellular injury that occurs is reversible; however, the injury will become irreversible if tissue perfusion is prolonged or severe enough such that, at the cellular level, compensation is no longer possible. Our understanding of shock and the disease processes that result in shock made its most significant advances throughout the 20th century as our appreciation for the physiology and pathophysiology of shock matured. Most notably, our comprehension of the sympathetic and neuroendocrine stress responses on the cardiovascular system has flourished. The clinical manifestations of these physiologic responses are most often what lead practitioners to the diagnosis of shock as well as guide the management of patients in shock. However, hemodynamic parameters such as blood pressure and heart rate are relatively insensitive measures of shock, and additional considerations must be used to help aid in early diagnosis and treatment of patients in shock. The general approach to the management of patients in shock has been empiric: assuring a secure airway with adequate ventilation, control of hemorrhage in the bleeding patient, and restoration of vascular volume and tissue perfusion.

Historical Background

Integral to our understanding of shock is the appreciation that our bodies attempt to maintain a state of homeostasis. Claude Bernard suggested in the mid-19th century that the organism attempts to maintain constancy in the internal environment against external forces that attempt to disrupt the milieu interieur. Walter B. Cannon carried Bernard’s observations further and introduced the term homeostasis, emphasizing that an organism’s ability to survive was related to maintenance of homeostasis. The failure of physiologic systems to buffer the organism against external forces results in organ and cellular dysfunction, what is clinically recognized as shock. He first described the “fight or flight response,” generated by elevated levels of catecholamines in the bloodstream. Cannon’s observations on the battlefields of World War I led him to propose that the initiation of shock was due to a disturbance of the nervous system that resulted in vasodilation and hypotension. He proposed that secondary shock, with its attendant capillary permeability leak, was caused by a “toxic factor” released from the tissues.

In a series of critical experiments, Alfred Blalock documented that the shock state in hemorrhage was associated with reduced cardiac output due to volume loss, not a “toxic factor.” In 1934, Blalock proposed four categories of shock: hypovolemic, vasogenic, cardiogenic, and neurogenic. Hypovolemic shock, the most common type, results from loss of circulating blood volume. This may result from loss of whole blood (hemorrhagic shock), plasma, interstitial fluid (bowel obstruction), or a combination. Vasogenic shock results from decreased resistance within capacitance vessels, usually seen in sepsis. Neurogenic shock is a form of vasogenic shock in which spinal cord injury or spinal anesthesia causes vasodilation due to acute loss of sympathetic vascular tone. Cardiogenic shock results from failure of the heart as a pump, as in arrhythmias or acute myocardial infarction (MI).

This categorization of shock based on etiology persists today (Table 5-1). In recent clinical practice, further classification has described six types of shock: hypovolemic, septic (vasodilatory), neurogenic, cardiogenic, obstructive, and traumatic shock. Obstructive shock is a form of cardiogenic shock that results from mechanical impediment to circulation leading to depressed cardiac output rather than primary cardiac failure.
Key Points

1. Shock is defined as a failure to meet the metabolic demands of cells and tissues and the consequences that ensue.

2. A central component of shock is decreased tissue perfusion. This may be a direct consequence of the etiology of shock, such as in hypovolemic/hemorrhagic, cardiogenic, or neurogenic etiologies, or may be secondary to elaborated or released molecules or cellular products that result in endothelial/cellular activation, such as in septic shock or traumatic shock.

3. Physiologic responses to shock are based upon a series of afferent (sensing) signals and efferent responses that include neuroendocrine, metabolic, and immune/inflammatory signaling.

4. The mainstay of treatment of hemorrhagic/hypovolemic shock includes volume resuscitation with blood products. In the case of hemorrhagic shock, timely control of bleeding is essential and influences outcome.

5. Prevention of hypothermia, acidemia, and coagulopathy are essential in the management of patients in hemorrhagic shock.

6. The mainstay of treatment of septic shock is fluid resuscitation, initiation of appropriate antibiotic therapy, and control of the source of infection. This includes drainage of infected fluid collections, removal of infected foreign bodies, and debridement of devitalized tissues.

7. A combination of physiologic parameters and markers of organ perfusion/tissue oxygenation are used to determine if patients are in shock and to follow the efficacy of resuscitation.

8. Prevention of hypothermia, acidemia, and coagulopathy are essential in the management of patients in hemorrhagic shock.

9. Core principles in the management of patients in hemorrhagic shock include: (a) control of active hemorrhage must occur promptly (delay in control of bleeding increases mortality and recent battlefield data would suggest that in the young and otherwise healthy population commonly injured in combat, that control of bleeding is the paramount priority); (b) volume resuscitation with blood products (red blood cells, plasma, and platelets) with limited volume of crystalloid must occur while operative control of bleeding is achieved; (c) unrecognized or inadequately corrected hypoperfusion increases morbidity and mortality (i.e., inadequate resuscitation results in avoidable early deaths from shock); and (d) excessive fluid resuscitation may exacerbate bleeding (i.e., uncontrolled resuscitation is harmful). Thus, both inadequate or unrestrained volume resuscitation are harmful.

Likewise, observations in the management of septic shock have led to consensus statements and evolving guideline based management. Core principles in the management of patients in septic shock include: (a) septic shock is an emergency, and treatment/resuscitation should begin as early as possible; (b) specific anatomic diagnosis of infection requiring emergent source control be identified or excluded as rapidly as possible and that any required source control intervention be implemented as soon as medically and logistically practical; (c) initiation of broad spectrum antibiotics within 1 hour of diagnosis; (d) in the resuscitation from sepsis-induced hypoperfusion, at any time of the day or night, the patient must be moved from the bed to the operating theater in a surgical gown, and the patient must be placed on a high-flow anesthesia machine within 15 minutes of the beginning of surgery.

This includes etiologies such as pulmonary embolism or tension pneumothorax. In traumatic shock, soft tissue and bony injury lead to the activation of inflammatory cells and the release of circulating factors, such as cytokines and intracellular molecules that modulate the immune response. Recent investigations have revealed that the inflammatory mediators released in response to tissue injury (damage-associated molecular patterns [DAMPs]) are recognized by many of the same cellular receptors (pattern recognition receptors [PRRs]) and activate similar signaling pathways as do bacterial products elaborated in sepsis (pathogen-associated molecular patterns), such as lipopolysaccharide. These effects of tissue injury are combined with the effects of hemorrhage, creating a more complex and amplified deviation from homeostasis.

In the mid-to later 20th century, further development of experimental models contributed significantly to the understanding of the pathophysiology of shock. In 1947, Wiggers developed a sustainable, irreversible model of hemorrhagic shock based on uptake of shed blood into a reservoir to maintain a set level of hypotension. G. Tom Shires added further understanding of hemorrhagic shock with a series of clinical studies demonstrating that a large extracellular fluid deficit, greater than could be attributed to vascular refilling alone, occurred in severe hemorrhagic shock. The phenomenon of fluid redistribution after major trauma involving blood loss was termed third spacing and described the translocation of intravascular volume into the peritoneum, bowel, burned tissues, or crush injury sites. These seminal studies form the scientific basis for the current treatment of hemorrhagic shock with red blood cells and lactated Ringer’s solution or isotonic saline.

As resuscitation strategies evolved and patients survived the initial consequences of hemorrhage, new challenges of sustained shock became apparent. During the Vietnam War, aggressive fluid resuscitation with red blood cells and crystalloid solution or plasma resulted in survival of patients who previously would have succumbed to hemorrhagic shock. Renal failure became a less frequent clinical problem; however, a new disease process, acute fulminant pulmonary failure, appeared as an early cause of death after seemingly successful surgery to control hemorrhage. Initially called DaNang lung or shock lung, the clinical problem became recognized as acute respiratory distress syndrome (ARDS). This led to new methods of prolonged mechanical ventilation. Our current concept of ARDS is a component in the spectrum of multiple organ system failure.

Studies and clinical observations over the past two decades have extended the early observations of Canon, that “restoration of blood pressure prior to control of active bleeding may result in loss of blood that is sorely needed,” and challenged the appropriate endpoints in resuscitation of uncontrolled hemorrhage. Core principles in the management of patients in hemorrhagic shock include: (a) control of active hemorrhage must occur promptly (delay in control of bleeding increases mortality and recent battlefield data would suggest that in the young and otherwise healthy population commonly injured in combat, that control of bleeding is the paramount priority); (b) volume resuscitation with blood products (red blood cells, plasma, and platelets) with limited volume of crystalloid must occur while operative control of bleeding is achieved; (c) unrecognized or inadequately corrected hypoperfusion increases morbidity and mortality (i.e., inadequate resuscitation results in avoidable early deaths from shock); and (d) excessive fluid resuscitation may exacerbate bleeding (i.e., uncontrolled resuscitation is harmful). Thus, both inadequate or unrestrained volume resuscitation are harmful.
least 30 mL/kg of intravenous crystalloid fluid be given within the first 3 hours, and additional fluids be guided by frequent reassessment of hemodynamic status; (e) vaspressors (norepinephrine) should be added to achieve a mean arterial pressure of 65 mmHg if fluid resuscitation is inadequate.

**Current Definitions and Challenges**

A modern definition and approach to shock acknowledges that shock consists of inadequate tissue perfusion marked by decreased delivery of required metabolic substrates and inadequate removal of cellular waste products. This involves failure of oxidative metabolism that can involve defects of oxygen (O₂) delivery, transport, and/or utilization. Current challenges include moving beyond fluid resuscitation based upon endpoints of tissue oxygenation and using therapeutic strategies at the cellular and molecular level. This approach will help to identify compensated patients or patients early in the course of their disease, initiate appropriate treatment, and allow for continued evaluation for the efficacy of resuscitation and adjuncts.

Current investigations focus on determining the cellular events that often occur in parallel to result in organ dysfunction, shock irreversibility, and death. This chapter will review our current understanding of the pathophysiology and cellular responses of shock states. Current and experimental diagnostic and therapeutic modalities for the different categories of shock are reviewed, with a focus on hemorrhagic/hypovolemic shock and septic shock.

**PATHOPHYSIOLOGY OF SHOCK**

Regardless of etiology, the initial physiologic responses in shock are driven by tissue hypoperfusion and the developing cellular energy deficit. This imbalance between cellular supply and demand leads to neuroendocrine and inflammatory responses, the magnitude of which is usually proportional to the degree and duration of shock. The specific responses will differ based on the etiology of shock, as certain physiologic responses may be limited by the inciting pathology. For example, the cardiovascular response driven by the sympathetic nervous system is markedly blunted in neurogenic or septic shock. Additionally, decreased perfusion may occur as a consequence of cellular activation and dysfunction, such as in septic shock and to a lesser extent traumatic shock (Fig. 5-1). Many of the organ-specific responses are aimed at maintaining perfusion in the cerebral and coronary circulation. These are regulated at multiple levels including (a) stretch receptors and baroreceptors in the heart and vasculature (carotid sinus and aortic arch), (b) chemoreceptors, (c) cerebral ischemia responses, (d) release of endogenous vasoconstrictors, (e) shifting of fluid into the intravascular space, and (f) renal reabsorption and conservation of salt and water.

Furthermore, the pathophysiologic responses vary with time and in response to resuscitation. In hemorrhagic shock, the body can compensate for the initial loss of blood volume primarily through the neuroendocrine response to maintain hemodynamics. This represents the compensated phase of shock. With continued hypoperfusion, which may be unrecognized, cellular death and injury are ongoing, and the decompensation phase of shock ensues. Microcirculatory dysfunction, parenchymal tissue damage, and inflammatory cell activation can perpetuate hypoperfusion. Ischemia/reperfusion injury will often exacerbate the initial insult. These effects at the cellular level, if untreated, will lead to compromise of function at the organ system level, thus leading to the “vicious cycle” of shock (Fig. 5-2). Persistent hypoperfusion results in further hemodynamic derangements and cardiovascular collapse. This has been termed the irreversible phase of shock and can develop quite insidiously and may only be obvious in retrospect. At this point, there has occurred extensive enough parenchymal and microvascular injury such that volume resuscitation fails to reverse the process, leading to death of the patient. In experimental animal models of hemorrhagic shock (modified Wiggers model), this is

---

**Figure 5-1.** Pathways leading to decreased tissue perfusion and shock. Decreased tissue perfusion can result directly from hemorrhage/hypovolemia, cardiac failure, or neurologic injury. Decreased tissue perfusion and cellular injury can then result in immune and inflammatory responses. Alternatively, elaboration of microbial products during infection or release of endogenous cellular products from tissue injury can result in cellular activation to subsequently influence tissue perfusion and the development of shock. HMGB1 = high mobility group box 1; LPS = lipopolysaccharide; RAGE = receptor for advanced glycation end products.
Afferent Signals

Afferent impulses transmitted from the periphery are processed within the central nervous system (CNS) and activate the reflexive effector responses or efferent impulses. These effector responses are designed to expand plasma volume, maintain peripheral perfusion and tissue O<sub>2</sub> delivery, and restore homeostasis. The afferent impulses that initiate the body’s intrinsic adaptive responses and converge in the CNS originate from a variety of sources. The initial inciting event usually is loss of circulating blood volume. Other stimuli that can produce the neuroendocrine response include pain, hypoxemia, hypercarbia, acidosis, infection, change in temperature, emotional arousal, or hypoglycemia. The sensation of pain from injured tissue is transmitted via the spinothalamic tracts, resulting in activation of the hypothalamic-pituitary-adrenal axis, as well as activation of the autonomic nervous system (ANS) to induce direct sympathetic stimulation of the adrenal medulla to release catecholamines.

Baroreceptors also are an important afferent pathway in initiation of adaptive responses to shock. Volume receptors, sensitive to changes in both chamber pressure and wall stretch, are present within the atria of the heart. They become activated with low volume hemorrhage or mild reductions in right atrial pressure. Receptors in the aortic arch and carotid bodies respond to alterations in pressure or stretch of the arterial wall, responding to larger reductions in intravascular volume or pressure. These receptors normally inhibit induction of the ANS. When activated, these baroreceptors diminish their output, thus disinhibiting the effect of the ANS. The ANS then increases its output, principally via sympathetic activation at the vasomotor centers of the brain stem, producing centrally mediated constriction of peripheral vessels.

Chemoreceptors in the aorta and carotid bodies are sensitive to changes in O<sub>2</sub> tension, H<sup>+</sup> ion concentration, and carbon dioxide (CO<sub>2</sub>) levels. Stimulation of the chemoreceptors results in vasodilation of the coronary arteries, slowing of the heart rate, and vasoconstriction of the splanchnic and skeletal circulation. In addition, a variety of protein and nonprotein mediators are produced at the site of injury as part of the inflammatory response, and they act as afferent impulses to induce a host response. These mediators include histamine, cytokines,
eicosanoids, and endothelins, among others that are discussed in greater detail later in this chapter in the “Immune and Inflammatory Responses” section.

**Efferent Signals**

**Cardiovascular Response.** Changes in cardiovascular function are a result of the neuroendocrine response and ANS response to shock, and they constitute a prominent feature of both the body’s adaptive response mechanism and the clinical signs and symptoms of the patient in shock. Hemorrhage results in diminished venous return to the heart and decreased cardiac output. This is compensated by increased cardiac heart rate and contractility, as well as venous and arterial vasoconstriction. Stimulation of sympathetic fibers innervating the heart leads to activation of β-adrenergic receptors that increase heart rate and contractility in this attempt to increase cardiac output. Increased myocardial O₂ consumption occurs as a result of the increased workload; thus, myocardial O₂ supply must be maintained, or myocardial dysfunction will develop. The cardiovascular response in hemorrhage/hypovolemia differs from the responses elicited with the other etiologies of shock. These are compared in Table 5-2.

Direct sympathetic stimulation of the peripheral circulation via the activation of α-adrenergic receptors on arterioles induces vasoconstriction and causes a compensatory increase in systemic vascular resistance and blood pressure. The arterial vasoconstriction is not uniform; marked redistribution of blood flow results. Selective perfusion to tissues occurs due to regional variations in arteriolar resistance, with blood shunted away from less essential organ beds such as the intestine, kidney, and skin. In contrast, the brain and heart have autoregulatory mechanisms that attempt to preserve their blood flow despite a global decrease in cardiac output. Direct sympathetic stimulation also induces constriction of venous vessels, decreasing the capacitance of the circulatory system and accelerating blood return to the central circulation.

Increased sympathetic output induces catecholamine release from the adrenal medulla. Catecholamine levels peak within 24 to 48 hours of injury and then return to baseline. Persistent elevation of catecholamine levels beyond this time suggests ongoing noxious afferent stimuli. The majority of the circulating epinephrine is produced by the adrenal medulla, while norepinephrine is derived from synapses of the sympathetic nervous system. Catecholamine effects on peripheral tissues include stimulation of hepatic glycogenolysis and gluconeogenesis to increase circulating glucose availability to peripheral tissues, an increase in skeletal muscle glycogenolysis, suppression of insulin release, and increased glucagon release.

**Hormonal Response.** The stress response includes activation of the ANS as discussed previously in the “Afferent Signals” section, as well as activation of the hypothalamic-pituitary-adrenal axis. Shock stimulates the hypothalamus to release corticotropin-releasing hormone, which results in the release of adrenocorticotropic hormone (ACTH) by the pituitary. ACTH subsequently stimulates the adrenal cortex to release cortisol. Cortisol acts synergistically with epinephrine and glucagon to induce a catabolic state. Cortisol stimulates gluconeogenesis and insulin resistance, resulting in hyperglycemia as well as muscle cell protein breakdown and lipolysis to provide substrates for hepatic gluconeogenesis. Cortisol causes retention of sodium and water by the nephrons of the kidney. In the setting of severe hypovolemia, ACTH secretion occurs independently of cortisol negative feedback inhibition.

The renin-angiotensin system is activated in shock. Decreased renal artery perfusion, β-adrenergic stimulation, and increased renal tubular sodium concentration cause the release of renin from the juxtaglomerular cells. Renin catalyzes the conversion of angiotensinogen (produced by the liver) to angiotensin I, which is then converted to angiotensin II by angiotensin-converting enzyme (ACE) produced in the lung. While angiotensin I has no significant functional activity, angiotensin II is a potent vasconstrictor of both splanchnic and peripheral vascular beds, and also stimulates the secretion of aldosterone, ACTH, and antiuretic hormone (ADH). Aldosterone, a mineralocorticoid, acts on the nephron to promote reabsorption of sodium, and as a consequence, water. Potassium and hydrogen ions are lost in the urine in exchange for sodium.

The pituitary also releases vasopressin or ADH in response to hypovolemia, changes in circulating blood volume sensed by baroreceptors and left atrial stretch receptors, and increased plasma osmolality detected by hypothalamic osmoreceptors. Epinephrine, angiotensin II, pain, and hyperglycemia increase production of ADH. ADH levels remain elevated for about 1 week after the initial insult, depending on the severity and persistence of the hemodynamic abnormalities. ADH acts on the distal tubule and collecting duct of the nephron to increase water permeability, decrease water and sodium losses, and preserve intravascular volume. Also known as arginine vasopressin, ADH acts as a potent mesenteric vasoconstrictor, shunting circulating blood away from the splanchnic organs during hypovolemia. This may contribute to intestinal ischemia and predispose to intestinal mucosal barrier dysfunction in

The hemodynamic responses are indicated by arrows to show an increase (↑), severe increase (↑↑), decrease (↓), severe decrease (↓↓), varied response (↑↓), or little effect (→). CVP = central venous pressure; PCWP = pulmonary capillary wedge pressure; $SVO_2$ = mixed venous oxygen saturation; SVR = systemic vascular resistance.
Vasopressin also increases hepatic gluconeogenesis and increases hepatic glycolysis.

In septic states, endotoxin directly stimulates arginine vasopressin secretion independently of blood pressure, osmotic, or intravascular volume changes. Proinflammatory cytokines also contribute to arginine vasopressin release. Interestingly, patients on chronic therapy with ACE inhibitors are more at risk of developing hypotension and vasodilatory shock with open heart surgery. Low plasma levels of arginine vasopressin were confirmed in these patients.

**Circulatory Homeostasis**

**Preload.** At rest, the majority of the blood volume is within the venous system. Venous return to the heart generates ventricular end-diastolic wall tension, a major determinant of cardiac output. Gravitational shifts in blood volume distribution are quickly corrected by alterations in venous capacity. With decreased arteriolar inflow, there is active constriction of the venous smooth muscle and passive elastic recoil in the thin-walled systemic veins. This increases venous return to the heart, thus maintaining ventricular filling.

Most alterations in cardiac output in the normal heart are related to changes in preload. Increases in sympathetic tone have a minor effect on skeletal muscle beds but produce a dramatic reduction in splanchnic blood volume, which normally holds 20% of the blood volume.

The normal circulating blood volume is maintained within narrow limits by the kidney’s ability to manage salt and water balance with external losses via systemic and local hemodynamic changes and hormonal effects of renin, angiotensin, and ADH. These relatively slow responses maintain preload by altering circulating blood volume. Acute responses to intravascular volume include changes in venous tone, systemic vascular resistance, and intrathoracic pressure, with the slower hormonal changes less important in the early response to volume loss. Furthermore, the net effect of preload on cardiac output is influenced by cardiac determinants of ventricular function, which includes coordinated atrial activity and tachycardia.

**Ventricular Contraction.** The Frank-Starling curve describes the force of ventricular contraction as a function of its preload. This relationship is based on force of contraction being determined by initial muscle length. Intrinsic cardiac disease will shift the Frank-Starling curve and alter mechanical performance of the heart. In addition, cardiac dysfunction has been demonstrated experimentally in burns and in hemorrhagic, traumatic, and septic shock.

**Afterload.** Afterload is the force that resists myocardial work during contraction. Arterial pressure is the major component of afterload influencing the ejection fraction. This vascular resistance is determined by precapillary smooth muscle sphincters. Blood viscosity also will increase vascular resistance. As afterload increases in the normal heart, stroke volume can be maintained by increases in preload. In shock, with decreased circulating volume and therefore diminished preload, this compensatory mechanism to sustain cardiac output is impeded. The stress response with acute release of catecholamines and sympathetic nerve activity in the heart increases contractility and heart rate.

**Microcirculation.** The microvascular circulation plays an integral role in regulating cellular perfusion and is significantly influenced in response to shock. The microvascular bed is innervated by the sympathetic nervous system and has a profound effect on the larger arterioles. Following hemorrhage, larger arterioles vasoconstrict; however, in the setting of sepsis or neurogenic shock, these vessels vasodilate. Additionally, a host of other vasoactive proteins, including vasopressin, angiotensin II, and endothelin-1, also lead to vasoconstriction to limit organ perfusion to organs such as skin, skeletal muscle, kidneys, and the GI tract to preserve perfusion of the myocardium and CNS.

Flow in the capillary bed is heterogeneous in shock states, which likely is secondary to multiple local mechanisms, including endothelial cell swelling, dysfunction, and activation marked by the recruitment of leukocytes and platelets. Together, these mechanisms lead to diminished capillary perfusion that may persist after resuscitation. In hemorrhagic shock, correction of hemodynamic parameters and restoration of O2 delivery generally leads to restoration of tissue O2 consumption and tissue O2 levels. In contrast, regional tissue dysoxia often persists in sepsis, despite similar restoration of hemodynamics and O2 delivery. Whether this defect in O2 extraction in sepsis is the result of heterogeneous impairment of the microcirculation (intraparenchymal shunting) or impaired tissue parenchymal cell oxidative phosphorylation and O2 consumption by the mitochondria is not resolved.13 Interesting data suggest that in sepsis the response to limit O2 consumption by the tissue parenchymal cells is an adaptive response to the inflammatory signaling and decreased perfusion.

An additional pathophysiologic response of the microcirculation to shock is failure of the integrity of the endothelium of the microcirculation and development of capillary leak, intracellular swelling, and the development of an extracellular fluid deficit. Seminal work by Shires helped to define this phenomenon.8,17 There is decreased capillary hydrostatic pressure secondary to changes in blood flow and increased cellular uptake of fluid. The result is a loss of extracellular fluid volume. The cause of intracellular swelling is multifactorial, but dysfunction of energy-dependent mechanisms, such as active transport by the sodium-potassium pump contributes to loss of membrane integrity.

Capillary dysfunction also occurs secondary to activation of endothelial cells by circulating inflammatory mediators generated in septic or traumatic shock. This exacerbates endothelial cell swelling and capillary leak, as well as increases leukocyte adherence. This results in capillary occlusion, which may persist after resuscitation, and is termed no-reflow. Further ischemic injury ensues as well as release of inflammatory cytokines to compound tissue injury. Experimental models have shown that neutrophil depletion in animals subjected to hemorrhagic shock produces fewer capillaries with no-reflow and lower mortality.14

---

**METABOLIC EFFECTS**

Cellular metabolism is based primarily on the hydrolysis of adenosine triphosphate (ATP). The splitting of the phosphoanhydride bond of the terminal or γ-phosphate from ATP is the source of energy for most processes within the cell under normal conditions. The majority of ATP is generated in our bodies through aerobic metabolism in the process of oxidative phosphorylation in the mitochondria. This process is dependent on the availability of O2 as a final electron acceptor in the electron transport chain. As O2 tension within a cell decreases, there is a decrease in oxidative phosphorylation, and the generation
of ATP slows. When O₂ delivery is so severely impaired such that oxidative phosphorylation cannot be sustained, the state is termed *dysxia*. When oxidative phosphorylation is insufficient, the cells shift to anaerobic metabolism and glycolysis to generate ATP. This occurs via the breakdown of cellular glycogen stores to pyruvate. Although glycolysis is a rapid process, it is not efficient, allowing for the production of only 2 mol of ATP from 1 mol of glucose. This is compared to complete oxidation of 1 mol of glucose that produces 38 mol of ATP. Additionally, under hypoxic conditions in anaerobic metabolism, pyruvate is converted into lactate, leading to an intracellular metabolic acidosis.

There are numerous consequences secondary to these metabolic changes. The depletion of ATP potentially influences all ATP-dependent cellular processes. This includes maintenance of cellular membrane potential, synthesis of enzymes and proteins, cell signaling, and DNA repair mechanisms. Decreased intracellular pH also influences vital cellular functions such as normal enzyme activity, cell membrane ion exchange, and cellular metabolic signaling. These changes also will lead to changes in gene expression within the cell. Furthermore, acidosis leads to changes in calcium metabolism and calcium signaling. Compounded, these changes may lead to irreversible cell injury and death.

Epinephrine and norepinephrine have a profound impact on cellular metabolism. Hepatic glycogenolysis, gluconeogenesis, ketogenesis, skeletal muscle protein breakdown, and adipose tissue lipolysis are increased by catecholamines. Cortisol, glucagon, and ADH also contribute to the catabolism during shock. Epinephrine induces further release of glucagon, while inhibiting the pancreatic β-cell release of insulin. The result is a catabolic state with glucose mobilization, hyperglycemia, protein breakdown, negative nitrogen balance, lipolysis, and insulin resistance during shock and injury. The relative underuse of glucose by peripheral tissues preserves it for the glucose-dependent organs such as the heart and brain.

**Cellular Hypoperfusion**

Hypoperfused cells and tissues experience what has been termed *oxygen debt*, a concept first proposed by Crowell in 1961. The O₂ debt is the deficit in tissue oxygenation over time that occurs during shock. When O₂ delivery is limited, O₂ consumption can be inadequate to match the metabolic needs of cellular respiration, creating a deficit in O₂ requirements at the cellular level. The measurement of O₂ deficit uses calculation of the difference between the estimated O₂ demand and the actual value obtained for O₂ consumption. Under normal circumstances, cells can “repay” the O₂ debt during reperfusion. The magnitude of the O₂ debt correlates with the severity and duration of hypoperfusion. Surrogate values for measuring O₂ debt include base deficit and lactate levels and are discussed later in the “Hypovolemic/Hemorrhagic” section.

In addition to induction of changes in cellular metabolic pathways, shock also induces changes in cellular gene expression. The DNA binding activity of a number of nuclear transcription factors is altered by hypoxia and the production of O₂ radicals or nitrogen radicals that are produced at the cellular level by shock. Expression of other gene products such as heat shock proteins, vascular endothelial growth factor, inducible nitric oxide synthase (iNOS), heme oxygenase-1, and cytokines also are clearly increased by shock. Many of these shock-induced gene products, such as cytokines, have the ability to subsequently alter gene expression in specific target cells and tissues. The involvement of multiple pathways emphasizes the complex, integrated, and overlapping nature of the response to shock.

**Immune and Inflammatory Responses**

The inflammatory and immune responses are a complex set of interactions between circulating soluble factors and cells that can arise in response to trauma, infection, ischemia, toxic, or autoimmune stimuli. The processes are well regulated and can be conceptualized as an ongoing surveillance and response system that undergoes a coordinated escalation following injury to heal disrupted tissue or restore host-microbe equilibrium, as well as active suppression back to baseline levels. Failure to adequately control the activation, escalation, or suppression of the inflammatory response can lead to systemic inflammatory response syndrome and potentiate multiple organ failure.

Both the innate and adaptive branches of the immune system work in concert to rapidly respond in a specific and effective manner to challenges that threaten an organism’s well-being. Each arm of the immune system has its own set of functions, defined primarily by distinct classes of effector cells and their unique cell membrane receptor families. Alterations in the activity of the innate host immune system can be responsible for both the development of shock (i.e., septic shock following severe infection and traumatic shock following tissue injury with hemorrhage) and the pathophysiologic sequelae of shock such as the proinflammatory changes seen following hypoperfusion (see Fig. 5-1). When the predominantly paracrine mediators gain access to the systemic circulation, they can induce a variety of metabolic changes that are collectively referred to as the host inflammatory response. Understanding of the intricate, redundant, and interrelated pathways that comprise the inflammatory response to shock continues to expand. Despite limited understanding of how our current therapeutic interventions impact the host response to illness, inappropriate or excessive inflammation appears to be an essential event in the development of ARDS, multiple organ dysfunction syndrome (MODS), and posttraumatic immunosuppression that can prolong recovery.

Following direct tissue injury or infection, there are several mechanisms that lead to the activation of the active inflammatory and immune responses. These include release of bioactive peptides by neurons in response to pain and the release of intracellular molecules by broken cells, such as heat shock proteins, mitochondrial products, heparan sulfate, high mobility group box 1, and RNA. Only recently has it been realized that the release of intracellular products from damaged and injured cells can have paracrine and endocrine-like effects on distant tissues to activate the inflammatory and immune responses. This hypothesis, which was first proposed by Matzinger, is known as *danger signaling*. Under this novel paradigm of immune function, endogenous molecules are capable of signaling the presence of danger to surrounding cells and tissues. These molecules that are released from cells are known as *damage associated molecular patterns* (DAMPs, Table 5-3). DAMPs are recognized by cell surface receptors to effect intracellular signaling that primes and amplifies the immune response. These receptors are known as *pattern recognition receptors* (PRRs) and include the Toll-like receptors (TLRs) and the receptor for advanced glycation end products. Interestingly, TLRs and PRRs were first recognized for their role in signaling as part of the immune response to the
entry of microbes and their secreted products into a normally sterile environment. These bacterial products, including lipopolysaccharide, are known as pathogen-associated molecular patterns. The salutary consequences of PRR activation most likely relate to the initiation of the repair process and the mobilization of antimicrobial defenses at the site of tissue disruption. However, in the setting of excessive tissue damage, the inflammation itself may lead to further tissue damage, amplifying the response both at the local and systemic level. PR activation leads to intracellular signaling and release of cellular products, including cytokines (Fig. 5-4).

Before the recruitment of leukocytes into sites of injury, tissue-based macrophages or mast cells act as sentinel responders, releasing histamines, eicosanoids, tryptases, and cytokines (Fig. 5-5). Together these signals amplify the immune response by further activation of neurons and mast cells, as well as increasing the expression of adhesion molecules on the endothelium. Furthermore, these mediators cause leukocytes to release platelet-activating factor, further increasing the stickiness of the endothelium. Additionally, the coagulation and kinin cascades impact the interaction of endothelium and leukocytes.

**Cytokines/Chemokines**

The immune response to shock encompasses the elaboration of mediators with both proinflammatory and anti-inflammatory properties (Table 5-4). Furthermore, new mediators, new relationships between mediators, and new functions of known mediators are continually being identified. As new pathways are uncovered, understanding of the immune response to injury and the potential for therapeutic intervention by manipulating the immune response following shock will expand. What seems clear at present, however, is that the innate immune response can help restore homeostasis, or if it is excessive, promote cellular and organ dysfunction.

Multiple mediators have been implicated in the host immune response to shock. It is likely that some of the most important mediators have yet to be discovered and the roles of many known mediators have not been defined. A comprehensive description of all of the mediators and their complex interactions is beyond the scope of this chapter. For a general overview, a brief description of the more extensively studied mediators, as well as some of the known effects of these substances, see the following discussion. A more comprehensive review can be found in Chapter 2, “Systemic Response to Injury and Metabolic Support.”

Tumor necrosis factor alpha (TNF-α) was one of the first cytokines to be described, and it is one of the earliest cytokines released in response to injurious stimuli. Monocytes, macrophages, and T cells release this potent proinflammatory cytokine. TNF-α levels peak within 90 minutes of stimulation and return frequently to baseline levels within 4 hours. Release of TNF-α may be induced by bacteria or endotoxin and leads to the development of shock and hypoperfusion, most commonly observed in septic shock. Production of TNF-α also may be induced following other insults, such as hemorrhage and ischemia. TNF-α levels correlate with mortality in animal models of hemorrhage. In contrast, the increase in serum TNF-α levels reported in trauma patients is far less than that seen in septic patients. Once released, TNF-α can produce peripheral vaso-dilation, activate the release of other cytokines, induce procoagulant activity, and stimulate a wide array of cellular metabolic changes. During the stress response, TNF-α contributes to the muscle protein breakdown and cachexia.

Interleukin-1 (IL-1) has actions similar to those of TNF-α. IL-1 has a very short half-life (6 minutes) and primarily acts in a paracrine fashion to modulate local cellular responses. Systemically, IL-1 produces a febrile response to injury by activating prostaglandins in the posterior hypothalamus, and causes anorexia by activating the satiety center. This cytokine also augments the secretion of ACTH, glucocorticoids, and β-endorphins. In conjunction with TNF-α, IL-1 can stimulate the release of other cytokines such as IL-2, IL-4, IL-6, IL-8, granulocyte-macrophage colony-stimulating factor, and interferon-γ.

IL-2 is produced by activated T cells in response to a variety of stimuli and activates other lymphocyte subpopulations and natural killer cells. The lack of clarity regarding the role of IL-2 in the response to shock is intimately associated with that of understanding immune function after injury. Some investigators have postulated that increased IL-2 secretion promotes shock-induced tissue injury and the development of shock. Others have demonstrated that depressed IL-2 production is associated with,

**Figure 5-4.** A schema of information flow between immune cells in early inflammation following tissue injury and infection. Cells require multiple inputs and stimuli before activation of a full response. DAMPs = damage associated molecular patterns; HMGB1 = high mobility group box 1; TNF = tumor necrosis factor.
and perhaps contributes to, the depression in immune function after hemorrhage that may increase the susceptibility of patients who develop shock to suffer infections.\textsuperscript{26,27} It has been postulated that overly exuberant proinflammatory activation promotes tissue injury, organ dysfunction, and the subsequent immune dysfunction/suppression that may be evident later.\textsuperscript{22} Emphasizing the importance of temporal changes in the production of mediators, both the initial excessive production of IL-2 and later depressed IL-2 production are probably important in the progression of shock.

*Figure 5-5.* Signaling via the pattern recognition receptor TLR4. LPS signaling via TLR4 requires the cofactors LPS binding protein (LBP), MD-2, and CD14. Endogenous danger signals released from a variety of sources also signal in a TLR4-dependent fashion, although it is as yet unknown what cofactors may be required for this activity. Once TLR4 is activated, an intracellular signaling cascade is initiated that involves both a MyD88-dependent and independent pathway. DAMP = damage associated molecular pattern; LPS = lipopolysaccharide; MD-2 = myeloid differentiation factor-2; MyD88 = myeloid differentiation primary response gene 88; NF-kB = nuclear factor kB; TLR4 = Toll-like receptor-4. (Reproduced with permission from Mollen KP, Levy RM, Prince JM, et al. Systemic inflammation and end organ damage following trauma involves functional TLR4 signaling in both bone marrow-derived cells and parenchymal cells, J Leukoc Biol. 2008 Jan;83(1):80-88.)
IL-6 is elevated in response to hemorrhagic shock, major operative procedures, or trauma. Elevated IL-6 levels correlate with mortality in shock states. IL-6 contributes to lung, liver, and gut injury after hemorrhagic shock.\(^{28}\) Thus, IL-6 may play a role in the development of diffuse alveolar damage and ARDS. IL-6 and IL-1 are mediators of the hepatic acute phase response to injury, and enhance the expression and activity of complement, C-reactive protein, fibrinogen, haptoglobin, amyloid A, and alpha\(_1\)-antitrypsin, and promote neutrophil activation.\(^{29}\)

IL-10 is considered an anti-inflammatory cytokine that may have immunosuppressive properties. Its production is increased after shock and trauma, and it has been associated with depressed immune function clinically, as well as an increased susceptibility to infection.\(^{30}\) IL-10 is secreted by T cells, monocytes, and macrophages, and inhibits proinflammatory cytokine secretion, O\(_2\) radical production by phagocytes, adhesion molecule expression, and lymphocyte activation.\(^{30,31}\) Administration of IL-10 depresses cytokine production and improves some aspects of immune function in experimental models of shock and sepsis.\(^{32,33}\)

Recent studies point to the importance of chemokines, a specific set of cytokines, that have the ability to induce chemotaxis of leukocytes. Chemokines bind to specific chemokine receptors and transduce chemotactic signals to leukocytes. The significance of this large family of chemoattractant cytokines in immunology is difficult to understand, as almost every facet of the immune system is influenced by chemokines, including immune system development, immune surveillance, immune priming, effector responses, and immune regulation.\(^{34}\)

### Complement

The complement cascade can be activated by injury, shock, and severe infection, and contributes to host defense and proinflammatory activation. Significant complement consumption occurs after hemorrhagic shock.\(^{35}\) In trauma patients, the degree of complement activation is proportional to the magnitude of injury and may serve as a marker for severity of injury. Patients in septic shock also demonstrate activation of the complement pathway, with elevations of the activated complement proteins C3a and C5a. Activation of the complement cascade can contribute to the development of organ dysfunction. Activated complement factors C3a, C4a, and C5a are potent mediators of increased vascular permeability, smooth muscle cell contraction, histamine and arachidonic acid by-product release, and adherence of neutrophils to vascular endothelium. Activated complement acts synergistically with endotoxin to induce the release of TNF-\(\alpha\) and IL-1. The development of ARDS and MODS in trauma patients correlates with the intensity of complement activation.\(^{36}\) Complement and neutrophil activation may correlate with mortality in multiply injured patients.

### Neutrophils

Neutrophil activation is an early event in the upregulation of the inflammatory response; neutrophils are the first cells to be recruited to the site of injury. Polymorphonuclear leukocytes (PMNs) remove infectious agents, foreign substances that have penetrated host barrier defenses, and nonviable tissue through phagocytosis. However, activated PMNs and their products may also produce cell injury and organ dysfunction. Activated PMNs generate and release a number of substances that may induce cell or tissue injury, such as reactive O\(_2\) species, lipid-peroxidation products, proteolytic enzymes (elastase, cathepsin G), and vasoactive mediators (leukotrienes, eicosanoids, and platelet-activating factor). Oxygen-free radicals, such as superoxide anion, hydrogen peroxide, and hydroxyl radical, are released and induce lipid peroxidation, inactivate enzymes, and consume antioxidants (such as glutathione and tocopherol). Ischemia-reperfusion activates PMNs and causes PMN-induced organ injury. In animal models of hemorrhagic shock, activation of PMNs correlates with irreversibility of shock and mortality, and neutrophil depletion prevents the pathophysiologic sequelae of hemorrhagic and septic shock. Human data corroborate the activation of neutrophils in trauma and shock and suggest a role in the development of MODS.\(^{37}\) Plasma markers of PMN activation, such as elastase, correlate with severity of injury in humans.

Interactions between endothelial cells and leukocytes are important in the inflammatory process. The vascular endothelium contributes to regulation of blood flow, leukocyte adherence, and the coagulation cascade. Extracellular ligands such as intercellular adhesion molecules, vascular cell adhesion molecules, and the selectins (E-selectin, P-selectin) are expressed on the surface of endothelial cells, and are responsible for leukocyte adhesion to the endothelium. This interaction allows activated neutrophils to migrate into the tissues to combat infection, but also can lead to PMN-mediated cytotoxicity and microvascular and tissue injury.

### Cell Signaling

A host of cellular changes occur following shock. Although many of the intracellular and intercellular pathways that are important in shock are being elucidated, undoubtedly there are many more that have yet to be identified. Many of the mediators produced during shock interact with cell surface receptors on target cells to alter target cell metabolism. These signaling pathways may be altered by changes in cellular oxygenation, redox state, high-energy phosphate concentration, gene expression, or intracellular electrolyte concentration induced by shock. Cells communicate with their external environment through the use of cell surface membrane receptors, which, once bound by a ligand, transmit their information to the interior of the cell through a variety of signaling cascades. These signaling pathways may subsequently alter the activity of specific enzymes, the expression or breakdown of important proteins, or affect intracellular energy metabolism. Intracellular calcium (Ca\(^{2+}\)) homeostasis and regulation represents one such pathway. Intracellular Ca\(^{2+}\) concentrations regulate many aspects of cellular metabolism; many important enzyme systems require Ca\(^{2+}\) for
full activity. Profound changes in intracellular Ca\(^{2+}\) levels and Ca\(^{2+}\) transport are seen in models of shock.\(^{38}\) Alterations in Ca\(^{2+}\) regulation may lead to direct cell injury, changes in transcription factor activation, alterations in the expression of genes important in homeostasis, and the modulation of the activation of cells by other shock-induced hormones or mediators.\(^{39,40}\)

A proximal portion of the intracellular signaling cascade consists of a series of kinases that transmit and amplify the signal through the phosphorylation of target proteins. The O\(_2\) radicals produced during shock and the intracellular redox state are known to influence the activity of components of this cascade, such as protein tyrosine kinases, mitogen activated kinases, and protein kinase C.\(^{41,42}\) Either through changes in these signaling pathways, changes in the activation of enzyme systems through Ca\(^{2+}\)-mediated events, or direct conformational changes to oxygen-sensitive proteins, O\(_2\) radicals also regulate the activity of a number of transcription factors that are important in gene expression, such as nuclear factor \(\kappa\)B, APETALA1, and hypoxia-inducible factor 1.\(^{43,44}\) It is therefore becoming increasingly clear that oxidant-mediated direct cell injury is merely one consequence of the production of O\(_2\) radicals during shock.

The study of the effects of shock on the regulation of gene expression as an important biologic effect was stimulated by the work of Buchman and colleagues.\(^{46}\) The effects of shock on the expression and regulation of numerous genes and gene products has been studied in both experimental animal models and human patients. These studies include investigations into single genes of interest as well as large-scale genomic and proteomic analysis.\(^{55-57}\) Changes in gene expression are critical for adaptive and survival cell signaling. Polymorphisms in gene promoters that lead to a differential level of expression of gene products are also likely to contribute significantly to varied responses to similar insults.\(^{58,59}\)

In a recent study, the genetic responses to traumatic injury in humans or endotoxin delivery to healthy human volunteers demonstrated that severe stresses produce a global re prioritization affecting >80% of the cellular functions and pathways.\(^{60}\) The similarities in genomic responses among different injuries revealed a fundamental human response to stressors involving dysregulated immune responses (Fig. 5-6). Furthermore, in traumatic injury patients, complications like nosocomial infections and organ failure were not associated with any genomic evidence of a second hit and differed only in the magnitude and duration of this genomic reprioritization.

**FORMS OF SHOCK**

**Hypovolemic/Hemorrhagic**

The most common cause of shock in the surgical or trauma patient is loss of circulating volume from hemorrhage. Acute blood loss results in reflexive decreased baroreceptor stimulation from stretch receptors in the large arteries, resulting in decreased inhibition of vasoconstrictor centers in the brain stem, increased chemoreceptor stimulation of vasomotor centers, and diminished output from atrial stretch receptors. These changes increase vasoconstriction and peripheral arterial resistance. Hypovolemia also induces sympathetic stimulation, leading to epinephrine and norepinephrine release, activation of the renin-angiotensin cascade, and increased vasopressin release. Peripheral vasoconstriction is prominent, while lack of sympathetic effects on cerebral and coronary vessels and local autoregulation promote maintenance of cardiac and CNS blood flow.

---

**Figure 5-6.** The concurrent dysregulated innate immune responses that promote inflammation and dysregulated adaptive immune responses that result in immunosuppression occur in patients following traumatic injury. However, these genetic responses can result in complicated outcomes in trauma patients if the magnitude or duration of these responses are pronounced. (Reproduced with permission from Xiao W, Mirdinos MN, Seok J, et al. A genomic storm in critically injured humans. J Exp Med. 2011 Dec 19;208(13):2581-2590.)

**Diagnosis.** Treatment of shock is initially empiric. A secure airway must be confirmed or established in obtunded patients. The priority is the initiation of volume infusion while the search for the cause of the hypotension is pursued. Shock in a trauma patient or postoperative patient should be presumed to be due to hemorrhage until proven otherwise. The clinical signs of shock may be evidenced by agitation, cool clammy extremities, tachycardia, weak or absent peripheral pulses, and hypotension. Such apparent clinical shock results from at least 25% to 30% loss of the blood volume. However, substantial volumes of blood may be lost before the classic clinical manifestations of shock are evident. Thus, when a patient is significantly tachycardic or hypotensive, this represents both significant blood loss and physiologic decompensation. The clinical and physiologic response to hemorrhage has been classified according to the magnitude of volume loss. Loss of up to 15% of the circulating volume (700 to 750 mL for a 70-kg patient) may produce little in terms of obvious symptoms, while loss of up to 30% of the circulating volume (1.5 L) may result in mild tachycardia, tachypnea, and anxiety. Hypotension, marked tachycardia (i.e., pulse greater than 110 to 120 bpm), and confusion may not be evident until more than 30% of the blood volume has been lost; loss of 40% of circulating volume (2 L) is immediately life threatening and generally requires operative control of bleeding (Table 5-5). Young healthy patients with vigorous compensatory mechanisms may tolerate larger volumes of blood loss while manifesting fewer clinical signs despite the presence of significant peripheral hypoperfusion. These patients may maintain a near-normal blood pressure until a precipitous cardiovascular collapse occurs. Elderly patients may be taking medications that either promote bleeding (e.g., warfarin or aspirin), or mask the compensatory responses to bleeding (e.g., β-blockers). In addition, atherosclerotic vascular disease, diminishing cardiac compliance with age, inability to elevate heart rate or cardiac contractility in response to hemorrhage, and overall decline in physiologic reserve decrease the elderly...
patient’s ability to tolerate hemorrhage. Recent data in trauma patients suggest that a systolic blood pressure (SBP) of less than 110 mmHg is a clinically relevant definition of hypotension and hypoperfusion based upon an increasing rate of mortality below this pressure (Fig. 5-7).55

In addressing the sensitivity of vital signs and identifying major thoracoabdominal hemorrhage, a study retrospectively identified patients with injury to the trunk and an abbreviated injury score of 3 or greater who required immediate surgical intervention and transfusion of at least 5 units of blood within the first 24 hours. Ninety-five percent of patients had a heart rate greater than 80 bpm at some point during their postinjury course. However, only 59% of patients achieved a heart rate greater than 120 bpm. Ninety-nine percent of all patients had a recorded blood pressure of less than 120 mmHg at some point. Ninety-three percent of all patients had a recorded SBP of less than 110 mmHg.54 A more recent study corroborated that tachycardia was not a reliable sign of hemorrhage following trauma and was present in only 65% of hypotensive patients.55

Serum lactate and base deficit are measurements that are helpful to both estimate and monitor the extent of bleeding and shock. The amount of lactate that is produced by anaerobic respiration is an indirect marker of tissue hypoperfusion, cellular O2 debt, and the severity of hemorrhagic shock. Several studies have demonstrated that the initial serum lactate and serial lactate levels are reliable predictors of morbidity and mortality with hemorrhage following trauma (Fig. 5-8).56 Similarly, base deficit values derived from arterial blood gas analysis provide clinicians with an indirect estimation of tissue acidosis from hypoperfusion. Davis and colleagues stratified the extent of base deficit into mild (−3 to −5 mmol/L), moderate (−6 to −9 mmol/L), and severe (less than −10 mmol/L), and from this established a correlation between base deficit upon admission with transfusion requirements, the development of multiple organ failure, and death (Fig. 5-9).57 Both base deficit and lactate correlate with the extent of shock and patient outcome, but interestingly do not firmly correlate with each other.58-60 Evaluation of both values may be useful in trauma patients with hemorrhage.

Although hematocrit changes may not rapidly reflect the total volume of blood loss, admission hematocrit has been shown to be associated with 24 hour fluid and transfusion requirements and more strongly associated with PRBC transfusion than either tachycardia, hypotension, or acidosis.61 It must be noted that lack of a depression in the initial hematocrit does not rule out substantial blood loss or ongoing bleeding.

In management of trauma patients, understanding the patterns of injury of the patient in shock will help direct the evaluation and management. Identifying the sources of blood loss in patients with penetrating wounds is relatively simple because potential bleeding sources will be located along the known or suspected path of the wounding object. Patients with penetrating injuries who are in shock usually require operative intervention. Patients who suffer multisystem injuries from blunt trauma have multiple sources of potential hemorrhage. Blood loss sufficient to cause shock is generally of a large volume, and there are a limited number of sites that can harbor sufficient extravascular blood volume to induce hypotension (e.g., external, intrathoracic, infra-abdominal, retroperitoneal, and long bone fractures). In the nontrauma patient, the GI tract must always be considered as a site for blood loss. Substantial blood loss externally may be suspected from prehospital medical reports documenting a substantial blood loss at the scene of an accident, history of massive

![Figure 5-7](https://example.com/figure5-7.png)
blood loss from wounds, visible brisk bleeding, or presence of a large hematoma adjacent to an open wound. Injuries to major arteries or veins with associated open wounds may cause massive blood loss rapidly. Direct pressure must be applied and sustained to minimize ongoing blood loss. Tourniquets should be used for extremity bleeding stopped by direct pressure and applied in the prehospital setting as needed. Persistent bleeding from uncontrolled smaller vessels can, over time, precipitate shock if inadequately treated.

When major blood loss is not immediately visible in the setting of trauma, internal (intracavitary) blood loss should be suspected. Each pleural cavity can hold 2 to 3 L of blood and can therefore be a site of significant blood loss. Diagnostic and therapeutic tube thoracostomy may be indicated in unstable patients based on clinical findings and clinical suspicion. In a more stable patient, a chest radiograph may be obtained to look for evidence of hemothorax. Major retroperitoneal hemorrhage typically occurs in association with pelvic fractures, which is confirmed by pelvic radiography in the resuscitation bay. Intraperitoneal hemorrhage is probably the most common source of blood loss that induces shock. The physical exam for detection of substantial blood loss or injury is insensitive and unreliable; large volumes of intraperitoneal blood may be present before physical examination findings are apparent. Findings with intra-abdominal hemorrhage include abdominal distension, abdominal tenderness, or visible abdominal wounds. Hemodynamic abnormalities generally stimulate a search for blood loss before the appearance of obvious abdominal findings. Adjunctive tests are essential in the diagnosis of intraperitoneal bleeding; intraperitoneal blood may be rapidly identified by diagnostic ultrasound or diagnostic peritoneal lavage. Furthermore, patients that have sustained high-energy blunt trauma that are hemodynamically stable or that have normalized their vital signs in response to initial volume resuscitation should undergo computed tomography scans to assess for head, chest, and/or abdominal bleeding.

**Treatment.** Control of ongoing hemorrhage is an essential component of the resuscitation of the patient in shock. As mentioned in the previous “Diagnosis” section, treatment of hemorrhagic shock is instituted concurrently with diagnostic evaluation to identify a source. Patients who fail to respond to initial resuscitative efforts should be assumed to have ongoing active hemorrhage from large vessels and require prompt operative intervention. Based on trauma literature, patients with ongoing hemorrhage demonstrate increased survival if the elapsed time between the injury and control of bleeding is decreased. Although there are no randomized controlled trials, retrospective studies provide compelling evidence in this regard. To this end, Clarke and colleagues demonstrated that trauma

patients with major injuries isolated to the abdomen requiring emergency laparotomy had an increased probability of death with increasing length of time in the emergency department for patients who were in the emergency department for 90 minutes or less. This probability increased approximately 1% for each 3 minutes in the emergency department.

The appropriate priorities in these patients are as follows: (a) control the source of blood loss, (b) perform IV volume resuscitation with blood products in the hypotensive patient, and (c) secure the airway. In trauma, identifying the body cavity harboring active hemorrhage will help focus operative efforts; however, because time is of the essence, rapid treatment is essential, and diagnostic laparotomy or thoracotomy may be indicated. The actively bleeding patient cannot be resuscitated until control of ongoing hemorrhage is achieved. Our current understanding has led to the management strategy known as damage control resuscitation.65 This strategy begins in the emergency department, continues into the operating room, and into the intensive care unit (ICU). Initial resuscitation is limited to keep SBP around 80 to 90 mmHg. This prevents renewed bleeding from recently clotted vessels. Resuscitation and intravascular volume resuscitation is accomplished with blood products and limited crystalloids, which is addressed further later in this section. Too little volume allowing persistent severe hypotension and hypoperfusion is dangerous, yet too vigorous of a volume resuscitation may be just as deleterious. Control of hemorrhage is achieved in the operating room (or angiography suite once surgical causes of hemorrhage have been ruled out), and efforts to warm patients and to prevent coagulopathy using multiple blood products and pharmacologic agents are used in both the operating room and ICU.

Cannon and colleagues first made the observation that attempts to increase blood pressure in soldiers with uncontrolled sources of hemorrhage is counterproductive, with increased bleeding and higher mortality.6 The work was the foundation for the “hypotensive resuscitation” strategies. Several laboratory studies confirmed the observation that attempts to restore normal blood pressure with fluid infusion or vasopressors was rarely achievable and resulted in more bleeding and higher mortality.66 A prospective, randomized clinical study compared delayed fluid resuscitation (upon arrival in the operating room) with standard fluid resuscitation (with arrival by the paramedics) in hypotensive patients with penetrating torso injury.57 The authors reported that delayed fluid resuscitation resulted in lower patient mortality. Further laboratory studies demonstrated that fluid restriction in the setting of profound hypotension resulted in early deaths from severe hypoperfusion. These studies also showed that aggressive crystalloid resuscitation attempting to normalize blood pressure resulted in marked hemodilution, with hematocrits of 5%.66 Reasonable conclusions in the setting of uncontrolled hemorrhage include (a) any delay in surgery for control of hemorrhage increases mortality; (b) with uncontrolled hemorrhage, attempting to achieve normal blood pressure may increase mortality, particularly with penetrating injuries and short transport times; (c) a goal of SBP of 80 to 90 mmHg may be adequate in the patient with penetrating injury; and (d) profound hemodilution should be avoided by early transfusion of red blood cells. For the patient with blunt injury, where the major cause of death is a closed head injury, the increase in mortality with hypotension in the setting of brain injury must be avoided. In this setting, a SBP of 110 mmHg would seem to be more appropriate.

Patients who respond to initial resuscitative effort but then deteriorate hemodynamically frequently have injuries that require operative intervention. The magnitude and duration of their response will dictate whether diagnostic maneuvers can be performed to identify the site of bleeding. However, hemodynamic deterioration generally denotes ongoing bleeding for which some form of intervention (i.e., operation or interventional radiology) is required. Patients who have lost significant intravascular volume, but whose hemorrhage is controlled or has abated, often will respond to resuscitative efforts if the depth and duration of shock have been limited.

A subset of patients exists who fail to respond to resuscitative efforts despite adequate control of ongoing hemorrhage. These patients have ongoing fluid requirements despite adequate control of hemorrhage, have persistent hypotension despite restoration of intravascular volume necessitating vasopressor support, and may exhibit a futile cycle of uncorrectable hypothermia, hypoperfusion, acidosis, and coagulopathy that cannot be interrupted despite maximum therapy. These patients have deteriorated to decompensated or irreversible shock with peripheral vasodilation and resistance to vasopressor infusion. Mortality is almost inevitable once the patient manifests shock in its terminal stages. Unfortunately, this is often diagnosed in retrospect.

Fluid resuscitation is a major adjunct to physically controlling hemorrhage in patients with shock. The ideal type of fluid to be used continues to be debated; however, crystalloids continue to be the mainstay fluid of choice. Several studies have demonstrated increased risk of death in bleeding trauma patients treated with colloid compared to patients treated with crystalloid.68 In patients with severe hemorrhage, restoration of intravascular volume should be achieved with blood products.69

Ongoing studies continue to evaluate the use of hypertonic saline as a resuscitative adjunct in bleeding patients.70 The benefit of hypertonic saline solutions may be immunomodulatory. Specifically, these effects have been attributed to pharmacologic effects resulting in decreased reperfusion-mediated injury with decreased O2 radical formation, less impairment of immune function compared to standard crystalloid solution, and less brain swelling in the multi-injured patient. The reduction of total volume used for resuscitation makes this approach appealing as a resuscitation agent for combat injuries and may contribute to a decrease in the incidence of ARDS and multiple organ failure.

Transfusion of packed red blood cells and other blood products is essential in the treatment of patients in hemorrhagic shock. Current recommendations in stable ICU patients aim for a target hemoglobin of 7 to 9 g/dL.71 72 However, no prospective randomized trials have compared restrictive and liberal transfusion regimens in trauma patients with hemorrhagic shock. The current standard in severely injured patients is termed damage control resuscitation and consists of transfusion with red blood cells, fresh frozen plasma (FFP), and platelet units given in equal number.73 Civilian and military trauma data show that the development of coagulopathy of trauma is predictive of mortality.74 Data collected from a U.S. Army combat support hospital helped to propagate this practice, showing in patients that received massive transfusion of packed red blood cells (>10 units in 24 hours) that a high plasma to RBC ratio (1:1.4 units) was independently associated with improved survival.75 A number of civilian studies have demonstrated similar results.76 Similarly, platelet transfusion is important. The Pragmatic Randomized Optimal Platelet and Plasma Ratios (PROPR)
trial has demonstrated that damage-control resuscitation, a massive transfusion strategy targeting a balanced delivery of plasma-platelet-red blood cell in a ratio of 1:1:1, results in improved survival at 3 hours and a reduction in deaths caused by exsanguination in the first 24 hours. Studies have demonstrated that low platelet counts in trauma patients was associated with increased mortality and that increased platelet use appears to improve outcome. The benefit of platelet transfusion may be most pronounced in trauma patients with brain injury. It has been suggested that platelets should be transfused in the bleeding patient to maintain counts above 50 × 10^9/L. In addition, transfusion of whole blood is gaining in popularity, and ongoing studies are evaluating the benefit of this approach.

There is a potential role for other coagulation factor based products, such as fibrinogen concentrates and prothrombin complex concentrates. Use of these agents may be guided by a drop in fibrinogen levels to less than 1 g/L, or less specifically by thromboelastogram findings to suggest hyperfibrinolysis. Data also support the use of antifibrinolytic agents in bleeding trauma patients, specifically tranexamic acid (a synthetic lysine analogues that acts as a competitive inhibitor of plasmin and plasminogen). The multinational Clinical Randomization of an Antifibrinolytic in Significant Haemorrhage 2 (CRASH-2) trial suggested that early use of tranexamic acid limits rebleeding and reduces mortality (Fig 5-10). In the past, coagulopathy associated with the bleeding patient was presumed to be due solely to dilution and depletion of clotting factors and platelets. We now understand that an acute coagulopathy of trauma occurs as an immediate consequence of injury, with abnormal admission coagulation as a predictor of high mortality. Traditional measurement of platelets, INR, and PTT may not reflect the coagulopathy of trauma or response to therapy effectively. Recently, viscoelastic functional testing such as thromboelastography (TEG) has been utilized as a quicker, more comprehensive determination of coagulopathy and fibrinolysis in the injured patient. Holcomb et al recently reported that TEG predicted patients with substantial bleeding and red cell transfusion better than conventional coagulopathy tests, and it also predicted the need for platelet transfusion better than platelet count and the need for plasma transfusion better than fibrinogen levels.

Additional resuscitative adjuncts in patients with hemorrhagic shock include minimization of heat loss and maintaining normothermia. The development of hypothermia in the bleeding patient is associated with acidosis, hypotension, and coagulopathy. Hypothermia in bleeding trauma patients is an independent risk factor for bleeding and death. This likely is secondary to impaired platelet function and impairments in the coagulation cascade. Several studies have investigated the induction of controlled hypothermia in patients with severe shock based on the hypothesis of limiting metabolic activity and energy requirements, creating a state of “suspended animation.” These studies are promising and continue to be evaluated in large trials.

**Traumatic Shock**

The systemic response after trauma, combining the effects of soft tissue injury, long bone fractures, and blood loss, is clearly a different physiologic insult than simple hemorrhagic shock. Multiple organ failure, including acute respiratory distress syndrome (ARDS), develops relatively often in the blunt trauma patient, but rarely after pure hemorrhagic shock (such as a GI bleed). The hypoperfusion deficit in traumatic shock is magnified by the proinflammatory activation that occurs following the induction of shock. In addition to ischemia or ischemia-reperfusion, accumulating evidence demonstrates that even simple hemorrhage induces proinflammatory activation that results in many of the cellular changes typically ascribed only to septic shock. At the cellular level, this may be attributable to the release of cellular products termed damage associated molecular patterns (DAMPs, i.e., ribonucleic acid, uric acid, and high mobility group box 1) that activate the same set of cell surface receptors as bacterial products, initiating similar cell signaling. These receptors are termed pattern recognition receptors (PRRs) and include the TLR family of proteins. Examples of traumatic shock include small volume hemorrhage accompanied by soft tissue injury (femur fracture, crush injury), or any combination of hypovolemic, neurogenic, cardiogenic, and obstructive shock that precipitate rapidly progressive proinflammatory activation. In laboratory models of traumatic shock, the addition of a soft tissue or long bone injury to hemorrhage produces lethality with significantly less blood loss when the animals are stressed by hemorrhage. Treatment of traumatic shock is focused on correction of the individual elements to diminish the cascade of proinflammatory activation, and includes prompt control of hemorrhage, adequate volume resuscitation to correct O₂ debt, debridement of nonviable tissue, stabilization of bony injuries, and appropriate treatment of soft tissue injuries.

**Septic Shock (Vasodilatory Shock)**

In the peripheral circulation, profound vasoconstriction is the typical physiologic response to the decreased arterial pressure and tissue perfusion with hemorrhage, hypovolemia, or acute heart failure. This is not the characteristic response in vasodilatory shock. Vasodilatory shock is the result of dysfunction of the endothelium and vasculature secondary to circulating inflammatory mediators and cells or as a response to prolonged and severe hypoperfusion. Thus, in vasodilatory shock, hypotension results from failure of the vascular smooth muscle to constrict appropriately. Vasodilatory shock is characterized by peripheral vasodilation with resultant hypotension and resistance to treatment with vasopressors. Despite the hypotension, plasma catecholamine levels are elevated, and the renin-angiotensin system
is activated in vasodilatory shock. The most frequently encountered form of vasodilatory shock is septic shock. Other causes of vasodilatory shock include hypoxic lactic acidosis, carbon monoxide poisoning, uncompensated and irreversible hemorrhagic shock, terminal cardiogenic shock, and postcardiomyotomy shock (Table 5-6). Thus, vasodilatory shock seems to represent the final common pathway for profound and prolonged shock of any etiology.88

Despite advances in intensive care, the mortality rate for severe sepsis remains at 30% to 50%. In the United States, 750,000 cases of sepsis occur annually, one-third of which are fatal.89 Sepsis accounts for 9.3% of deaths in the United States, as many yearly as MI. Septic shock is a by-product of the body’s response to disruption of the host-microbe equilibrium, resulting in invasive or severe localized infection.

In the attempt to eradicate the pathogens, the immune and other cell types (e.g., endothelial cells) elaborate soluble mediators that enhance macrophage and neutrophil killing effector mechanisms, increase procoagulant activity and fibroblast activity to localize the invaders, and increase microvascular blood flow to enhance delivery of killing forces to the area of invasion. When this response is overly exuberant or becomes systemic rather than localized, manifestations of sepsis may be evident. These findings include enhanced cardiac output, peripheral vasodilation, fever, leukocytosis, hyperglycemia, and tachycardia. In septic shock, the vasodilatory effects are due, in part, to the upregulation of the inducible isoform of nitric oxide synthase (iNOS or NOS 2) in the vessel wall. iNOS produces large quantities of nitric oxide for sustained periods of time. This potent vasodilator suppresses vascular tone and renders the vasculature resistant to the effects of vasoconstricting agents. Additionally, endothelial activation or injury likely contributes to some degree of vascular dysfunction.

Diagnosis. Attempts to standardize terminology have led to the establishment of criteria for the diagnosis of sepsis in the hospitalized adult. These criteria include manifestations of the host response to infection in addition to identification of an offending organism. The terms sepsis and septic shock are used to quantify the magnitude of the systemic inflammatory reaction. Patients with sepsis have evidence of an infection, as well as systemic signs of inflammation (e.g., fever, leukocytosis, and tachycardia). Hypoperfusion with signs of organ dysfunction is termed severe sepsis. Septic shock requires the presence of the aforementioned signs, associated with more significant evidence of tissue hypoperfusion and systemic hypotension. Beyond the hypotension, maldistribution of blood flow and shunting in the microcirculation further compromise delivery of nutrients to the tissue beds.90,91 The Third International Consensus Definitions for Sepsis and Septic Shock (Sepsis-3) have refined the definitions and utilize a Sequential (Sepsis-related) Organ Failure Assessment (SOFA) score to help determine signs of organ dysfunction and to guide management.92

Recognizing septic shock begins with defining the patient at risk. The clinical manifestations of septic shock will usually become evident and prompt the initiation of treatment before bacteriologic confirmation of an organism or the source of an organism is identified. In addition to fever, tachycardia, and tachypnea, signs of hypoperfusion such as confusion, malaise, oliguria, or hypotension may be present. These should prompt an aggressive search for infection, including a thorough physical examination, inspection of all wounds, evaluation of intravascular catheters or other foreign bodies, obtaining appropriate cultures, and adjunctive imaging studies, as needed.

Treatment. Evaluation of the patient in septic shock begins with an assessment of the adequacy of their airway and ventilation. Severely obtunded patients and patients whose work of breathing is excessive require intubation and ventilation to prevent respiratory collapse. Because vasodilation and decrease in total peripheral resistance may produce hypotension, fluid resuscitation and restoration of circulatory volume with balanced salt solutions is essential. The Surviving Sepsis Campaign has updated treatment recommendations and care bundles with a most recent goal for care within the first hour93,94 (Table 5-7). Serum lactate should be measured as a marker of shock. Fluid resuscitation should begin within the first hour and should be at least 30 mL/kg for hypotensive patients. Incremental fluid boluses should be continued based upon endpoint of resuscitation, including clearance of lactate. Starch-based colloid solutions should be avoided as recent evidence suggests that these fluids may be deleterious in the setting of sepsis.90-95,98 Blood cultures should be obtained. Empiric antibiotics must be chosen carefully based on the most likely pathogens (gram-negative rods, gram-positive cocci, and anaerobes) because the portal of entry of the offending organism and its identity may not be evident until culture data return or imaging studies are completed. Knowledge of the bacteriologic profile of infections in an individual unit can be obtained from most hospital infection control departments and will suggest potential responsible organisms. Antibiotics should be tailored to cover the responsible organisms once culture data are available, and if appropriate, the

spectrum of coverage narrowed. Long-term, empiric, broad-spectrum antibiotic use should be minimized to reduce the development of resistant organisms and to avoid the potential complications of fungal overgrowth and antibiotic-associated colitis from overgrowth of Clostridium difficile. IV antibiotics will be insufficient to adequately treat the infectious episode in the settings of infected fluid collections, infected foreign bodies, and devitalized tissue. These situations require source control and involve percutaneous drainage and operative management to target a focus of infection. These situations may require multiple operations to ensure proper wound hygiene and healing.

After first-line therapy of the septic patient with antibiotics, IV fluids, and intubation if necessary, vasopressors may be necessary to treat patients with septic shock. Catecholamines are the vasopressors used most often, with norepinephrine being the first-line agent followed by epinephrine. Occasionally, patients with septic shock will develop arterial resistance to catecholamines. Arginine vasopressin, a potent vasoconstrictor, is often efficacious in this setting and is often added to norepinephrine.

The majority of septic patients have hyperdynamic physiology with supranormal cardiac output and low systemic vascular resistance. On occasion, septic patients may have low cardiac output despite volume resuscitation and even vasoppressor support. Dobutamine therapy is recommended for patients with cardiac dysfunction as evidenced by high filling pressures and low cardiac output or clinical signs of hypoperfusion after achievement of restoration of blood pressure following fluid resuscitation. Mortality in this group is high. Despite the increasing incidence of septic shock over the past several decades, the overall mortality rates have changed little. Studies of interventions, including immunotherapy, resuscitation to pulmonary artery endpoints with hemodynamic optimization (cardiac output and O2 delivery, even to supranormal values), and optimization of mixed venous O2 measurements up to 72 hours after admission to the ICU, have not changed mortality.

The advances made in the treatment of patients with sepsis and septic shock and collaborative groups such as the Surviving Sepsis Campaign continue to evaluate, modify, and put forth recommendations based upon data. Negative results from previous studies have led to the suggestion that earlier interventions directed at improving global tissue oxygenation may be of benefit. To this end, Rivers and colleagues reported that goal-directed therapy of septic shock and severe sepsis initiated in the emergency department and continued for 6 hours significantly improved outcome.70 This approach involved adjustment of cardiac preload, afterload, and contractility to balance O2 delivery with O2 demand. They found that goal-directed therapy during the first 6 hours of hospital stay (initiated in the emergency department) had significant effects, such as higher mean venous O2 saturation, lower lactate levels, lower base deficit, higher pH, and decreased 28-day mortality (49.2% vs. 33.3%) compared to the standard therapy group. The frequency of sudden cardiovascular collapse was also significantly less in the group managed with goal-directed therapy (21.0% vs. 10.3%). Interestingly, the goal-directed therapy group received more IV fluids during the initial 6 hours, but the standard therapy group required more IV fluids by 72 hours. The authors emphasize that continued cellular and tissue decompensation is subclinical and often irreversible when obvious clinically. Goal-directed therapy allowed identification and treatment of these patients with insidious illness (global tissue hypoxia in the setting of normal vital signs).

Several multicenter trials have been performed to further refine these finding. In the Protocolized Care for Early Septic Shock (ProCESS) trial, a multicenter, randomized trial in which patients were identified early in the emergency department as having septic shock and received antibiotics and other nonresuscitation aspects of care promptly, the investigators found no significant advantage, with respect to mortality or morbidity, of protocol-based resuscitation over bedside care that was provided according to the treating physician’s judgment. They also found no significant benefit of the mandated use of central venous catheterization and central hemodynamic monitoring in all patients. This last finding was recapitulated in the Protocolised Management in Sepsis (ProMISE) trial.69 Failure of these more recent trials to show a benefit of early goal-directed protocols vs. standard of care may be secondary to the generalized improvement in early recognition of sepsis and institution of protocolized care by efforts such as the Surviving Sepsis Campaign.

Hyperglycemia and insulin resistance are typical in critically ill and septic patients, including patients without underlying diabetes mellitus. A recent study reported significant positive impact of tight glucose management on outcome in critically ill patients.100 The two treatment groups in this randomized, prospective study were assigned to receive intensive insulin therapy (maintenance of blood glucose between 80 and 110 mg/dL) or conventional treatment (infusion of insulin only if the blood glucose level exceeded 215 mg/dL, with a goal between 180 and 200 mg/dL). The mean morning glucose level was significantly higher in the conventional treatment as compared to the intensive insulin therapy group (153 vs. 103 mg/dL). Mortality in the intensive insulin treatment group (4.6%) was significantly lower than in the conventional treatment group (8.0%), representing a 42% reduction in mortality. This reduction in mortality was most notable in the patients requiring longer than 5 days in the ICU. Furthermore, intensive insulin therapy reduced episodes of septicemia by 46%, reduced duration of antibiotic therapy, and decreased the need for prolonged ventilatory support and renal replacement therapy.

Another treatment protocol that has been demonstrated to increase survival in patients with ARDS investigated the use of lower ventilatory tidal volumes compared to traditional tidal volumes.103 The majority of the patients enrolled in this multicenter, randomized trial developed ARDS secondary to pneumonia or sepsis. The trial compared traditional ventilation treatment, which involved an initial tidal volume of 12 mL/kg of predicted body weight, with ventilation with a lower tidal volume, which involved an initial tidal volume of 6 mL/kg of predicted body weight. The trial was stopped after the enrollment of 861 patients because mortality was lower in the group treated with lower tidal volumes than in the group treated with traditional tidal volumes (31.0% vs. 39.8%, P = .007), and the number of days without ventilator use during the first 28 days after randomization was greater in this group (mean ± SD, 12 ± 11 vs. 10 ± 11; P = .007). The investigators concluded that in patients with acute lung injury and ARDS, mechanical ventilation with a lower tidal volume than is traditionally used results in decreased mortality and increases the number of days without ventilator use. Additional strategies in ARDS management include higher levels of positive end expiratory pressure (PEEP), alveolar recruitment maneuvers, and prone positioning. Prone positioning has become part of many standardized protocols. This is supported by several studies, including a
meta-analysis demonstrating that prone positioning is associated with significantly reduced mortality from ARDS in the low tidal volume era.102

The use of corticosteroids in the treatment of sepsis and septic shock has been controversial for decades. The observation that severe sepsis often is associated with adrenal insufficiency or glucocorticoid receptor resistance has generated renewed interest in therapy for septic shock with corticosteroids. A single IV dose of 50 mg of hydrocortisone improved mean arterial blood pressure response relationships to norepinephrine and phenylephrine in patients with septic shock and was most notable in patients with relative adrenal insufficiency. A study evaluated therapy with hydrocortisone (50 mg IV every 6 hours) and fludrocortisone (50 µg orally once daily) vs. placebo for 1 week in patients with septic shock.103 As in earlier studies, the authors performed corticotropin tests on these patients to document and stratify patients by relative adrenal insufficiency. In this study, 7-day treatment with low doses of hydrocortisone and fludrocortisone significantly and safely lowered the risk of death in patients with septic shock and relative adrenal insufficiency. In an international, multicenter, randomized trial of corticosteroids in sepsis (CORTICUS study; 499 analyzable patients), steroids showed no benefit in intent to treat mortality or shock reversal.104 This study suggested that hydrocortisone therapy cannot be recommended as routine adjuvant therapy for septic shock. However, if SBP remains less than 90 mmHg despite appropriate fluid and vasopressor therapy, hydrocortisone at 200 mg/day for 7 days in four divided doses or by continuous infusion should be considered.

Additional adjunctive immune modulation strategies have been developed for the treatment of septic shock. These include the use of antiendotoxin antibodies, anticytokine antibodies, cytokine receptor antagonists, immune enhancers, a non–isoform-specific nitric oxide synthase inhibitor, and O2• radical scavengers. These compounds are each designed to alter some aspect of the host immune response to shock that is hypothesized to play a key role in its pathophysiology. However, most of these strategies have failed to demonstrate efficacy in human patients despite utility in well-controlled animal experiments. It is unclear whether the failure of these compounds is due to poorly designed clinical trials, inadequate understanding of the interactions of the complex host immune response to injury and infection, or animal models of shock that poorly represent the human disease.

Cardiogenic Shock
Cardiogenic shock is defined clinically as circulatory pump failure leading to diminished forward flow and subsequent tissue hypoxia, in the setting of adequate intravascular volume. Hemodynamic criteria include sustained hypotension (i.e., SBP <90 mmHg for at least 30 minutes), reduced cardiac index (<2.2 L/min per square meter), and elevated pulmonary arterial wedge pressure (>15 mmHg).105 Mortality rates for cardiogenic shock are 50% to 80%. Acute, extensive MI is the most common cause of cardiogenic shock; a smaller infarction in a patient with existing left ventricular dysfunction also may precipitate shock. Cardiogenic shock complicates 5% to 10% of acute MIs. Conversely, cardiogenic shock is the most common cause of death in patients hospitalized with acute MI. Although shock may develop early after MI, it typically is not found on admission. Seventy-five percent of patients who have cardiogenic shock complicating acute MIs develop signs of cardiogenic shock within 24 hours after onset of infarction (average 7 hours).

Increased sympathetic stimulation of the heart, either through direct neural input or from circulating catecholamines, increases heart rate, myocardial contraction, and myocardial O₂ consumption, which may not be relieved by increases in coronary artery blood flow in patients with fixed stenoses of the coronary arteries. Diminished cardiac output may also decrease coronary artery blood flow, resulting in a scenario of increased myocardial O₂ demand at a time when myocardial O₂ supply may be limited. Acute heart failure may also result in fluid accumulation in the pulmonary microcirculatory bed, decreasing myocardial O₂ delivery even further.

**Diagnosis.** Rapid identification of the patient with pump failure and institution of corrective action are essential in preventing the ongoing spiral of decreased cardiac output from injury causing increased myocardial O₂ needs that cannot be met, leading to progressive and unremitting cardiac dysfunction. In evaluation of possible cardiogenic shock, other causes of hypotension must be excluded, including hemorrhage, sepsis, pulmonary embolism, and aortic dissection. Signs of circulatory shock include hypotension, cool and mottled skin, depressed mental status, tachycardia, and diminished pulses. Cardiac exam may include dysrhythmia, precordial heave, or distal heart tones. Confirmation of a cardiac source for the shock requires electrocardiogram and urgent echocardiography. Other useful diagnostic tests include chest radiograph, arterial blood gases, electrolytes, complete blood count, and cardiac enzymes. Invasive cardiac monitoring, which generally is not necessary, can be useful to exclude right ventricular infarction, hypovolemia, and possible mechanical complications.

Making the diagnosis of cardiogenic shock involves the identification of cardiac dysfunction or acute heart failure in a susceptible patient. In the setting of blunt traumatic injury, hemorrhagic shock from intra-abdominal bleeding, intrathoracic bleeding, and bleeding from fractures must be excluded, before implicating cardiogenic shock from blunt cardiac injury. Relatively few patients with blunt cardiac injury will develop cardiac pump dysfunction. Those who do generally exhibit cardiogenic shock early in their evaluation. Therefore, establishing the diagnosis of blunt cardiac injury is secondary to excluding other etiologies for shock and establishing that cardiac dysfunction is present. Invasive hemodynamic monitoring with a pulmonary artery catheter may uncover evidence of diminished cardiac output and elevated pulmonary artery pressure.

**Treatment.** After ensuring that an adequate airway is present and ventilation is sufficient, attention should be focused on support of the circulation. Intubation and mechanical ventilation often are required, if only to decrease work of breathing and facilitate sedation of the patient. Rapidly excluding hypovolemia and establishing the presence of cardiac dysfunction are essential. Treatment of cardiac dysfunction includes maintenance of adequate oxygenation to ensure adequate myocardial O₂ delivery and judicious fluid administration to avoid fluid overload and development of cardiogenic pulmonary edema. Electrolyte abnormalities, commonly hypokalemia and hypomagnesemia, should be corrected. Pain is treated with IV morphine sulfate or fentanyl. Significant dysrhythmias and heart block must be treated with antiarrhythmic drugs, pacing, or cardioversion, if necessary. Early consultation with cardiology is essential in current management of cardiogenic shock, particularly in the setting of acute MI.¹⁰⁵

When profound cardiac dysfunction exists, inotropic support may be indicated to improve cardiac contractility and cardiac output. Dobutamine primarily stimulates cardiac β₁-receptors to increase cardiac output but may also vasodilate peripheral vascular beds, lower total peripheral resistance, and lower systemic blood pressure through effects on β₂-receptors. Ensuring adequate preload and intravascular volume is therefore essential prior to instituting therapy with dobutamine. Dopamine stimulates receptors (vasoconstriction), β₁-receptors (cardiac stimulation), and β₂-receptors (vasodilation), with its effects on β-receptors predominating at lower doses. Dopamine may be preferable to dobutamine in treatment of cardiac dysfunction in hypotensive patients. Tachycardia and increased peripheral resistance from dopamine infusion may worsen myocardial ischemia. Titration of both dopamine and dobutamine infusions may be required in some patients.

Epinephrine stimulates α- and β-receptors and may increase cardiac contractility and heart rate; however, it also may have intense peripheral vasoconstrictor effects that impair further cardiac performance. Catecholamine infusions must be carefully controlled to maximize coronary perfusion, while minimizing myocardial O₂ demand. Balancing the beneficial effects of impaired cardiac performance with the potential side effects of excessive reflex tachycardia and peripheral vasoconstriction requires serial assessment of tissue perfusion using indices such as capillary refill, character of peripheral pulses, adequacy of urine output, or improvement in laboratory parameters of resuscitation such as pH, base deficit, and lactate. Invasive monitoring generally is necessary in these unstable patients. The phosphodiesterase inhibitors amrinone and milrinone may be required on occasion in patients with resistant cardiogenic shock. These agents have long half-lives and induce thrombocytopenia and hypotension, and use is reserved for patients unresponsive to other treatment.

Patients whose cardiac dysfunction is refractory to inotropics may require mechanical circulatory support with an intra-aortic balloon pump.¹¹⁰ Intra-aortic balloon pumping increases cardiac output and improves coronary blood flow by reduction of systolic afterload and augmentation of diastolic perfusion pressure. Unlike vasopressor agents, these beneficial effects occur without an increase in myocardial O₂ demand. An intra-aortic balloon pump can be inserted at the bedside in the ICU via the femoral artery through either a cutdown or using the percutaneous approach. Aggressive circulatory support of patients with cardiac dysfunction from intrinsic cardiac disease has led to more widespread application of these devices and more familiarity with their operation by both physicians and critical care nurses.

Preservation of existing myocardium and preservation of cardiac function are priorities of therapy for patients who have suffered an acute MI. Ensuring adequate oxygenation and O₂ delivery, maintaining adequate preload with judicious volume restoration, minimizing sympathetic discharge through adequate relief of pain, and correcting electrolyte imbalances are all straightforward nonspecific maneuvers that may improve existing cardiac function or prevent future cardiac complications. Anticoagulation and aspirin are given for acute MI. Although thrombolytic therapy reduces mortality in patients with acute MI, its role in cardiogenic shock is less clear. Patients in cardiac failure from an acute MI may benefit from pharmacologic or mechanical circulatory support in a manner similar to that of patients with cardiac failure related to blunt cardiac
injury. Additional pharmacologic tools may include the use of β-blockers to control heart rate and myocardial O₂ consumption, nitrates to promote coronary blood flow through vasodilation, and ACE inhibitors to reduce ACE-mediated vasoconstrictive effects that increase myocardial workload and myocardial O₂ consumption.

Current guidelines of the American Heart Association recommend percutaneous transluminal coronary angiography for patients with cardiogenic shock, ST elevation, left bundle-branch block, and age less than 75 years. Early definition of coronary anatomy and revascularization is the pivotal step in treatment of patients with cardiogenic shock from acute MI. When feasible, percutaneous transluminal coronary angioplasty (generally with stent placement) is the treatment of choice. Coronary artery bypass grafting seems to be more appropriate for patients with multiple vessel disease or left main coronary artery disease.

### Obstructive Shock

Although obstructive shock can be caused by a number of different etiologies that result in mechanical obstruction of venous return (Table 5-9), in trauma patients this is most commonly due to the presence of tension pneumothorax. Cardiac tamponade occurs when sufficient fluid has accumulated in the pericardial sac to obstruct blood flow to the ventricles. The hemodynamic abnormalities in pericardial tamponade are due to elevation of intracardiac pressures with limitation of ventricular filling in diastole with resultant decrease in cardiac output. Acutely, the pericardium does not distend; thus small volumes of blood may produce cardiac tamponade. If the effusion accumulates slowly (e.g., in the setting of uremia, heart failure, or malignant effusion), the quantity of fluid producing cardiac tamponade may reach 2000 mL. The major determinant of the degree of hypotension is the pericardial pressure. With either cardiac tamponade or tension pneumothorax, reduced filling of the right side of the heart from either increased intrapleural pressure secondary to air accumulation (tension pneumothorax) or increased intrapericardial pressure precluding atrial filling secondary to blood accumulation (cardiac tamponade) results in decreased cardiac output associated with increased central venous pressure.

### Diagnosis and Treatment

The diagnosis of tension pneumothorax should be made on clinical examination. The classic findings include respiratory distress (in an awake patient), hypotension, diminished breath sounds over one hemithorax, hyper-resonance to percussion, jugular venous distention, and shift of mediastinal structures to the unaffected side with tracheal deviation. In most instances, empiric treatment with pleural decompression is indicated rather than delaying to wait for radiographic confirmation. When a chest tube cannot be immediately inserted, such as in the prehospital setting, the pleural space can be decompressed with a large caliber needle. Immediate return of air should be encountered with rapid resolution of hypotension. Unfortunately, not all of the clinical manifestations of tension pneumothorax may be evident on physical examination. Hyperresonance may be difficult to appreciate in a noisy resuscitation area. Jugular venous distention may be absent in a hypovolemic patient. Tracheal deviation is a late finding and often is not apparent on clinical examination. Practically, three findings are sufficient to make the diagnosis of tension pneumothorax: respiratory distress or hypotension, decreased lung sounds, and hypertympany to percussion. Chest X-ray findings that may be visualized include deviation of mediastinal structures, depression of the hemidiaphragm, and hypo-opacification with absent lung markings. As discussed previously, definitive treatment of a tension pneumothorax is immediate tube thoracostomy. The chest tube should be inserted rapidly, but carefully, and should be large enough to evacuate any blood that may be present in the pleural space. Most recommend placement is in the fourth intercostal space (nipple level) at the anterior axillary line.

Cardiac tamponade results from the accumulation of blood within the pericardial sac, usually from penetrating trauma or chronic medical conditions such as heart failure or uremia. Although precordial wounds are most likely to injure the heart and produce tamponade, any projectile or wounding agent that passes in proximity to the mediastinum can potentially produce tamponade. Blunt cardiac rupture, a rare event in trauma victims who survive long enough to reach the hospital, can produce refractory shock and tamponade in the multiply-injured patient. The manifestations of cardiac tamponade, such as total circulatory collapse and cardiac arrest, may be catastrophic, or they may be more subtle. A high index of suspicion is warranted to make a rapid diagnosis. Patients who present with circulatory arrest from cardiac tamponade require emergency pericardial decompression, usually through a left thoracotomy. The indications for this maneuver are discussed in Chapter 7. Cardiac tamponade also may be associated with dyspnea, orthopnea, cough, peripheral edema, chest pain, tachycardia, muffled heart tones, jugular venous distention, and elevated central venous pressure. Beck’s triad consists of hypotension, muffled heart tones, and neck vein distention. Unfortunately, absence of these clinical findings may not be sufficient to exclude cardiac injury and cardiac tamponade. Muffled heart tones may be difficult to appreciate in a busy trauma center, and jugular venous distention and central venous pressure may be diminished by coexistent bleeding. Therefore, patients at risk for cardiac tamponade whose hemodynamic status permits additional diagnostic tests frequently require additional diagnostic maneuvers to confirm cardiac injury or tamponade.

Invasive hemodynamic monitoring may support the diagnosis of cardiac tamponade if elevated central venous pressure, pulsus paradoxus (i.e., decreased systemic arterial pressure with inspiration), or elevated right atrial and right ventricular pressure by pulmonary artery catheter are present. These hemodynamic profiles suffer from lack of specificity, the duration of time required to obtain them in critically injured patients, and their inability to exclude cardiac injury in the absence of tamponade. Chest radiographs may provide information on the possible trajectory of a projectile, but rarely are diagnostic because

the acutely filled pericardium distends poorly. Echocardiography has become the preferred test for the diagnosis of cardiac tamponade. Good results in detecting pericardial fluid have been reported, but the yield in detecting pericardial fluid depends on the skill and experience of the ultrasonographer, body habitus of the patient, and absence of wounds that preclude visualization of the pericardium. Standard two-dimensional or transesophageal echocardiography are sensitive techniques to evaluate the pericardium for fluid, and are typically performed by examiners skilled at evaluating ventricular function, valvular abnormalities, and integrity of the proximal thoracic aorta. Unfortunately, these skilled examiners are rarely immediately available at all hours of the night, when many trauma patients present; therefore, waiting for this test may result in inordinate delays. In addition, although both ultrasound techniques may demonstrate the presence of fluid or characteristic findings of tamponade (large volume of fluid, right atrial collapse, poor distensibility of the right ventricle), they do not exclude cardiac injury per se. Pericardiocentesis to diagnose pericardial blood and potentially relieve tamponade may be used. Performing pericardiocentesis under ultrasound guidance has made the procedure safer and more reliable. An indwelling catheter may be placed for several days in patients with chronic pericardial effusions. Needle pericardiocentesis may not evacuate clotted blood and has the potential to produce cardiac injury, making it a poor alternative in busy trauma centers.

Diagnostic pericardial window represents the most direct method to determine the presence of blood within the pericardium. The procedure is best performed in the operating room under general anesthesia. It can be performed through either the subxiphoid or transdiaphragmatic approach. Adequate equipment and personnel to rapidly decompress the pericardium, explore the injury, and repair the heart should be present. Once the pericardium is opened and tamponade relieved, hemodynamics usually improve dramatically and formal pericardial exploration can ensue. Exposure of the heart can be achieved by extending the incision to a median sternotomy, performing a left anterior thoracotomy, or performing bilateral anterior thoracotomies (“clamshell”).

**Neurogenic Shock**

Neurogenic shock refers to diminished tissue perfusion as a result of loss of vasomotor tone to peripheral arterial beds. Loss of vasoconstrictor impulses results in increased vascular capacitance, decreased venous return, and decreased cardiac output. Neurogenic shock is usually secondary to spinal cord injuries from vertebral body fractures of the cervical or high thoracic region that disrupt sympathetic regulation of peripheral vascular tone (Table 5-10). Rarely, a spinal cord injury without bony fracture, such as an epidural hematoma impinging on the spinal cord, can produce neurogenic shock. Sympathetic input to the heart, which normally increases heart rate and cardiac contractility, and input to the adrenal medulla, which increases catecholamine release, may also be disrupted, preventing the typical reflex tachycardia that occurs with hypovolemia. Acute spinal cord injury results in activation of multiple secondary injury mechanisms: (a) vascular compromise to the spinal cord with loss of autoregulation, vasospasm, and thrombosis; (b) loss of cellular membrane integrity and impaired energy metabolism; and (c) neurotransmitter accumulation and release of free radicals. Importantly, hypotension contributes to the worsening of acute spinal cord injury as the result of further reduction in blood flow to the spinal cord. Management of acute spinal cord injury with attention to blood pressure control, oxygenation, and hemodynamics, essentially optimizing perfusion of an already ischemic spinal cord, seems to result in improved neurologic outcome. Patients with hypotension from spinal cord injury are best monitored in an ICU and carefully followed for evidence of cardiac or respiratory dysfunction.

**Diagnosis.** Acute spinal cord injury may result in bradycardia, hypotension, cardiac dysrhythmias, reduced cardiac output, and decreased peripheral vascular resistance. The severity of the spinal cord injury seems to correlate with the magnitude of cardiovascular dysfunction. Patients with complete motor injuries are over five times more likely to require vasopressors for neurogenic shock compared to those with incomplete lesions. The classic description of neurogenic shock consists of decreased blood pressure associated with bradycardia (absence of reflexive tachycardia due to disrupted sympathetic discharge), warm extremities (loss of peripheral vasoconstriction), motor and sensory deficits indicative of a spinal cord injury, and radiographic evidence of a vertebral column fracture. Patients with multisystem trauma that includes spinal cord injuries often have head injuries that may make identification of motor and sensory deficits difficult in the initial evaluation. Furthermore, associated injuries may occur that result in hypovolemia, further complicating the clinical presentation. In a subset of patients with spinal cord injuries from penetrating wounds, most of the patients with hypotension had blood loss as the etiology (74%) rather than neurogenic causes, and few (7%) had the classic findings of neurogenic shock. In the multiply injured patient, other causes of hypotension including hemorrhage, tension pneumothorax, and cardiogenic shock, must be sought and excluded.

**Treatment.** After the airway is secured and ventilation is adequate, fluid resuscitation and restoration of intravascular volume often will improve perfusion in neurogenic shock. Most patients with neurogenic shock will respond to restoration of intravascular volume alone, with satisfactory improvement in perfusion and resolution of hypotension. Administration of vasoconstrictors will improve peripheral vascular tone, decrease vascular capacitance, and increase venous return, but should only be considered once hypovolemia is excluded as the cause of the hypotension and the diagnosis of neurogenic shock is established. If the patient’s blood pressure has not responded to what is felt to be adequate volume resuscitation, dopamine may be used first. A pure α-agonist, such as phenylephrine, may be used primarily or in patients unresponsive to dopamine. Specific treatment for the hypotension is often of brief duration, as the need to administer vasoconstrictors typically lasts 24 to 48 hours. On the other hand, life-threatening cardiac dysrhythmias and hypotension may occur up to 14 days after spinal cord injury.

The duration of the need for vasopressor support for neurogenic shock may correlate with the overall prognosis or chances of improvement in neurologic function. Appropriate rapid restoration of blood pressure and circulatory perfusion may improve perfusion to the spinal cord, prevent progressive

spinal cord ischemia, and minimize secondary cord injury. Restoration of normal blood pressure and adequate tissue perfusion should precede any operative attempts to stabilize the vertebral fracture.

ENDPOINTS IN RESUSCITATION

Shock is defined as inadequate perfusion to maintain normal organ function. With prolonged anaerobic metabolism, tissue acidosis and O₂ debt accumulate. Thus, the goal in the treatment of shock is restoration of adequate organ perfusion and tissue oxygenation. Resuscitation is complete when O₂ debt is repaid, tissue acidosis is corrected, and aerobic metabolism restored. Clinical confirmation of this endpoint remains a challenge.

Resuscitation of the patient in shock requires simultaneous evaluation and treatment; the etiology of the shock often is not initially apparent. Hemorrhagic shock, septic shock, and traumatic shock are the most common types of shock encountered on surgical services. To optimize outcome in bleeding patients, early control of the hemorrhage and adequate volume resuscitation, including both red blood cells and crystalloid solutions, are necessary. Expedient operative resuscitation is mandatory to limit the magnitude of activation of multiple mediator systems and to abort the microcirculatory changes, which may evolve insidiously into the cascade that ends in irreversible hemorrhagic shock. Attempts to stabilize an actively bleeding patient anywhere but in the operating room are inappropriate. Any intervention that delays the patient’s arrival in the operating room for control of hemorrhage increases mortality, thus the important concept of operating room resuscitation of the critically injured patient.

Recognition by care providers of the patient who is in the compensated phase of shock is equally important, but more difficult based on clinical criteria. Compensated shock exists when inadequate tissue perfusion persists despite normalization of blood pressure and heart rate. Even with normalization of blood pressure, heart rate, and urine output, 80% to 85% of trauma patients have inadequate tissue perfusion, as evidenced by increased lactate or decreased mixed venous O₂ saturation. Persistent, occult hypoperfusion is frequent in the ICU, with a resultant significant increase in infection rate and mortality in major trauma patients. Patients failing to reverse their lactic acidosis within 12 hours of admission (acidosis that was persistent despite normal heart rate, blood pressure, and urine output) developed an infection three times as often as those who normalized their lactate levels within 12 hours of admission. In addition, mortality was fourfold higher in patients who developed infections. Both injury severity score and occult hypotension (lactic acidosis) longer than 12 hours were independent predictors of infection. Thus, recognition of subclinical hypoperfusion requires information beyond vital signs and urinary output.

Endpoints in resuscitation can be divided into systemic or global parameters, tissue-specific parameters, and cellular parameters. Global endpoints include vital signs, cardiac output, pulmonary artery wedge pressure, O₂ delivery and consumption, lactate, and base deficit (Table 5-11).

Assessment of Endpoints in Resuscitation

Inability to repay O₂ debt is a predictor of mortality and organ failure; the probability of death has been directly correlated to the calculated O₂ debt in hemorrhagic shock. Direct measurement of the O₂ debt in the resuscitation of patients is difficult. The easily obtainable parameters of arterial blood pressure, heart rate, urine output, central venous pressure, and pulmonary artery occlusion pressure are poor indicators of the adequacy of tissue perfusion. Therefore, surrogate parameters have been sought to estimate the O₂ debt; serum lactate and base deficit have been shown to correlate with O₂ debt.

**Lactate.** Lactate is generated by conversion of pyruvate to lactate by lactate dehydrogenase in the setting of insufficient O₂. Lactate is released into the circulation and is predominantly taken up and metabolized by the liver and kidneys. The liver accounts for approximately 50% and the kidney for about 30% of whole body lactate uptake. Elevated serum lactate is an indirect measure of the O₂ debt, and therefore an approximation of the magnitude and duration of the severity of shock. The admission lactate level, highest lactate level, and time interval to normalize the serum lactate are important prognostic indicators for survival. For example, in a study of 76 consecutive patients, 100% survival was observed among the patients with normalization of lactate within 24 hours, 78% survival when lactate normalized between 24 and 48 hours, and only 14% survival if it took longer than 48 hours to normalize the serum lactate. In contrast, individual variability of lactate may be too great to permit accurate prediction of outcome in any individual case. Base deficit and volume of blood transfusion required in the first 24 hours of resuscitation may be better predictors of mortality than the plasma lactate alone.

**Base Deficit.** Base deficit is the amount of base in millimoles that is required to titrate 1 L of whole blood to a pH of 7.40 with the sample fully saturated with O₂ at 37°C (98.6°F) and a partial pressure of CO₂ of 40 mmHg. It usually is measured by arterial blood gas analysis in clinical practice as it is readily and quickly available. The mortality of trauma patients can be stratified according to the magnitude of base deficit measured in the first 24 hours after admission. In a retrospective study of over 3000 trauma admissions, patients with a base deficit worse than 15 mmol/L had a mortality of 70%. Base deficit can be stratified into mild (3 to 5 mmol/L), moderate (6 to 14 mmol/L), and severe (15 mmol/L) categories, with a trend toward higher mortality with worsening base deficit in patients with trauma. Both the magnitude of the perfusion deficit as indicated by the base deficit and the time required to correct it are major factors determining outcome in shock.

Indeed, when elevated base deficit persists (or lactic acidosis) in the trauma patient, ongoing bleeding is often the...
etiology. Trauma patients admitted with a base deficit greater than 15 mmol/L required twice the volume of fluid infusion and six times more blood transfusion in the first 24 hours compared to patients with mild acidosis. Transfusion requirements increased as base deficit worsened and ICU and hospital lengths of stay increased. Mortality increased as base deficit worsened; the frequency of organ failure increased with greater base deficit.59 The probability of trauma patients developing ARDS has been reported to correlate with severity of admission base deficit and lowest base deficit within the first 24 hours postinjury.59 Persistently high base deficit is associated with abnormal \( O_2 \) utilization and higher mortality. Monitoring base deficit in the resuscitation of trauma patients assists in assessment of \( O_2 \) transport and efficacy of resuscitation.58

Factors that may compromise the utility of the base deficit in estimating \( O_2 \) debt are the administration of bicarbonate, hypothermia, hypcapnia (overventilation), heparin, ethanol, and ketoacidosis. However, the base deficit remains one of the most widely used estimates of \( O_2 \) debt for its clinical relevance, accuracy, and availability.

**Near Infrared Spectroscopy.** Near infrared (NIR) spectroscopy can measure tissue oxygenation and redox state of cytochrome \( a,a_3 \) on a continuous, noninvasive basis. The NIR probe emits multiple wavelengths of light in the NIR spectrum (650 to 1100 nm). Photons are then either absorbed by the tissue or reflected back to the probe. Maximal exercise in laboratory studies resulted in reduction of cytochrome \( a,a_3 \); this correlated with tissue lactate elevation. NIR spectroscopy can be used to compare tissue oxyhemoglobin levels (indicating tissue \( O_2 \) supply to cytochrome \( a,a_3 \), with mitochondrial \( O_2 \) consumption), thus demonstrating flow-independent mitochondrial oxidative dysfunction and the need for further resuscitation. Trauma patients with decoupled oxyhemoglobin and cytochrome \( a,a_3 \) have redox dysfunction and have been shown to have a higher incidence of organ failure (89% vs. 13%).121,122

**Tissue PH, Oxygen, and Carbon Dioxide Concentration.** Tissue probes with optical sensors have been used to measure tissue \( pH \) and partial pressure of \( O_2 \) and \( CO_2 \) in subcutaneous sites, muscle, and the bladder. These probes may use transcutaneous methodology with Clark electrodes or direct percutaneous probes.223,124 The percutaneous probes can be inserted through an 18-gauge catheter and hold promise as continuous monitors of tissue perfusion.

**Right Ventricular End-Diastolic Volume Index.** Right ventricular end-diastolic volume index (RVEDVI) seems to more accurately predict preload for cardiac index than does pulmonary artery wedge pressure.125 Chang and colleagues reported that 50% of trauma patients had persistent splanchnic ischemia that was reversed by increasing RVEDVI. RVEDVI is a parameter that seems to correlate with preload-related increases in cardiac output. More recently, these authors have described left ventricular power output as an endpoint (LVP >320 mmHg L/min per square meter), which is associated with improved clearance of base deficit and a lower rate of organ dysfunction following injury.126

HISTORICAL BACKGROUND

Although treatment of infection has long been an integral part of the surgeon’s practice, the body of knowledge that led to the present field of surgical infectious disease was derived from the evolution of germ theory and antisepsis. Application of the latter to clinical practice, concurrent with the development of anesthesia, was pivotal in allowing surgeons to expand their repertoire to encompass complex procedures that previously were associated with extremely high rates of morbidity and mortality due to postoperative infections. However, until recently the occurrence of infection related to the surgical wound was the rule rather than the exception. In fact, the development of modalities to effectively prevent and treat infection has occurred only within the last several decades.

A number of observations by 19th century physicians and investigators were critical to our current understanding of the pathogenesis, prevention, and treatment of surgical infections. In 1846, Ignaz Semmelweis, a Magyar physician, took a post at the Allgemein Krankenhaus in Vienna. He noticed that the mortality rate from puerperal (“childbed”) fever was nearly three times higher in the teaching ward than in the ward where patients were delivered by midwives. He also made the observation that women who delivered prior to arrival on the teaching ward had a negligible mortality rate. When a colleague died from overwhelming infection resulting from a knife scratch received during an autopsy of a woman who had died of puerperal fever, Semmelweis observed that pathologic changes in his friend were identical to those of women dying from this postpartum disease. He hypothesized that puerperal fever was caused by putrid material carried on the examining fingers of medical students and physicians who cared for women dying of the disease, and who often went from the autopsy room to the wards. The low mortality rate in the midwives’ ward, Semmelweis realized, was because midwives did not participate in autopsies. Fired with the zeal of his revelation, he posted a notice on the door to the ward requiring all caregivers to rinse their hands thoroughly in chlorine water prior to entering the area. This simple intervention reduced the mortality rate from puerperal fever on the teaching ward to 1.5%, surpassing the record of the midwives. In 1861, he published his classic work on childbed fever based on records from his practice. Unfortunately, Semmelweis’ ideas were not well accepted by the authorities of the time.1 Increasingly frustrated by the indifference of the medical profession, he began writing open letters to well-known obstetricians in Europe and was committed to an asylum due to concerns that he was losing his mind. He died shortly thereafter. His achievements were only recognized after Pasteur’s description of the germ theory of disease.

Louis Pasteur performed a body of work during the latter part of the 19th century that provided the underpinnings of modern microbiology, at the time known as *germ theory*. His work in humans followed experiments identifying infectious agents in silkworms. He was able to elucidate the principle that contagious diseases are caused by specific microbes and that these microbes are foreign to the infected organism. Using this principle, he developed techniques of sterilization critical to oenology and identified several bacteria responsible for human illnesses, including *Staphylococcus* and *Streptococcus pneumoniae* (pneumococcus).

Joseph Lister, the son of a wine merchant, was appointed professor of surgery at the Glasgow Royal Infirmary in 1859. In his early practice, he noted that more than half of his patients undergoing amputation died because of postoperative infection. After hearing of Pasteur’s work, Lister experimented with the use of a solution of carbolic acid, which he knew was being used to treat sewage. He first reported his findings to the British Medical Association in 1867 using dressings saturated with carbolic acid on 12 patients with compound fractures; 10 recovered
without amputation, one survived with amputation, and one died of causes unrelated to the wound. In spite of initial resistance, his methods were quickly adopted throughout much of Europe.

From 1878 until 1880, Robert Koch was the district medical officer for Wollstein, an area in Prussia where anthrax was endemic. Performing experiments in his home, without the benefit of scientific equipment and academic contact, Koch developed techniques for culture of *Bacillus anthracis* and proved the ability of this organism to cause anthrax in healthy animals. He developed the following four postulates to identify the association of organisms with specific diseases: (a) the suspected pathogenic organism should be present in all cases of the disease and absent from healthy animals, (b) the suspected pathogen should be isolated from a diseased host and grown in a pure culture in vitro, (c) cells from a pure culture of the suspected organism should cause disease in a healthy animal, and (d) the organism should be reisolated from the newly diseased animal and shown to be the same as the original. He used these same techniques to identify the organisms responsible for cholera and tuberculosis. During the next century, Koch’s postulates, as they came to be called, became critical to the understanding of surgical infections.

The first intra-abdominal operation to treat infection via “source control” (i.e., surgical intervention to eliminate the source of infection) was appendectomy. This operation was pioneered by Charles McBurney at the New York College of Physicians and Surgeons, among others. McBurney’s classic report on early operative intervention for appendicitis was presented before the New York Surgical Society in 1889. Appendectomy for the treatment of appendicitis, previously an often fatal disease, was popularized after the 1902 coronation of King Edward VII of England was delayed due to his falling ill with appendicitis. Edward insisted on carrying out his schedule, despite worsening abdominal pain. Sir Frederick Treves, a prominent London surgeon, was among the consultants in attendance upon Edward. As the prince’s condition deteriorated, and as he continued to insist that he would go to Westminster Abbey to be crowned, Treves told him, “Then Sire, you will go as a corpse.” Edward relented, Treves drained a large periappendiceal abscess, and the king lived.

During the 20th century the development of effective antimicrobials added a new dimension to modern surgical practice. Sir Alexander Fleming, after serving in the British Army Medical Corps during World War I, continued his work on the natural antibacterial action of the blood and antiseptics. In 1928, while studying influenza virus, he noted a zone of inhibition around a mold colony (*Penicillium notatum*) that serendipitously grew on a plate of *Staphylococcus*, and he named the active substance penicillin. Penicillin, along with the sulfonamide antibiotics, were among the first of hundreds of potent antimicrobials that became a critical component of the armamentarium to prevent and treat aggressive, lethal surgical infections.

Concurrent with the development of antimicrobial agents were advances in the field of clinical microbiology. Many new microbes were identified, including numerous anaerobes. The autochthonous microflora of the skin, gastrointestinal tract, and other parts of the body that the surgeon encountered in the process of an operation were characterized in great detail. However, it remained unclear whether these organisms were commensals or pathogens. Subsequently, the initial clinical observations of surgeons such as Frank Meloney, William Altemeier, and others provided the key when they observed that aerobic and anaerobic host flora could synergize to cause serious soft tissue and severe intra-abdominal infection. Thus, the concepts that resident

---

**Key Points**

1. **Sepsis** is a life-threatening syndrome reflecting both an infection and the systemic host response to it. It has a broad variety of presentations and manifestations that hold in common some form of organ dysfunction. Outcomes in patients with sepsis are improved with an organized approach to therapy that addresses rapid resuscitation, antibiotics, and source control.

2. **Source control** is a key concept in the treatment of most surgically relevant infections. Infected or necrotic material must be drained or removed as part of the treatment plan in this setting. Delays in adequate source control are associated with worsened outcomes.

3. **Principles relevant to appropriate antibiotic prophylaxis for surgery:** (a) select an agent with activity against organisms commonly found at the site of surgery, (b) administer the initial dose of the antibiotic within 30 minutes prior to incision, (c) redose the antibiotic during long operations based upon the half-life of the agent to ensure adequate tissue levels, and (d) limit the antibiotic regimen to no more than 24 hours after surgery for routine prophylaxis.

4. **When using antimicrobial agents for therapy of serious infection,** several principles should be followed: (a) identify likely sources of infection, (b) select an agent (or agents) that will have efficacy against likely organisms for these sources, (c) begin therapy rapidly with broad coverage, as inadequate or delayed antibiotic therapy results in increased mortality, (d) when possible, obtain cultures early and use results to refine therapy, (e) if no infection is identified after 3 days, strongly consider discontinuation of antibiotics, based upon the patient’s clinical course, and (f) discontinue antibiotics after an appropriate course of therapy.

5. **The incidence of surgical site infections can be reduced by appropriate patient preparation, timely perioperative antibiotic administration, maintenance of perioperative normothermia and normoglycemia, and appropriate wound management.**

6. **The keys to good outcomes in patients with necrotizing soft tissue infection are early recognition and appropriate debridement of infected tissue with repeated debridement until no further signs of infection are present.**

7. **Transmission of HIV and other infections spread by blood and body fluids from patient to healthcare worker can be minimized by practicing universal precautions, which include routine use of barriers when anticipating contact with blood or body fluids, washing of hands and other skin surfaces immediately after contact with blood or body fluids, and careful handling and disposal of sharp instruments during and after use.**
microbes were nonpathogenic until they entered a sterile body cavity at the time of surgery, and that many, if not most, surgical infections were polymicrobial in nature, became critical ideas.\(^8,9\) These tenets became firmly established after microbiology laboratories demonstrated the invariable presence of aerobes and anaerobes in peritoneal cultures obtained at the time of surgery for intra-abdominal infection due to perforated viscus or gangrenous appendicitis. Clinical trials provided ample evidence that optimal therapy for these infections required effective source control and the administration of antimicrobial agents directed against both types of pathogens.

William Osler made an observation in 1904 in his treatise *The Evolution of Modern Medicine* that was to have profound implications for the future of treatment of infection: “Except on few occasions, the patient appears to die from the body’s response to infection rather than from it.”\(^10\) The discovery of cytokines began to allow insight into the human organism’s response to infection, and led to an explosion in our understanding of the host inflammatory response. Expanding knowledge of the multiple pathways activated during the response to invasion by infectious organisms has permitted the design of new therapies targeted at modifying the inflammatory response to infection, which seems to cause much of the organ dysfunction and failure. Preventing and treating this process of multiple organ failure during infection is one of the major challenges of modern critical care and surgical infectious disease.

**PATHOGENESIS OF INFECTION**

**Host Defenses**

The mammalian host possesses several layers of endogenous defense mechanisms that serve to prevent microbial invasion, limit proliferation of microbes within the host, and contain or eradicate invading microbes. These defenses are integrated and redundant so that the various components function as a complex, highly regulated system that is extremely effective in coping with microbial invaders. They include site-specific defenses that function at the tissue level, as well as components that freely circulate throughout the body in both blood and lymph. Systemic host defenses invariably are recruited to a site of infection, a process that begins immediately upon introduction of microbes into a sterile area of the body. Perturbation of one or more components of these defenses (e.g., via immunosuppressants, foreign body, chronic illness, or burns) may have substantial negative impact on resistance to infection.

Entry of microbes into the mammalian host is precluded by a number of barriers that possess either an epithelial (integument) or mucosal (respiratory, gut, and urogenital) surface. Barrier function, however, is not solely limited to physical characteristics. Host barrier cells may secrete substances that limit microbial proliferation or prevent invasion. Also, resident or commensal microbes adhere to the physical surface and to each other may preclude invasion, particularly of virulent organisms; this is termed *colonization resistance*.\(^11\)

The most extensive physical barrier is the integument or skin. In addition to the physical barrier posed by the epithelial surface, the skin harbors its own resident microflora that may block the attachment and invasion of noncommensal microbes. Microbes also are held in check by chemicals secreted by sebaceous glands and by the constant shedding of epithelial cells. The endogenous microflora of the integument primarily comprises gram-positive aerobic microbes belonging to the genera *Staphylococcus* and *Streptococcus*, as well as *Corynebacterium* and *Propionibacterium* species. These organisms plus *Enterococcus faecalis* and *faecium*, *Escherichia coli* and other *Enterobacteriaceae*, and yeast such as *Candida albicans* can be isolated from the inframountibial regions of the body. Diseases of the skin (e.g., eczema and dermatitis) are associated with overgrowth of skin commensal organisms, and barrier breaches invariably lead to the introduction of these microbes.

The respiratory tract possesses several host defense mechanisms that facilitate the maintenance of sterility in the distal bronchi and alveoli. In the upper respiratory tract, respiratory mucus traps larger particles, including microbes. This mucus is then passed into the upper airways and oropharynx by ciliated epithelial cells, where the mucus is cleared via coughing. Smaller particles arriving in the lower respiratory tract are cleared via phagocytosis by pulmonary alveolar macrophages. Any process that diminishes these host defenses can lead to development of bronchitis or pneumonia.

The urogenital, biliary, pancreatic ductal, and distal respiratory tracts do not possess resident microflora in healthy individuals, although microbes may be present if these barriers are affected by disease (e.g., malignancy, inflammation, calculi, or foreign body), or if microorganisms are introduced from an external source (e.g., urinary catheter or pulmonary aspiration). In contrast, significant numbers of microbes are encountered in many portions of the gastrointestinal tract, with vast numbers being found within the oropharynx and distal colon or rectum, although the specific organisms differ.

One would suppose that the entire gastrointestinal tract would be populated via those microbes found in the oropharynx, but this is not the case.\(^11\) This is because after ingestion these organisms routinely are killed in the highly acidic, low-motility environment of the stomach during the initial phases of digestion. Thus, only small numbers of microbes populate the gastric mucosa (∼10⁸ to 10⁹ colony-forming units [CFU]/mL). This population expands in the presence of drugs or disease states that diminish gastric acidity. Microbes that are not destroyed within the stomach enter the small intestine, in which a certain amount of microbial proliferation takes place, such that approximately 10⁶ to 10⁸ CFU/mL are present in the terminal ileum. The relatively low-oxygen, static environment of the colon is accompanied by the exponential growth of microbes that comprise the most extensive host endogenous microflora. Anaerobic microbes outnumber aerobic species approximately 100:1 in the distal colon, and approximately 10¹ⁱ to 10¹² CFU/g are present in feces. Large numbers of facultative and strict anaerobes (*Bacteroides fragilis, distasonis, and thetaiotaomicron, Bifidobacterium, Clostridium, Eubacterium, Fusobacterium, Lactobacillus, and Peptostreptococcus* species) as well as several orders of magnitude fewer aerobic microbes (*E. coli* and other *Enterobacteriaceae, E. faecalis and faecium, C. albicans* and other *Candida* spp.) are present. Intriguingly, although colonization resistance on the part of this extensive, well-characterized host microflora effectively prevents invasion of enteric pathogens such as *Salmonella*, *Shigella*, *Vibrio*, and other enteropathogenic bacterial species, these same organisms provide the initial inoculum for infection should perforation of the gastrointestinal tract occur. It is of great interest that only some of these microbial species predominate in established intra-abdominal infections.

Once microbes enter a sterile body compartment (e.g., the pleural or peritoneal cavity) or tissue, additional host defenses act to limit and/or eliminate these pathogens. Initially, several
primitive and relatively nonspecific host defenses act to contain the nidus of infection, which may include microbes as well as debris, devitalized tissue, and foreign bodies, depending on the nature of the injury. These defenses include the physical barrier of the tissue itself, as well as the capacity of proteins such as lactoferrin and transferrin to sequester the critical microbial growth factor iron, thereby limiting microbial growth. In addition, fibrinogen within the inflammatory fluid has the ability to trap large numbers of microbes during the process in which it polymerizes into fibrin. Within the peritoneal cavity, unique host defenses exist, including a diaphragmatic pumping mechanism whereby particles—including microbes—within peritoneal fluid are expelled from the abdominal cavity via specialized structures (stomata) on the undersurface of the diaphragm that lead to thoracic lymphatic channels. Concurrently, containment by the omentum and intestinal ileus serve to wall off infections. However, the latter processes and fibrin trapping have a high likelihood of contributing to the formation of an intra-abdominal abscess.

Microbes also immediately encounter a series of host defense mechanisms that reside within the vast majority of tissues of the body. These include resident macrophages and low levels of complement (C) proteins and immunoglobulins (e.g., antibodies). The response in macrophages is initiated by genome-encoded pattern recognition receptors that respond to invading microbes. With exposure to a foreign organism, these receptors recognize microbial pathogen-associated molecular patterns (PAMPs) and endogenous danger-associated molecular patterns (DAMPs). Toll-like receptors (TLRs) are a well-defined example of a PAMP that plays an important role in pathogen signaling. Resident macrophages secrete a wide array of substances in response to the aforementioned processes, some of which appear to regulate the cellular components of the host defense response. This results in recruitment and proliferation of inflammatory cells. Macrophage cytokine synthesis is upregulated. Secretion of tumor necrosis factor-alpha (TNF-α), of interleukins (IL)-1β, 6, and 8; and of gamma interferon (IFN-γ) occurs within the tissue milieu, and depending on the magnitude of the host defense response, the systemic circulation. Concurrently, a counterregulatory response is initiated consisting of binding protein (TNF-BP), cytokine receptor antagonists (e.g., IL-1ra), and anti-inflammatory cytokines (IL-4 and IL-10).

The interaction of microbes with these first-line host defenses leads to microbial opsonization (C1q, C3bi, and IgFc), phagocytosis, and both extracellular (CSb6-9 membrane attack complex) and intracellular microbial destruction (via cellular ingestion into phagocytic vacuoles). Concurrently, the classical and alternate complement pathways are activated both via direct contact with and via IgM and IgG binding to microbes, leading to the release of a number of different biologically active complement protein fragments (C3a, C4a, C5a), acting to markedly enhance vascular permeability. Bacterial cell wall components and a variety of enzymes expelled from leukocyte phagocytic vacuoles during microbial phagocytosis and killing act in this capacity as well.

Simultaneously, the release of substances to which polymorphonuclear leukocytes (PMNs) in the bloodstream are attracted takes place. These consist of C5a, microbial cell wall peptides containing N-formyl-methionine, and macrophage secretion of cytokines such as IL-8. This process of host defense recruitment leads to further influx of inflammatory fluid into the area of incipient infection and is accompanied by diapedesis of large numbers of PMNs, a process that begins within several minutes and may peak within hours or days. The magnitude of the response and eventual outcome is generally related to several factors: (a) the initial number of microbes, (b) the rate of microbial proliferation in relation to containment and killing by host defenses, (c) microbial virulence, and (d) the potency of host defenses. In regard to the latter, drugs or disease states that diminish any or multiple components of host defenses are associated with higher rates and potentially more grave infections.

**Definitions**

Several possible outcomes can occur subsequent to microbial invasion and the interaction of microbes with resident and recruited host defenses: (a) eradication; (b) containment, often leading to the presence of purulence, the hallmark of chronic infections (e.g., a furuncle in the skin and soft tissue or abscess within the parenchyma of an organ or potential space); (c) locoregional infection (cellulitis, lymphangitis, and aggressive soft tissue infection) with or without distant spread of infection (metastatic abscess); or (d) systemic infection (bacteremia or fungemia). Obviously, the latter represents the failure of resident and recruited host defenses at the local level, and is associated with significant morbidity and mortality. Disease progression commonly occurs such that serious locoregional infection is associated with concurrent systemic infection. A chronic abscess also may intermittently drain and/or be associated with bacteremia.

*Infection* is defined by the presence of microorganisms in host tissue or the bloodstream. The classic findings of *ruber, calor, and dolor* in areas such as the skin or subcutaneous tissue are common at the site of infection. Most infections in normal individuals with intact host defenses are associated with these local manifestations, plus systemic manifestations such as elevated temperature, elevated white blood cell (WBC) count, tachycardia, or tachypnea. The systemic manifestations noted previously comprise what has been termed the *systemic inflammatory response syndrome* (SIRS). SIRS reflects a proinflammatory state in response to a variety of disease processes, including infection, pancreatitis, polytrauma, malignancy, and burns. There are a variety of systemic manifestations of infection, with the classic factors of fever, tachycardia, and tachypnea broadened to include a variety of other variables (Table 6-1).

The definition of *sepsis* is evolving. Earlier models described sepsis as SIRS caused by infection. This was based upon the idea that sepsis is mediated by the production of a cascade of proinflammatory mediators produced in response to exposure to microbial products. These products include lipopolysaccharide (endotoxin, LPS) derived from gram-negative organisms; peptidoglycans and teichoic acids from gram-positive organisms; many different microbial cell wall components, such as mannan from yeast and fungi; and many others.

There are several issues, however, with basing a sepsis diagnosis on the presence of SIRS. One problem is that it is insufficiently specific. Patients can exhibit SIRS criteria without the presence of the more whole-body dysregulation consistent with sepsis, and conversely can suffer from sepsis without meeting SIRS criteria. Patients with SIRS do not necessarily progress to sepsis and do not necessarily have worsened outcomes because of the SIRS diagnosis; in other words, SIRS is not inherently life-threatening. Another issue is that the SIRS criteria can vary and are inconsistently applied. Numerous definitions exist, specifying differing physiologic and laboratory criteria for the
diagnosis. This creates difficulty in clinical, epidemiological, and research settings. Further, sepsis is not a purely inflammatory phenomenon, as both pro- and anti-inflammatory cascades have been shown to be activated in septic patients. Basing a diagnosis upon inflammatory markers alone disregards non-inflammatory organ dysfunction, which may not manifest as SIRS but can contribute to mortality. A final concern is that defining sepsis using SIRS criteria implies that SIRS, sepsis, severe sepsis, and septic shock exist upon a continuum, and while SIRS and sepsis have common features, the former does not necessarily lead to the latter. This being said, SIRS criteria have utility in that they point toward an organism experiencing physiological stress. The presence of SIRS warrants further investigation by the clinician.16

An international consensus panel proposed new definitions of sepsis and septic shock in 2016. What is known as the Sepsis-3 model defines sepsis as life-threatening organ dysfunction caused by a dysregulated host response to infection. Organ dysfunction is quantified by an increase of ≥2 points on the Sequential Organ Failure Assessment (SOFA). The SOFA score looks at PaO₂/FiO₂ ratio, bilirubin, platelet count, mean arterial pressure (MAP), Glasgow Coma Scale (GCS) score, creatinine level, and urine output (Table 6-2). An increase in SOFA score of 2 or more is correlated with a 10% in-hospital mortality risk, which is suggestive of the life-threatening nature of sepsis. An abbreviated version of the scoring system, the quick SOFA (qSOFA) is recommended as a screening and monitoring tool for patients with suspected sepsis. The qSOFA suggests potentially life-threatening sepsis when at least two of the following parameters are met: altered mental status, systolic blood pressure of 100 mmHg or less, and respiratory rate greater than 22 breaths/minute. The qSOFA can readily identify patients at risk of poor outcome from sepsis without reliance upon laboratory or imaging data.16

Under the older nomenclature, severe sepsis was characterized as sepsis combined with the presence of new-onset organ failure. The Sepsis-3 definitions consider the term “severe sepsis” to be redundant, as by this definition all sepsis involves organ dysfunction. Under the Sepsis-3 guidelines, septic shock is a subset of sepsis in which circulatory and cellular metabolic derangements are profound enough to significantly increase the risk of death. Sepsis is the most common cause of death in non-coronary critical care units and the 11th most common cause of death overall in the United States, with a mortality rate of 10.3 cases per 100,000 population in 2010.17 Septic shock is the most severe manifestation of infection, with an attendant mortality rate in excess of 40%. It can be identified by persistent arterial hypotension requiring vasopressors to maintain mean arterial pressure (MAP) ≥65, and by serum lactate >2 mmol/L (18 mg/dL) despite adequate volume resuscitation.16,18,10

### Microbiology of Infectious Agents

A partial list of common pathogens that cause infections in surgical patients is provided in Table 6-3.

**Bacteria**

Bacteria are responsible for the majority of surgical infections. Specific species are identified using Gram stain and growth characteristics on specific media. The Gram stain is an important evaluation that allows rapid classification of bacteria by color. This color is related to the staining characteristics of the bacterial cell wall: gram-positive bacteria stain blue and gram-negative bacteria stain red. Bacteria are classified based upon a number of additional characteristics, including morphology (cocci and bacilli), the pattern of division (single organisms, groups of organisms in pairs [diplococci], clusters [staphylococci], and chains [streptococci]), and the presence and location of spores.

Gram-positive bacteria that frequently cause infections in surgical patients include aerobic skin commensals (Staphylococcus aureus and Enterococcus faecalis and faecium) and staphylococci, and streptococci). Aerobic skin commensals cause a large percentage of surgical site infections (SSIs), either alone or in conjunction with other pathogens; enterococci can cause nosocomial infections (urinary tract infections [UTIs] and bacteremia) in immunocompromised or chronically ill patients, but are of relatively low virulence in healthy individuals.

There are many pathogenic gram-negative bacterial species that are capable of causing infection in surgical patients. Most gram-negative organisms of interest to the surgeon are bacilli belonging to the family Enterobacteriaceae, including Escherichia coli, Klebsiella pneumoniae, Serratia marcescens, and Enterobacter, Citrobacter, and Acinetobacter species. Other gram-negative bacilli of note include Pseudomonas, including P aeruginosa and fluorescens, and Stenotrophomonas species.
Anaerobic organisms divide poorly or are unable to grow in air, as most do not possess the enzyme catalase, which allows for metabolism of reactive oxygen species. Anaerobes are the predominant indigenous flora in many areas of the human body, with the particular species being dependent on the site. For example, Propionibacterium acnes and other species are a major component of the skin microflora and cause the infectious manifestation of acne. As noted previously, large numbers of anaerobes contribute to the microflora of the oropharynx and colon.

Infection due to Mycobacterium tuberculosis was once one of the most common causes of death in Europe, causing one in four deaths in the 17th and 18th centuries. In the 19th and 20th centuries, thoracic surgical intervention was often required for severe pulmonary disease, now an increasingly uncommon occurrence in developed countries. This organism and other related organisms (M avium-intracellulare and M leprae) are known as acid-fast bacilli. Other acid-fast bacilli include Nocardia. These organisms typically are slow growing, sometimes necessitating observation in culture for weeks to months prior to final identification, although deoxyribonucleic acid (DNA)-based analysis is increasingly available to provide a means for preliminary, rapid detection.

**Fungi**

Fungi are typically identified by use of special stains (e.g., potassium hydroxide, India ink, methenamine silver, or Giemsa). Initial identification is assisted by observation of the form of branching and septation in stained specimens or in culture.

**Viruses**

Due to their small size and necessity for growth within cells, viruses are difficult to culture, requiring a longer time than is typically optimal for clinical decision making. Previously, viral infection was identified by indirect means (i.e., the host antibody response); modern techniques identify the presence of viral DNA or ribonucleic acid (RNA) using methods such as polymerase chain reaction. Similar to many fungal infections, most clinically relevant viral infections in surgical patients occur in the immunocompromised host, particularly those receiving immunosuppression to prevent rejection of a solid organ allograft. Relevant viruses include adenoviruses, cytomegalovirus, Epstein-Barr virus, herpes simplex virus, and varicella-zoster virus. Surgeons must be aware of the manifestations of hepatitis B and C viruses, as well as human immunodeficiency
virus infections, including their capacity to be transmitted to healthcare workers (see “General Principles”). Prophylactic and therapeutic use of antiviral agents is discussed elsewhere in this textbook.

**PREVENTION AND TREATMENT OF SURGICAL INFECTIONS**

**General Principles**

Maneuvers to diminish the presence of exogenous (surgeon and operating room environment) and endogenous (patient) microbes are termed **prophylaxis** and consist of a variety of mechanical and chemical modalities. The Centers for Disease Control and Prevention (CDC) publishes updated, evidence-based guidelines on best practices for prevention of surgical site infections. Important principles in prophylaxis can be grouped into factors pertaining to skin preparation, antimicrobial therapy, and patient physiological management.

**Patient skin preparation** should begin the night before a planned surgical procedure with a full body bath or shower using soap or an antiseptic agent. Hair removal from an operative site should be performed in the operating room with clippers rather than with a razor, to avoid creating nicks in the skin that could foster bacterial growth. Prior to incision, the skin should be cleansed with an alcohol-based antiseptic agent. There is no clear evidence that use of antimicrobial-containing fluids for either irrigation or soaking prosthetic materials is beneficial in preventing infections. Preoperative antimicrobial therapy should be administered when appropriate, based on clinical guidelines, and occur within a time frame that allows bactericidal concentration of the agent in tissues before the incision is made.

**Physiological management of the intraoperative patient** includes maintenance of euglycemia (serum glucose <200 mg/dL) and normothermia, and optimization of tissue oxygenation.

**Source Control**

The primary precept of surgical infectious disease therapy consists of drainage of all purulent material, debridement of all infected, devitalized tissue and debris, and/or removal of foreign bodies at the site of infection, plus remediation of the underlying cause of infection. This is termed **source control**. A discrete, walled-off purulent fluid collection (i.e., an abscess)
requires drainage, either surgically or via percutaneous drain insertion. An ongoing source of contamination (e.g., bowel perforation) or the presence of an aggressive, rapidly spreading infection (e.g., necrotizing soft tissue infection) invariably requires expedient, aggressive operative intervention, both to remove contaminated material and infected tissue (e.g., radical debridement or amputation) and to remove the initial cause of infection (e.g., bowel resection). Delay in operative intervention, whether due to misdiagnosis or the need for additional diagnostic studies, is associated with increased morbidity and occasional mortality. Other treatment modalities such as antimicrobial agents, albeit critical, are of secondary importance to effective surgery with regard to treatment of surgical infections. Rarely, if ever, can an aggressive surgical infection be cured only by the administration of antibiotics, and never in the face of an ongoing source of contamination.22

### Appropriate Use of Antimicrobial Agents

A classification of antimicrobial agents, mechanisms of action, and spectrums of activity is shown in Table 6-5. As discussed previously, prophylaxis consists of the administration of an antimicrobial agent or agents prior to initiation of certain specific types of surgical procedures in order to reduce the number of microbes that enter the tissue or body cavity. Agents are selected according to their activity against microbes likely to be present at the surgical site, based on knowledge of host microflora. For example, patients undergoing elective colorectal surgery should receive antimicrobial prophylaxis directed against skin flora, gram-negative aerobes, and anaerobic bacteria. There are a wide variety of agents that meet these criteria with recently published guidelines.23

By definition, prophylaxis is limited to the time prior to and during the operative procedure; in the vast majority of cases only a single dose of antibiotic is required, and only for certain types of procedures (see “Surgical Site Infections”). However, patients who undergo complex, prolonged procedures in which the duration of the operation exceeds the serum drug half-life should receive an additional dose or doses of the antimicrobial agent.23 There is no evidence that administration of postoperative doses of an antimicrobial agent provides additional benefit, and this practice should be discouraged, as it is costly and is associated with increased rates of microbial drug resistance. Guidelines for prophylaxis are provided in Table 6-6.

Empiric therapy is the use of antimicrobial agents when the risk of a surgical infection is high, based on the underlying disease process (e.g., ruptured appendicitis), or when significant contamination during surgery has occurred (e.g., inadequate bowel preparation or considerable spillage of colon contents). Obviously, prophylaxis merges into empiric therapy in situations in which the risk of infection increases markedly because of intraoperative findings. Empiric therapy also is often employed in critically ill patients in whom a potential site of infection has been identified and severe sepsis or septic shock occurs. Empiric therapy should be limited to a short course of treatment (3 to 5 days) and should be curtailed as soon as possible based on microbiologic data (i.e., absence of positive cultures) coupled with improvements in the clinical course of the patient.

Empiric therapy can merge into therapy of established infection in some patients. However, among surgical patients, the manner in which therapy is employed, particularly in relation to the use of microbiologic data (culture and antibiotic sensitivity patterns), differs depending on whether the infection is monomicrobial or polymicrobial. Monomicrobial infections frequently are nosocomial infections occurring in postoperative patients, such as UTIs, pneumonia, or bacteremia. Evidence of systemic inflammatory response syndrome (fever, tachycardia, tachypnea, or elevated leukocyte count) in such individuals, coupled with evidence of local infection (e.g., an infiltrate on chest roentgenogram plus a positive Gram stain in bronchoalveolar lavage samples) should lead the surgeon to initiate empiric antibiotic therapy. An appropriate approach to antimicrobial treatment involves de-escalation therapy, where initial antimicrobial selection is broad, with a narrowing of agents based on patient response and culture results. Initial drug selection must be based on initial evidence (gram-positive vs. gram-negative microbes, yeast), coupled with institutional and unit-specific drug sensitivity patterns. It is important to ensure that antimicrobial coverage chosen is adequate, since delay in appropriate antibiotic treatment has been shown to be associated with significant increases in mortality. A critical component of this approach is appropriate collection of culture specimens to allow for thorough analysis, since within 48 to 72 hours culture and sensitivity reports will allow refinement of the antibiotic regimen to select the most efficacious agent.

Although the primary therapeutic modality to treat polymicrobial surgical infections is source control, antimicrobial agents play an important role. Culture results are of lesser importance in managing these types of infections, as it has been repeatedly demonstrated that only a limited cadre of microbes predominate in the established infection, selected from a large number present at the time of initial contamination. Invariably it is difficult to identify all microbes that comprise the initial polymicrobial inoculum. For this reason, the antibiotic regimen should not be modified solely on the basis of culture information, as it is less important than the clinical course of the patient. As long as appropriately broad-spectrum coverage for aerobic and anaerobic microbes is provided, a worsening of the patient’s clinical course should direct the surgeon to investigate whether effective source control has been achieved.24 Duration of antibiotic administration should be decided at the time the drug regimen is prescribed. As mentioned previously, prophylaxis is limited to a single dose administered immediately prior to creating the incision. Empiric therapy should be limited to 3 to 5 days or less and should be curtailed if the presence of a local site or systemic infection is not revealed.25 In fact, prolonged use of empirical antibiotic therapy in culture-negative critically ill patients is associated with increased mortality, highlighting the need to discontinue therapy when there is no proven evidence of infection.26

Therapy for monomicrobial infections follows standard guidelines: 3 to 5 days for UTIs, 7 to 8 days for pneumonia, and 7 to 14 days for bacteremia. Longer courses of therapy in this setting do not result in improved care and are associated with increased risk of superinfection by resistant organisms.27-29 There is some evidence that measuring and monitoring serum procalcitonin trends in the setting of infection allows earlier cessation of antibiotics without decrement in the rate of clinical cure.30 Antibiotic therapy for osteomyelitis, endocarditis, or prosthetic infections in which it is hazardous to remove the device consists of prolonged courses of treatment for 6 to 12 weeks. The specific agents are selected based on analysis of the degree to which the organism is killed in vitro using the minimum inhibitory concentration (MIC) of a standard pure

The sensitivities printed here are generalizations. The clinician should confirm sensitivity patterns at the locale where the patient is being treated since these patterns may vary widely depending on location.
inoculum of $10^5$ CFU/mL of the organism isolated from the site of infection or bloodstream. Sensitivities are reported in relation to the achievable blood level of each antibiotic in a panel of agents. The least toxic, least expensive agent to which the organism is most sensitive should be selected. Serious or recrudescence infection may require therapy with two or more agents, particularly if a multidrug-resistant pathogen is causative, limiting therapeutic options to drugs to which the organism is only moderately sensitive. Commonly, an agent may be administered intravenously for 1 to 2 weeks, followed by treatment with an oral drug. However, this should only be undertaken in patients who demonstrate progressive clinical improvement, and the oral agent should be capable of achieving high serum levels as well (e.g., fluoroquinolones).

The 2016 Surgical Infection Society guidelines on management of intra-abdominal infection recommend antibiotic duration of no more than 24 hours in patients with traumatic bowel perforation who receive surgical treatment within 12 hours, gastroduodenal perforations operated upon within 24 hours, ischemic nonperforated bowel, and gangrenous acute appendicitis or cholecystitis without perforation. More extensive intraperitoneal infection (perforated appendicitis, for example) should have treatment limited to 4 days. Patients with a greater degree of contamination may require longer courses of therapy; as in all facets of clinical practice, the therapeutic plan must be individualized to the patient. In the later phases of postoperative antibiotic treatment of serious intra-abdominal infection, the absence of an elevated white blood cell (WBC) count, lack of band forms of PMNs on peripheral smear, and lack of fever ($<38^\circ$C [100.5$^\circ$F]) provide close to complete assurance that infection has been eradicated. $^1$ There is also emerging data that suggest following a patient’s procalcitonin level may provide the clinician with useful information regarding whether an infection has resolved and allow more expedient cessation of therapy. $^{32,33}$ Patients who do not improve with 5 to 7 days of antibiotic therapy should be reevaluated for inadequate source control or a new extra-abdominal source of infection.

**Allergy** to antimicrobial agents must be considered prior to prescribing them. First, it is important to ascertain whether a patient has had any type of allergic reaction in association with administration of a particular antibiotic. However, one should take care to ensure that the purported reaction consists of true allergic symptoms and signs, such as urticaria, bronchospasm, or other similar manifestations, rather than indigestion or nausea. Penicillin allergy is quite common, the reported incidence ranging from 0.7% to 10%. Although avoiding the use of any β-lactam drug is appropriate in patients who manifest significant allergic reactions to penicillins, the incidence of cross-reactivity appears low for all related agents, with 1% cross-reactivity for carbapenems, 5% to 7% cross-reactivity for cephalosporins, and extremely small or nonexistent cross-reactivity for monobactams. $^{34}$

Severe allergic manifestations, such as anaphylaxis, to a specific class of agents generally preclude the use of any agents in that class, except under circumstances in which use of a certain drug represents a lifesaving measure. In some centers, patients undergo intradermal testing using a dilute solution of a particular antibiotic to determine whether a severe allergic reaction would be elicited by parenteral administration. A pathway, including such intradermal testing, has been effective in reduction of vancomycin use to 16% in surgical patients with reported allergy to penicillin. $^{35}$ This type of testing rarely is employed because it is simpler to select an alternative class of agent. Should administration of a specific agent to which the patient is

allergic become necessary, desensitization using progressively higher doses of antibiotic can be undertaken, providing the initial testing does not cause severe allergic manifestations.

Misuse of antimicrobial agents is rampant in both the inpatient and outpatient settings, and is associated with an enormous financial impact on healthcare costs, adverse reactions due to drug toxicity and allergy, the occurrence of new infections such as *Clostridium difficile* colitis, and the development of multiagent drug resistance among nosocomial pathogens. Each of these factors has been directly correlated with overall drug administration. It has been estimated that in the United States in excess of $20 billion is spent on antibiotics each year. The responsible practitioner limits prophylaxis to the period during the operative procedure, does not convert prophylaxis into empiric therapy except under well-defined conditions, sets the duration of antibiotic therapy from the outset, curtails antibiotic administration when clinical and microbiologic evidence does not support the presence of an infection, and limits therapy to a short course in every possible instance. Prolonged treatment associated with drains and tubes has not been shown to be beneficial.

**INFECTIONS OF SIGNIFICANCE IN SURGICAL PATIENTS**

**Surgical Site Infections**

Surgical site infections (SSIs) are infections of the tissues, organs, or spaces exposed by surgeons during performance of an invasive procedure. SSIs are classified into incisional and organ/space infections, and the former are further subclassified into superficial (limited to skin and subcutaneous tissue) and deep incisional categories. The development of SSIs is related to three factors: (a) the degree of microbial contamination of the wound during surgery; (b) the duration of the procedure; and (c) host factors such as diabetes, malnutrition, obesity, immune suppression; and a number of other underlying disease states. Table 6-7 lists risk factors for development of SSIs. By definition, an incisional SSI has occurred if a surgical wound drains purulent material or if the surgeon judges it to be infected and opens it.

Surgical wounds are classified based on the presumed magnitude of the bacterial load at the time of surgery (Table 6-8). Clean wounds (class I) include those in which no infection is present; only skin microflora potentially contaminate the wound, and no hollow viscus that contains microbes is entered. Class I D wounds are similar except that a prosthetic device (e.g., mesh or valve) is inserted. Clean/contaminated wounds (class II) include those in which a hollow viscus such as the respiratory, alimentary, or genitourinary tracts with indigenous bacterial flora is opened under controlled circumstances without significant spillage of contents.

While elective colorectal cases have classically been included as class II cases, a number of studies in the last decade have documented higher SSI rates (9–25%). One study identified two-thirds of infections presenting after discharge from hospital, highlighting the need for careful follow-up of these patients. Infection is also more common in cases involving entry into the rectal space. In a recent single-center quality improvement study using a multidisciplinary approach, one group of clinicians has demonstrated the ability to decrease SSI from 9.8% to 4.0%. The responsible practitioner limits prophylaxis to the period during the operative procedure, does not convert prophylaxis into empiric therapy except under well-defined conditions, sets the duration of antibiotic therapy from the outset, curtails antibiotic administration when clinical and microbiologic evidence does not support the presence of an infection, and limits therapy to a short course in every possible instance. Prolonged treatment associated with drains and tubes has not been shown to be beneficial.

</table>
Contaminated wounds (class III) include open accidental wounds encountered early after injury, those with extensive introduction of bacteria into a normally sterile area of the body due to major breaks in sterile technique (e.g., open cardiac massage), gross spillage of viscus contents such as from the intestine, or incision through inflamed, albeit nonpurulent tissue. Dirty wounds (class IV) include traumatic wounds in which a significant delay in treatment has occurred and in which necrotic tissue is present, those created in the presence of overt infection as evidenced by the presence of purulent material, and those created to access a perforated viscus accompanied by a high degree of contamination. The microbiology of SSIs is reflective of the initial host microflora such that SSIs following creation of a class I wound are invariably caused by skin microbes found on that portion of the body, while SSIs subsequent to a class II wound created for the purpose of elective colon resection may be caused by either skin microbes or colonic microflora, or both.

Surgical management of the wound is a critical determinant of the propensity to develop an SSI. In healthy individuals, classes I and II wounds may be closed primarily, while skin closure of class III and IV wounds is associated with high rates of incisional SSIs (~25–50%). The superficial aspects of these latter types of wounds should be packed open and allowed to heal by secondary intention, although selective use of delayed primary closure has been associated with a reduction in incisional SSI rates. One clear example based on data from clinical trials is that class III wounds in healthy patients undergoing appendectomy for perforated or gangrenous appendicitis can be primarily closed as long as antibiotic therapy directed against aerobes and anaerobes is administered. This practice leads to SSI rates of approximately 3% to 4%.

Recent investigations have studied the effect of additional maneuvers in an attempt to further reduce the rate of SSIs. The adverse effects of hyperglycemia on WBC function have been well described. A number of studies in patients undergoing several different types of surgery describe increased risk of SSI in patients with hyperglycemia, and the 2017 CDC guidelines for prevention of surgical site infection recommend maintaining blood glucose <200 mg/dL (11.1 mmol/L) in all patients during the perioperative period.

The respective effects of body temperature and the level of inhaled oxygen during surgery on SSI rates also have been studied, and both hypothermia and hypoxia during surgery are associated with a higher rate of SSI. There is conflicting evidence regarding whether supplying higher levels of inhaled oxygen to perioperative patients reduces the rate of SSI. Although an initial study provided evidence that patients who received high levels of inhaled oxygen during colorectal surgery developed fewer SSIs, a later meta-analysis suggested that the overall benefit is small and may not warrant use. The 2017 CDC guidelines, however, support administration of increased FiO₂ during surgery and after extubation in patients with normal pulmonary function receiving general anesthesia as there has been some evidence of benefit. Further evaluation via multicenter studies is needed prior to implementation of hyperoxia as standard therapy, but it is clear that intraoperative hypothermia and hypoxia should be prevented.

Effective therapy for incisional SSIs consists solely of incision and drainage without the additional use of antibiotics. Antibiotic therapy is reserved for patients in whom evidence of significant cellulitis is present, or who concurrently manifest a systemic inflammatory response syndrome. The open wound often is allowed to heal by secondary intention, with dressings being changed as the clinical team deems appropriate. The use of topical antibiotics and antiseptics to further wound healing remains unproven, although anecdotal studies indicate their potential utility in complex wounds that do not heal with routine measures. Despite a paucity of prospective studies, vacuum-assisted closure is increasingly used in management of large, complex open wounds and can be applied to wounds in locations that are difficult to manage with dressings (Fig. 6-1). One also should consider obtaining wound cultures in patients who develop SSIs and who have been hospitalized or reside in long-term care facilities due to the increasing incidence of infection caused by multidrug-resistant organisms.

In the United States, hospitals are required to conduct surveillance for the development of SSIs for a period of 30 days.

![Figure 6-1](image_url). Negative pressure wound therapy in a patient after amputation for wet gangrene (A) and in a patient with enterocutaneous fistula (B). It is possible to adapt these dressings to fit difficult anatomy and provide appropriate wound care while reducing frequency of dressing change. It is important to evaluate the wound under these dressings if the patient demonstrates signs of sepsis with an unidentified source, since typical clues of wound sepsis such as odor and drainage are hidden by the suction apparatus.
after the operative procedure. Such surveillance has been associated with greater awareness and a reduction in SSI rates, probably in large part based upon the impact of observation and promotion of adherence to appropriate care standards. Beginning in 2012, all hospitals receiving reimbursement from the Centers for Medicare & Medicaid Services (CMS) are required to report SSIs.

A recent refinement of risk indexes has been implemented through the National Healthcare Safety Network, a secure, web-based system of surveillance used by the CDC for surveillance of healthcare-associated infections. This refinement utilized data reported from 847 hospitals in nearly one million patients over a 2-year period to develop procedure-specific risk indices for SSIs.

SSIs are associated with considerable morbidity and occasional lethality, as well as substantial healthcare costs and patient inconvenience and dissatisfaction. A number of healthcare organizations within the United States are interested in evaluating performance of hospitals and physicians with respect to implementing processes that support delivery of standard of care. One major process of interest is reduction in SSIs, since the morbidity (and subsequent cost) of this complication is high. Several of these organizations are noted in Table 6-9. Appropriate guidelines in this area incorporating the principles discussed previously have been developed and disseminated. However, observers have noted that adherence to these guidelines has been poor. Most experts believe that better adherence to evidence-based practice recommendations and implementing systems of care with redundant safeguards will result in reduction of surgical complications and better patient outcomes. More important, the CMS, the largest third-party insurance payer in the United States, has required reporting by hospitals of many processes related to reduction of surgical infections, including appropriate use of perioperative antibiotics. This information, which is reported publicly by hospitals, has led to significant improvement in reported rates of these process measures. However, the effect of this approach on the incidence of SSIs is not known at this time.

### Intra-Abdominal Infections

Microbial contamination of the peritoneal cavity is termed peritonitis or intra-abdominal infection and is classified according to etiology. Primary microbial peritonitis occurs when microbes invade the normally sterile confines of the peritoneal cavity via hematogenous dissemination from a distant source of infection or direct inoculation. This process is more common among patients who retain large amounts of peritoneal fluid due to ascites, and among those individuals who are being treated for renal failure via peritoneal dialysis. These infections invariably are monomicrobial and rarely require surgical intervention. The diagnosis is established based on identification of risk factors as noted previously, physical examination that reveals diffuse tenderness and guarding without localized findings, absence of a surgically treatable source of infection on an imaging study, and the presence of more than 250 neutrophils/mL in fluid obtained via paracentesis. Cultures typically will demonstrate the presence of gram-positive organisms in patients undergoing peritoneal dialysis. In patients without this risk factor, the most common etiologic organisms are E coli, K pneumoniae, and S pneumoniae. Treatment consists of administration of an antibiotic to which the organism is sensitive; often 14 to 21 days of therapy are required. Removal of indwelling devices, if present, may be required for effective therapy of recurrent infections.

Secondary microbial peritonitis occurs subsequent to contamination of the peritoneal cavity due to perforation or severe inflammation and infection of an intra-abdominal organ. Examples include appendicitis, perforation of any portion of the gastrointestinal tract, or diverticulitis. As noted previously, effective therapy requires source control to resect or repair the diseased organ; debridement of necrotic, infected tissue and debris; and administration of antimicrobial agents directed against aerobes and anaerobes. This type of antibiotic regimen should be chosen because in most patients the precise diagnosis cannot be established until exploratory laparotomy is performed, and the most morbid form of this disease process is colonic perforation, due to the large number of microbes present. A combination of agents or single agents with a broad spectrum of activity can be used for this purpose; conversion of a parenteral to an oral regimen when the patient’s ileus resolves provides results similar to those achieved with intravenous antibiotics. Effective source control and antibiotic therapy is associated with low failure rates and a mortality rate of approximately 5% to 6%; inability to control the source of infection is associated with mortality greater than 40%.

The response rate to effective source control and use of appropriate antibiotics has remained approximately 70% to 90% over the past several decades. Patients in whom standard therapy fails typically develop one or more of the following: an intra-abdominal abscess, leakage from a gastrointestinal anastomosis leading to postoperative peritonitis, or tertiary (persistent) peritonitis. The latter is a poorly understood entity that is more common in immunosuppressed patients in whom peritoneal host defenses do not effectively clear or sequester

the initial secondary microbial peritoneal infection. Microbes such as \textit{E faecalis} and \textit{faecium}, \textit{S epidermidis}, \textit{C albicans}, and \textit{P aeruginosa} commonly are identified, typically in combination, and their presence may be due to their lack of responsiveness to the initial antibiotic regimen, coupled with diminished activity of host defenses. Unfortunately, even with effective antimicrobial agent therapy, this disease process is associated with mortality rates in excess of 50%.\textsuperscript{14}

Formerly, the presence of an intra-abdominal abscess mandated surgical reexploration and drainage. Today, the vast majority of such abscesses can be effectively diagnosed via abdominal computed tomographic (CT) imaging techniques and drained percutaneously. Surgical intervention is reserved for those individuals who harbor multiple abscesses, those with abscesses in proximity to vital structures such that percutaneous drainage would be hazardous, and those in whom an ongoing source of contamination (e.g., enteric leak) is identified. The necessity of antimicrobial agent therapy and precise guidelines that dictate duration of catheter drainage have not been established. A short course (3 to 5 days) of antibiotics that possess aerobic and anaerobic activity seems reasonable so long as the patient has good clinical response to therapy, and most practitioners leave the drainage catheter in situ until it is clear that cavity collapse has occurred, output is less than 10 to 20 mL/d, no evidence of an ongoing source of contamination is present, and the patient’s clinical condition has improved.\textsuperscript{33}

**Organ-Specific Infections**

Hepatic abscesses are rare, currently accounting for approximately 15 per 100,000 hospital admissions in the United States. Pyogenic abscesses account for approximately 80\% of cases, the remaining 20\% being equally divided among parasitic and fungal forms.\textsuperscript{65} Formerly, pyogenic liver abscesses mainly were caused by phlebitis due to neglected appendicitis or diverticulitis. Today, manipulation of the biliary tract to treat a variety of diseases has become a more common cause, although in nearly 50\% of patients no cause is identified. The most common aerobic bacteria identified in recent series include \textit{E coli}, \textit{K pneumoniae}, and other enteric bacilli, enterococci, and \textit{Pseudomonas} spp., while the most common anaerobic bacteria are \textit{Bacteroides} spp., anaerobic streptococci, and \textit{Fusobacterium} spp. \textit{C albicans} and other related yeast cause the majority of fungal hepatic abscesses. Small (<1 cm), multiple abscesses should be sampled and treated with a 4- to 6-week course of antibiotics. Larger abscesses are generally amenable to percutaneous drainage, with parameters for antibiotic therapy and drain removal similar to those mentioned previously. Splenic abscesses are extremely rare and are treated in a similar fashion. Recurrent hepatic or splenic abscesses may require operative intervention—unroofing and marsupialization or splenectomy, respectively.

Secondary pancreatic infections (e.g., infected pancreatic necrosis or pancreatic abscess) occur in approximately 10\% to 15\% of patients who develop severe pancreatitis with necrosis. The surgical treatment of this disorder was pioneered by Bradley and Allen, who noted significant improvements in outcome for patients undergoing repeated pancreatic debridement of infected pancreatic necrosis.\textsuperscript{66} Care of patients with severe acute pancreatitis includes staging with dynamic, contrast-enhanced helical CT scan to evaluate the extent of pancreatitis (unless significant renal dysfunction exists, in which case one should forego the use of contrast material) coupled with the use of one of several prognostic scoring systems. Patients who exhibit clinical signs of instability (e.g., oliguria, hypoxemia, large-volume fluid resuscitation) should be carefully monitored in the ICU and undergo follow-up contrast CT examination when renal function has stabilized to evaluate for development of local pancreatic complications (Fig. 6-2). Routine use of prophylactic antibiotics to prevent infected pancreatic necrosis is not indicated. Early enteral feeding using nasojejunal feeding tubes placed past the ligament of Treitz has been associated with decreased development of infected pancreatic necrosis, possibly due to a decrease in gut translocation of bacteria.\textsuperscript{67,68}

The presence of secondary pancreatic infection should be suspected in patients whose systemic inflammatory response (fever, elevated WBC count, or organ dysfunction) fails to resolve, or in those individuals who initially recuperate, only to develop sepsis syndrome 2 to 3 weeks later. CT-guided aspiration of fluid from the pancreatic bed for performance of Gram stain and culture analysis can be useful. A positive Gram stain or culture from CT-guided aspiration, or identification of gas within the pancreas on CT scan, mandate surgical intervention.

The approach of open necrosectomy with repeated debridements, although life-saving, is associated with significant morbidity and prolonged hospitalization. Efforts to reduce the amount of surgical injury, while still preserving the improved outcomes associated with debridement of the infected sequestrum, have led to a variety of less invasive approaches, including endoscopic and laparoscopic techniques.\textsuperscript{69} There are a limited number of randomized trials reporting the use of these new techniques. An important concept common to all of these approaches, however, is the attempt to delay surgical intervention, since a number of trials have identified increased mortality when intervention occurs during the first 2 weeks of illness.

Data supporting the use of endoscopic approaches to infected pancreatic necrosis include nearly a dozen case series and a randomized trial.\textsuperscript{70,71} The reported mortality rate was 5\%, with a 30\% complication rate. Most authors noted the common requirement for multiple endoscopic debridements (similar to the open approach), with a median of four sessions required. Fewer series report experience with the laparoscopic approach, either transgastric or transperitoneal, entering the necrosis through the transverse mesocolon or gastrocolic ligament. Laparoscopic intervention is limited by the difficulty in achieving

*Figure 6-2. Contrast-enhanced CT scan of pancreas 1.5 weeks after presentation showing large central peripancreatic fluid collection (arrow).*
Infections of the Skin and Soft Tissue
These infections can be classified according to whether surgical intervention is required. For example, superficial skin and skin structure infections such as cellulitis, erysipelas, and lymphangitis invariably are effectively treated with antibiotics alone, although a search for a local underlying source of infection should be undertaken. Generally, drugs that possess activity against the causative gram-positive skin microflora are selected. Furuncles or boils may drain spontaneously or require surgical incision and drainage. Antibiotics are prescribed if significant cellulitis is present or if cellulitis does not rapidly resolve after surgical drainage. Community-acquired methicillin-resistant S aureus (MRSA) infection should be suspected if infection persists after treatment with adequate drainage and administration of first-line antibiotics. These infections may require more aggressive drainage and altered antimicrobial therapy.

Aggressive soft tissue infections are rare, difficult to diagnose, and require immediate surgical intervention plus administration of antimicrobial agents. Failure to rapidly recognize and treat these infections results in an extremely high mortality rate (~80–100%), and even with expedient therapy mortality rates are high (16–24%). Eponyms and differing classifications in the past have led to a hodgepodge of terminology—such as Meleney’s synergistic gangrene, Fournier’s gangrene, rapidly spreading cellulitis, gas gangrene, and necrotizing fasciitis—regarding these serious infections. Today it seems best to delineate them based on the soft tissue layer(s) of involvement.
BASIC CONSIDERATIONS

PART I

SKIN AND SOFT TISSUE INFECTIONS

Skin and soft tissue infections (e.g., skin and superficial soft tissue, deep soft tissue, and muscle) and the pathogen(s) that cause them.

Patients at risk for these types of infections include those who are elderly, immunosuppressed, or diabetic, and/or who suffer from peripheral vascular disease, though extremely aggressive necrotizing soft tissue infections (often caused by streptococci) have been described among healthy individuals as well. The common thread among these host factors appears to be compromise of the fascial blood supply, and if this is coupled with the introduction of exogenous microbes, the result can be devastating.

Initially, the diagnosis is established solely upon a constellation of clinical findings, not all of which are present in every patient. Not surprisingly, patients often develop sepsis syndrome or septic shock without an obvious cause. The extremities, perineum, trunk, and torso are most commonly affected, in that order. Careful examination should be undertaken for an entry site such as a small break or sinus in the skin from which grayish, turbid semipurulent material (“dishwater pus”) can be expressed, as well as for the presence of skin changes (bronze hue or brawny induration), blebs, or crepitus. The patient often develops pain at the site of infection that appears to be out of proportion to any of the physical manifestations. Any of these findings mandates immediate surgical intervention, which should consist of incision and direct visualization of potentially infected tissue (including deep soft tissue, fascia, and underlying muscle) and radical resection of affected areas. Radiologic studies should not be undertaken in patients in whom the diagnosis seriously is considered, as they delay surgical intervention and frequently provide confusing information. Unfortunately, surgical extirpation of infected tissue frequently entails amputation and/or disfiguring procedures; the surgeon must bear in mind that incomplete procedures are associated with higher rates of morbidity and mortality and debride all nonviable tissue (Fig. 6-4).

During the procedure, a Gram stain should be performed on tissue fluid. Antimicrobial agents directed against gram-positive and gram-negative aerobes and anaerobes (e.g., vancomycin plus a carbapenem), as well as high-dose aqueous penicillin G (16,000,000 to 20,000,000 U/d), the latter to treat clostridial pathogens, should be administered. Approximately 50% of such infections are polymicrobial, the remainder being caused by a single organism such as S pyogenes, P aeruginosa, or C perfringens. The microbiology of these polymicrobial infections is similar to that of secondary microbial peritonitis, with the exception that gram-positive cocci are more commonly encountered. Most patients should be returned to the operating room on a scheduled basis to determine if disease progression has occurred. If so, additional resection of infected tissue and debridement should take place. Antibiotic therapy can be refined based on culture and sensitivity results, particularly in the case of monomicrobial soft tissue infections. Hyperbaric oxygen therapy may be of use in patients with infection caused by gas-forming organisms (e.g., C perfringens), although the evidence to support efficacy is limited to underpowered studies and case reports. In the absence of such infection, hyperbaric oxygen therapy has not been shown to be effective.

Postoperative Nosocomial Infections

Surgical patients are prone to develop a wide variety of nosocomial infections during the postoperative period, which include SSIs, UTIs, pneumonia, and bacteremia. SSIs are discussed earlier, and the latter types of nosocomial infections are related to prolonged use of indwelling tubes and catheters for the purpose of urinary drainage, ventilation, and venous and arterial access, respectively.

The presence of a postoperative UTI should be considered based on urinalysis demonstrating WBCs or bacteria, a positive test for leukocyte esterase, or a combination of these elements. The diagnosis is established after >10^4 CFU/mL of microbes are identified by culture techniques in symptomatic patients, or >10^5 CFU/mL in asymptomatic individuals. Treatment for 3 to 5 days with a single antibiotic directed against the most common organisms (e.g., E Coli, K pneumoniae) that achieves high levels in the urine is appropriate. Initial therapy is directed by Gram stain results and is refined as culture results become available. Postoperative surgical patients should have indwelling urinary catheters removed as quickly as possible to avoid the development of a UTI.

Prolonged mechanical ventilation is associated with nosocomial pneumonia. These patients present with more severe disease, are more likely to be infected with drug-resistant pathogens, and suffer increased mortality compared to patients who develop community-acquired pneumonia. The diagnosis of pneumonia is established by presence of purulent sputum, elevated leukocyte count, fever, and new chest X-ray abnormalities, such as consolidation. The presence of two of the clinical findings, plus chest X-ray findings, significantly increases the likelihood of pneumonia. Consideration should be given to performing bronchoalveolar lavage to obtain samples for Gram stain and culture. Some authors advocate quantitative cultures as a means to identify a threshold for diagnosis. Surgical patients should be weaned from mechanical ventilation as soon as feasible, based on oxygenation and inspiratory effort, as risk of pneumonia increases with increased time on mechanical ventilation.

Infection associated with indwelling intravascular catheters is a common problem among hospitalized patients. Because of the complexity of many surgical procedures, these devices are increasingly used for physiologic monitoring, vascular access, drug delivery, and hyperalimentation. Among the several million catheters inserted each year in the United States, approximately 25% will become colonized, and approximately 5% will be associated with bacteremia. Duration of catheterization, insertion or manipulation under emergency or nonsterile conditions, use for hyperalimentation, and the use of multilumen catheters increase the risk of infection. Use of a central line insertion protocol that includes full barrier precautions and chlorhexidine skin prep has been shown to decrease the incidence of infection. Although no randomized trials have been performed, peripherally inserted central venous catheters have a catheter-related infection rate similar to those inserted in the subclavian or jugular veins.

Many patients who develop intravascular catheter infections are asymptomatic, often exhibiting solely an elevation in the blood WBC count. Blood cultures obtained from a peripheral site and drawn through the catheter that reveals the presence of the same organism increase the index of suspicion for the presence of a catheter infection. Obvious purulence at the exit site of the skin tunnel, severe sepsis syndrome due to any type of organism when other potential causes have been excluded, or bacteremia due to gram-negative aerobes or fungi should lead to catheter removal. Selected catheter infections due to low-virulence microbes such as S epidermidis can be effectively treated in approximately 50% to 60% of patients with a 14- to 21-day course of an antibiotic, which should be considered when no other vascular access site exists. The use of antibiotic-bonded catheters and chlorhexidine sponges at the insertion
site has been associated with lower rates of colonization. Use of ethanol or antimicrobial catheter “locks” have shown promise in reducing incidence of infection in dialysis catheters. The surgeon should carefully consider the need for any type of vascular access devices, rigorously attend to their maintenance to prevent infection, and remove them as quickly as possible. Use of systemic antibacterial or antifungal agents to prevent catheter infection is of no utility and is contraindicated.

**Sepsis**

As previously discussed, sepsis is increasing in incidence, with more than 1.1 million cases estimated per year in the United States with an annual cost of $24 billion. This rate is expected to increase as the population of aged in the United States increases. One third of sepsis cases occur in surgical populations and sepsis is a major cause of morbidity and mortality. The treatment of sepsis has improved over the last decade, with mortality rates dropping to under 30%. Factors contributing to this improvement relate both to recent randomized prospective trials demonstrating improved outcomes with new therapies, and to improvements in the process of care delivery to the sepsis patient. The “Surviving Sepsis Campaign,” a multidisciplinary group that develops treatment recommendations, published guidelines incorporating evidence-based sepsis treatment strategies most recently in 2016. These guidelines are summarized in Table 6-10.

**FIGURE 6-4.** Necrotizing soft tissue infection. (A) This patient presented with hypotension due to severe late necrotizing fasciitis and myositis due to β-hemolytic streptococcal infection. The patient succumbed to his disease after 16 hours despite aggressive debridement. (B) This patient presented with spreading cellulites and pain on motion of his right hip 2 weeks after total colectomy. Cellulitis on right anterior thigh is outlined. (C) Classic dishwater edema of tissues with necrotic fascia. (D) Right lower extremity after debridement of fascia to viable muscle.
Patients presenting with sepsis should receive resuscitation fluids early in the course of therapy. While former guidelines advocated fluids until the patient’s central venous pressure was 8 to 12 mmHg, newer guidelines recommend using dynamic monitoring systems (such as ultrasound) as well as assessment of physiological response to fluids by evaluating variables such as heart rate, blood pressure, and urine output to determine adequate resuscitation volumes. Resuscitation endpoints include achieving a goal mean arterial pressure of ≥65 mmHg, urine output of ≥0.5 mL/kg per hour, and normalization of serum lactate. Delaying this resuscitative step for as little as 3 hours has been shown to result in worse outcomes.\(^7\) Resuscitation may necessitate placement of a central venous catheter.

A number of studies have demonstrated the importance of early empiric antibiotic therapy in patients who develop sepsis or nosocomial infection; the Surviving Sepsis guidelines advocate for initiation of treatment within the first hour of the patient’s care. This therapy should be initiated as soon as possible with broad-spectrum antibiotics directed against the most likely organisms. Use of institution- and unit-specific sensitivity patterns are critical in selecting an appropriate agent for patients with nosocomial infection. Obtain appropriate cultures before

---

### Summary of Surviving Sepsis Campaign guidelines

**Initial Evaluation and Infection Issues**

**Initial resuscitation:** Begin resuscitation immediately in patients with hypotension or elevated serum lactate with resuscitation goal of at least 30 mL/kg IV crystalloid given in the first 3 hours. Ongoing fluid administration should be guided by physiologic response as measured by clinical variables (e.g., heart rate, blood pressure, urine output) and/or other invasive or noninvasive monitoring. Resuscitation goals include mean arterial pressure >65 mmHg, urine output >0.5 mL/kg per h, and mixed venous oxygen saturation >65%.

Target resuscitation to normalize lactate in patients with elevated lactate levels.

**Diagnosis:** Obtain appropriate cultures prior to antibiotics, but do not delay antibiotic therapy. Imaging studies should be performed promptly to confirm a source of infection.

**Antibiotic therapy:** Begin IV antibiotic therapy as early as possible and within the first hour after recognition of severe sepsis/septic shock. Use broad spectrum antibiotic regimen with penetration into presumed source, reassess regimen daily with de-escalation as appropriate, discontinue antibiotics in 7 to 10 days for most infections, stop antibiotics for noninfectious issues. Consider the use of serial procalcitonin levels, which may allow earlier cessation of antibiotic therapy.

**Source control:** Establish anatomic site of infection as rapidly as possible; implement source control measures as soon as possible after initial resuscitation. Remove intravascular access devices if potentially infected.

### Hemodynamic Support and Adjunctive Therapy

**Fluid therapy:** Fluid resuscitate using crystalloid, with continued fluid challenges so long as hemodynamic parameters continue to improve (i.e., for so long as the patient remains fluid-responsive). Albumin may be used as an adjunct if large volumes of crystalloid are required, but hydroxyethyl starch and gelatin-based fluids should not be used.

**Vasopressors/Inotropics Therapy:** Maintain MAP of >65 mmHg. Centrally-administered norepinephrine is the first-line choice. Add vasopressin if needed to raise MAP or to reduce norepinephrine requirement. Epinephrine is an alternative to vasopressin but has greater risk of reduced splanchnic blood flow. Dopamine is an appropriate alternative only in select patients (bradycardia, low risk of arrhythmia), and there is no role for low-dose “renal protection” dopamine. Phenylephrine is not recommended. Insert arterial catheters for patients requiring vasopressors. Consider dobutamine infusion for persistent hypotension after appropriate resuscitation and use of vasopressor agents.

**Steroids:** Consider intravenous hydrocortisone (dose <300 mg/day) for adult septic shock when hypotension responds poorly to fluids and vasopressors.

### Other Supportive Therapy

**Blood product administration:** Transfuse red blood cells when hemoglobin decreases to <7.0 g/dL in the absence of extenuating circumstances (e.g., myocardial ischemia, hemorrhage). It is not necessary to use fresh frozen plasma to correct INR abnormalities in the absence of bleeding. Consider prophylactic transfusion of platelets when counts are less than 10,000/mL in the absence of bleeding, <20,000/mL if there is a risk of bleeding, and <50,000 in the setting of active bleeding or need for procedure.

**Mechanical ventilation:** Target an initial tidal volume of 6 mL/kg body weight and plateau pressure of <30 cm H\(_2\)O in patients with acute lung injury. Use PEEP to avoid lung collapse. Adopt a conservative fluid strategy. In the setting of sepsis-induced ARDS with PaO\(_2/\)FiO\(_2\) ratio <150, use prone ventilation over continued supine position or high-frequency oscillatory ventilation. Use a weaning protocol to evaluate the potential for discontinuing mechanical ventilation. Pulmonary artery catheter placement is not indicated for routine monitoring.

**Sedation:** Minimize sedation using specific titration endpoints.

**Glucose control:** Use protocolized approach to blood glucose management targeting upper blood glucose target of 180 mg/dL.

**Prophylaxis:** Use stress ulcer (proton pump inhibitor or H\(_2\) blocker) and deep venous thrombosis (low-dose unfractionated or fractionated heparin) prophylaxis.

**Limitation of support:** Discuss advance care planning with patients and families and set realistic expectations.

starting antibiotics so that appropriate de-escalation of therapy can take place when results return, but only if doing so does not delay the initiation of treatment.

In patients who require vasopressor therapy, the first-line agent should be norepinephrine. This can be augmented with vasopressin, if needed, to achieve MAP ≥65 mmHg. It is important to titrate therapy based on other parameters such as mixed venous oxygen saturation and plasma lactate levels to reduce the risk of vasopressor-induced perfusion deficits. Patients who have persistently poor perfusion despite adequate fluid resuscitation may require addition of inotropic agents (epinephrine, dobutamine) or adjunctive therapy with low-dose corticosteroids (hydrocortisone 200 mg/day).86

Patients with acute lung injury associated with sepsis should receive mechanical ventilation with tidal volumes of 6 mL/kg and pulmonary airway plateau pressures of ≤30 cm H₂O. Finally, red blood cell transfusion should be reserved for patients with hemoglobin of <7 g/dL, with a more liberal transfusion strategy reserved for those patients with severe coronary artery disease, ongoing blood loss, or severe hypoxemia.86

**Resistant Organisms**

Penicillin was first available for widespread clinical use in the 1940s, and within a year resistant strains of *S aureus* had emerged. There are two major factors responsible for antibiotic resistance. First, there may be a genetic component innate to an organism that prevents the effect of a particular antibiotic. For instance, if an organism does not have a target receptor specific to the mechanism of action of a particular antibiotic, the antibiotic will not be effective against this organism. A good example is penicillin and gram-negative organisms, as these microbes lack penicillin-binding proteins. The second component driving resistance is inducible and related to natural selection. Over generations of exposure to a particular antibiotic, selection pressure will drive proliferation of more organisms resistant to that antibiotic. This acquired antibiotic resistance can be mutational, leading to changes in the chromosomal makeup of the microbe, or it can be extrachromosomal, induced by transfer of exogenous genetic material in the form of a plasmid or transposon. In either case, cellular mechanisms of resistance that develop include target site modification, changes in bacterial permeability or antibiotic uptake, activation of drug efflux systems, and drug deactivation. Given that millions of kilograms of antibiotics are used annually in people, in agriculture, and for animal use, environmental selection pressures are high, and antibiotic resistance has now been described in all classes of antibiotics in common use. Antibiotic resistance comes at a high cost, with a significant increase in mortality associated with infection from resistant organisms, and an economic cost of billions of dollars per year.

There are several drug-resistant organisms of interest to the surgeon. MRSA most commonly occurs as a hospital-associated infection in chronically ill patients who have received multiple courses of antibiotics. However, strains of MRSA have emerged in the community among patients without preexisting risk factors for disease.73 These strains, which produce a toxin known as Panton-Valentine leukocidin, make up an increasingly high percentage of surgical site infections since they are resistant to commonly employed prophylactic antimicrobial agents.88 Extended spectrum β-lactamase (ESBL)-producing strains of *Enterobacteriaceae*, originally geographically localized and infrequent, have become much more widespread and common in the last decade.86 These strains, typically *Klebsiella* species or *E coli*, produce a plasmid-mediated inducible β-lactamase. Commonly encountered plasmids also confer resistance to many other antibiotic classes. A common laboratory finding with ESBL is sensitivity to first-, second-, or third-generation cephalosporins, with resistance to other agents. Unfortunately, use of this seemingly active agent leads to rapid induction of resistance and failure of antibiotic therapy. The appropriate antibiotic choice in this setting is a carbapenem.

While *Enterococcus* was considered a low-virulence organism in the past, infections caused by *E faecium* and *faecalis* have been found to be increasingly severe, especially in the immunocompromised host. The last decade has seen increased isolation of a vancomycin-resistant strain of *Enterococcus*. This resistance is transposon-mediated via the vanA gene and is typically seen in *E faecium* strains. A real infection control concern is potential for transfer of genetic material to *S aureus* in a host coinfected with both organisms. This is thought to be the mechanism behind emerging cases of vancomycin resistance in *S aureus*.86

**Blood-Borne Pathogens**

The risk of human immunodeficiency virus (HIV) transmission from patient to surgeon is low. As of May 2011, there had been six cases of surgeons with HIV seroconversion from a possible occupational exposure, with no new cases reported since 1999. Of the numbers of healthcare workers with likely occupationally acquired HIV infection (*n* = 200), surgeons were one of the lower risk groups (compared to nurses at 60 cases and nonsurgeon physicians at 19 cases).90 The estimated risk of transmission from a needlestick from a source with HIV-infected blood is estimated at 0.3%. Transmission of HIV (and other infections spread by blood and body fluid) from patient to healthcare worker can be minimized by observation of universal precautions, including: (a) routine use of barriers (gloves, gown, mask, eye protection) when anticipating contact with blood or body fluids, (b) washing hands and other skin surfaces immediately after contact with blood or body fluids, and (c) careful handling and disposal of sharp instruments during and after use.

Postexposure prophylaxis for HIV has significantly decreased the risk of seroconversion for healthcare workers with occupational exposure to HIV. Steps to initiate postexposure prophylaxis should be initiated within hours for the most effective preventive therapy. Postexposure prophylaxis with a three-drug regimen should be initiated for healthcare workers with significant exposure to patients with an HIV-positive status. If a patient’s HIV status is unknown, it may be advisable to begin postexposure prophylaxis while testing is carried out, particularly if the patient is at high risk for infection due to HIV (e.g., has had a history of intravenous drug use). Generally, postexposure prophylaxis is not warranted for exposure to sources with unknown status, such as deceased persons or needles from a sharps container.92

The risks of acquiring HIV infection for surgeons are related to the prevalence of HIV infection in the patient population, the probability of transmission from a percutaneous injury suffered while caring for an infected patient, the number of such injuries sustained, and the use of postexposure prophylaxis. Average risk of HIV seroconversion is 0.3% from a percutaneous exposure, and 0.09% from a mucous membrane exposure. The overall risk is influenced by the degree of viral inoculum.
transmitted from patient to surgeon, with greater risk of seroconversion associated with hollow-bore needle injury, with larger-volume blood transmission, with direct introduction of infected blood into an artery or vein, and in exposure to blood with higher viral load. One study in Glasgow, Scotland, calculated annual risks and found a range in seroconversion rates from 1 in 200,000 for general surgeons not utilizing postexposure prophylaxis to as low as 1 in 10,000,000 with use of routine postexposure prophylaxis after significant exposures.92,93

Hepatitis B virus (HBV) is a DNA virus that affects only humans. Primary infection with HBV generally is self-limited, but it can cause fulminant hepatitis or progress to a chronic carrier state. Death from chronic liver disease or hepatocellular cancer occurs in roughly 30% of chronically infected persons. Surgeons and other healthcare workers are at high risk for this blood-borne infection and should receive the HBV vaccine; children are routinely vaccinated in the United States.94 This vaccine has contributed to a significant decline in the number of new cases of HBV per year in the United States, from approximately 250,000 annually in the 1980s to 3350 in 2010.95,96

Hepatitis C virus (HCV), previously known as non-A, non-B hepatitis, is a RNA flavivirus first identified in the late 1980s. This virus is confined to humans and chimpanzees. A chronic carrier state develops in 75% to 80% of patients with the infection, with chronic liver disease occurring in three-fourths of this subgroup. The number of new infections per year has declined since the 1980s due to routine testing of blood donors of this subgroup. The number of new infections per year has declined since the 1980s due to routine testing of blood donors.

Fortunately, HCV is not transmitted efficiently through occupational exposures to blood, with the seroconversion rate after accidental needlestick approximately 1.8%.97 To date, a vaccine to prevent HCV infection has not been developed. Experimental studies in chimpanzees with HCV immunoglobulin using a model of needlestick injury have failed to demonstrate a protective effect, and no effective antiviral agents for postexposure prophylaxis are available. Treatment of patients with HCV infection historically included ribavirin and pegylated gamma interferon; the development of novel direct-acting antiviral agents such as sofosbuvir, boceprevir, and telaprevir has led to changes in this strategy.98,99

**BIOLOGIC WARFARE AGENTS**

Several infectious organisms have been studied by the United States and the former Soviet Union and presumably other entities for potential use as biologic weapons. Programs involving biologic agents in the United States were halted by presidential decree in 1971. However, concern remains that these agents could be used by rogue states or terrorist organizations as weapons of mass destruction, as they are relatively inexpensive to make in terms of infrastructure development.

Given these concerns, physicians, including surgeons, should familiarize themselves with the manifestations of infection due to these pathogens. The typical agent is selected for the ability to be spread via the inhalational route, as this is the most efficient mode of mass exposure. Several potential agents are discussed in the following sections.

**Bacillus anthracis (Anthrax)**

Anthrax is a zoonotic disease occurring in domesticated and wild herbivores. The first identification of inhalational anthrax as a disease occurred among woolsorters in England in the late 1800s. The largest recent epidemic of inhalational anthrax occurred in 1979 in Sverdlovsk, Russia, after accidental release of anthrax spores from a military facility. Inhalational anthrax develops after a 1- to 6-day incubation period, with nonspecific symptoms, including malaise, myalgia, and fever. Over a short period of time these symptoms worsen, with development of respiratory distress, chest pain, and diaphoresis. Characteristic chest roentgenographic findings include a widened mediastinum and pleural effusions. Rapid antigen tests are under development for identification of this gram-positive rod, so a key element of establishing the diagnosis is eliciting an exposure history. Postexposure prophylaxis consists of administration of either ciprofloxacin or doxycycline.100 If an isolate is demonstrated to be penicillin-sensitive, the patient should be switched to amoxicillin. Inhalational exposure followed by the development of symptoms is associated with a high mortality rate. Treatment options include combination therapy with ciprofloxacin, clindamycin, and rifampin. Clindamycin is added to block toxin production, while rifampin penetrates into the central nervous system and intracellular locations.

**Yersinia pestis (Plague)**

Plague is caused by the gram-negative organism *Y. pestis*. The naturally occurring disease in humans is transmitted via flea bites from rodents. It was the first biologic warfare agent, and was used in the Crimean city of Caffa by the Tartar army, whose soldiers catapulted bodies of plague victims at the Genoese. When plague is used as a biologic warfare agent, clinical manifestations include epidemic pneumonia with blood-tinged sputum if aerosolized bacteria are used, or bubonic plague if fleas are used as carriers. Individuals who develop a painful enlarged lymph node lesion, termed a “bubo,” associated with fever, severe malaise, and exposure to fleas should be suspected to have plague. Diagnosis is confirmed via aspirate of the bubo and a direct antibody stain to detect plague bacillus, whose morphology is a bipolar, safety-pin-shaped gram-negative rod. Postexposure prophylaxis for patients exposed to plague consists of doxycycline. Treatment of the pneumonic or bubonic/septicemic form includes administration of either streptomycin, an aminoglycoside, doxycycline, a fluoroquinolone, or chloramphenicol.101

**Smallpox**

Variola, the causative agent of smallpox, was a major cause of infectious morbidity and mortality until its eradication in the late 1970s. Even in the absence of laboratory-preserved virus, the prolonged viability of variola virus has been demonstrated in scabs up to 13 years after collection. The potential for reverse genetic engineering using the known sequence of smallpox also makes it a potential biologic weapon. This has resulted in the United States undertaking a vaccination program for key healthcare workers.102 Variola virus is highly infectious in the aerosolized form; after an incubation period of 10 to 12 days, clinical manifestations of malaise, fever, vomiting, and headache appear, followed by development of a characteristic centripetal rash (which is found to predominate on the face and extremities). The fatality rate may reach 30%. Postexposure prophylaxis with smallpox vaccine has been noted to be effective for up to 4 days postexposure. Cidofovir, an acyclic nucleoside phosphonate analogue, has demonstrated activity in animal models of poxvirus infections and may offer promise for the treatment of smallpox.103
Francisella tularensis (Tularemia)

The principal reservoir of this gram-negative aerobic organism is the tick. After inoculation, this organism proliferates within macrophages. Tularemia is considered a potential bioterrorist threat due to a very high infectivity rate after aerosolization. Patients with tularemia pneumonia develop a cough and demonstrate pneumonia on chest roentgenogram. Enlarged lymph nodes occur in approximately 85% of patients. The organism can be cultured from tissue samples, but this is difficult, and the diagnosis is based on acute-phase agglutination tests. Treatment of inhalational tularemia consists of administration of an aminoglycoside or second-line agents such as doxycycline and ciprofloxacin.

Trauma
Clay Cothren Burlew and Ernest E. Moore

INTRODUCTION
Trauma, or injury, is defined as cellular disruption caused by environmental energy that is beyond the body’s resilience, which is compounded by cell death due to ischemia/reperfusion. Trauma is the most common cause of death for all individuals between the ages of 1 and 44 years, and is the third most common cause of death regardless of age. It is also the leading cause of years of productive life lost. Unintentional injuries account for over 135,000 deaths per year, with homicides, suicides, and other causes are responsible for another 60,000 deaths each year. However, death rate underestimates the magnitude of the societal toll. For example, in 2014 there were almost 200,000 injury-related deaths, but 37.2 million injured patients treated in emergency departments (EDs). Injury-related medical expenditures are estimated to be $117 billion each year in the United States. The aggregate lifetime cost for all injured patients is estimated to be in excess of $260 trillion. For these reasons, trauma must be considered a major public health issue. The American College of Surgeons Committee on Trauma addresses this issue by assisting in the development of trauma centers and systems. The organization of trauma systems has had a significant favorable impact on patient outcomes, although system integration and maldistribution of trauma centers remain challenges.

INITIAL EVALUATION AND RESUSCITATION OF THE INJURED PATIENT
Primary Survey
The Advanced Trauma Life Support (ATLS) course of the American College of Surgeons Committee on Trauma was developed in the late 1970s, based on the premise that appropriate and timely care can improve the outcome for the injured patient. ATLS provides a structured approach to the trauma patient with standard algorithms of care; it emphasizes the “golden hour” concept that timely, prioritized interventions are necessary to prevent death and disability. The ATLS format and basic tenets are followed throughout this chapter, with some modifications. The initial management of seriously injured patients consists of phases that include the primary survey/concurrent resuscitation, the secondary survey/diagnostic evaluation, definitive care, and the tertiary survey. The first step in patient management is performing the primary survey, the goal of which is to identify and treat conditions that constitute an immediate threat to life. The ATLS course refers to the primary survey as assessment of the “ABCs” (Airway, Breathing, and Circulation). The timing of emergent intubation in the hypovolemic patient remains controversial because of the risk of further compromising cardiac function. Although the concepts within the primary survey are presented in a sequential fashion, in reality they are pursued simultaneously in coordinated team resuscitation. Life-threatening injuries must be identified (Table 7-1) and treated before progressing to the secondary survey.

Airway Management With Cervical Spine Protection. Ensuring a patent airway is the first priority in the primary survey. This is essential because efforts to restore cardiovascular integrity will be futile unless the oxygen content of the blood is adequate. Simultaneously, all patients with blunt trauma require cervical spine immobilization until injury is excluded. This is typically accomplished by applying a hard cervical collar or placing sandbags on both sides of the head with the patient’s forehead taped across the bags. Soft collars do not effectively immobilize the cervical spine. For penetrating neck wounds, however, cervical collars are not recommended because they provide no benefit and may interfere with assessment and treatment.
Key Points

1. Trauma is the most common cause of death for all individuals between the ages of 1 and 44 years and is the third most common cause of death regardless of age.

2. The initial management of seriously injured patients usually follows the primary survey (the “ABCs”—Airway, Breathing, and Circulation), although at times restoring Circulatory volume may proceed active Airway intervention; the goals of the primary survey are to identify and treat conditions that constitute an immediate threat to life.

3. All patients with blunt injury should be assumed to have unstable cervical spine injuries until proven otherwise; one must maintain cervical spine precautions and in-line stabilization.

4. Patients with ongoing hemodynamic instability, whether “nonresponders” or “transient responders,” require prompt intervention; one must consider the dominant causes of acute shock, i.e., hemorrhagic, cardiogenic, and neurogenic shock.

5. Patients with trauma-induced coagulopathy (TIC) are at risk for massive transfusion and need to be identified early.

6. Indications for immediate operative intervention for penetrating cervical injury include hemodynamic instability and significant external arterial hemorrhage; the management algorithm for hemodynamically stable patients is based on the presenting symptoms and anatomic location of injury, with the neck being divided into three distinct zones.

7. The gold standard for determining if there is a blunt descending aortic injury is computed tomography angiography (CTA) scanning; indications are primarily based on injury mechanism.

8. The abdomen is a diagnostic black box. Physical examination and FAST ultrasound can identify patients requiring emergent laparotomy. Computed tomography (CT) scanning is the mainstay of evaluation in the remaining patients to more precisely identify the site and magnitude of injury.

9. Manifestation of the “bloody vicious cycle” (the lethal combination of coagulopathy, hypothermia, and metabolic acidosis) is the most common indication for damage control surgery. The primary objectives of damage control laparotomy are to control bleeding and limit gastrointestinal spillage.

10. Blunt injuries to the carotid and vertebral arteries are usually managed with systemic antithrombotic therapy.

11. The abdominal compartment syndrome may be primary (i.e., due to the injury of abdominal organs, bleeding, and packing) or secondary (i.e., due to reperfusion visceral edema, retroperitoneal edema, and ascites).

Patients who are conscious, without tachypnea, and have a normal voice are unlikely to require early airway intervention. Exceptions are penetrating injuries to the neck with an expanding hematoma; evidence of chemical or thermal injury to the mouth, nares, or hypopharynx; extensive subcutaneous air in the neck; complex maxillofacial trauma; or airway bleeding. Although these patients may initially have an adequate airway, it may become compromised if soft tissue swelling, hematoma formation, or edema progresses. In these cases, preemptive intubation should be performed before airway access becomes challenging.

Patients who have an abnormal voice, abnormal breathing sounds, tachypnea, or altered mental status require further airway evaluation. Blood, vomit, the tongue, teeth, foreign objects, and soft tissue swelling can cause airway obstruction; suctioning affords immediate relief in many patients. In the comatose patient, the tongue may fall backward and obstruct the hypopharynx; this can be relieved by either a chin lift or jaw thrust. An oral airway or a nasal trumpet is also helpful in maintaining airway patency, although the former is usually not tolerated by an awake patient. Establishing a definitive airway (i.e., endotracheal intubation) is indicated in patients with apnea; inability to protect the airway due to altered mental status; impending airway compromise due to inhalation injury, hematoma, facial bleeding, soft tissue swelling, or aspiration; and inability to maintain oxygenation. Altered mental status is the most common indication for intubation. Agitation or obtundation, often attributed to intoxication or drug use, may actually be due to hypoxia. But the timing of endotracheal intubation may be critical in the hypovolemic patient because positive airway pressure may further compromise cardiac function and precipitate cardiac arrest; thus, Circulation may take priority over Airway.

Options for endotracheal intubation include nasotracheal, orotracheal, or operative routes. Nasotracheal intubation can be accomplished only in patients who are breathing spontaneously. Although nasotracheal intubation is frequently used by prehospital providers, the technique is limited in the ED to those patients requiring emergent airway support in whom chemical paralysis

Immediately life-threatening injuries to be identified during the primary survey

- Airway
  - Airway obstruction
  - Airway injury
- Breathing
  - Tension pneumothorax
  - Open pneumothorax
  - Massive air leak from tracheobronchial injury
  - Flail chest with underlying pulmonary contusion
- Circulation
  - Hemorrhagic shock
  - Massive hemorthorax
  - Massive hemoperitoneum
  - Mechanically unstable pelvis fracture with bleeding
  - Extremity blood loss
  - Cardiogenic shock
  - Cardiac tamponade
  - Neurogenic shock
- Disability
  - Intracranial hemorrhage
  - Cervical spine injury
cannot be used. Orotracheal intubation is the preferred technique to establish a definitive airway. Because all patients are presumed to have cervical spine injuries, manual in-line cervical immobilization is essential. Correct endotracheal placement is verified with direct laryngoscopy, capnography, audible bilateral breath sounds, and finally a chest film. The GlideScope®, a video laryngoscope that uses fiberoptics to visualize the vocal cords, is being employed more frequently. Advantages of orotracheal intubation include the direct visualization of the vocal cords, ability to use larger-diameter endotracheal tubes, and applicability to apneic patients. The disadvantage of orotracheal intubation is that conscious patients usually require neuromuscular blockade, which may result in the inability to intubate, aspiration, or medication complications. Those who attempt rapid-sequence induction must be thoroughly familiar with the procedure (see Chapter 13).

Patients in whom attempts at intubation have failed or who are precluded from intubation due to extensive facial injuries require operative establishment of an airway. Cricothyroidotomy (Fig. 7-1) is performed through a generous vertical incision, with sharp division of the subcutaneous tissues. Visualization may be improved by having an assistant retract laterally on the neck incision using retractors. The cricothyroid membrane is verified by digital palpation and opened in a horizontal direction. The airway may be stabilized before incision of the membrane using a tracheostomy hook; the hook should be placed under the thyroid cartilage to elevate the airway. A 6.0 endotracheal tube (maximum diameter in adults) is then advanced through the cricothyroid opening and sutured into place. In patients under the age of 11, cricothyroidotomy is relatively contraindicated due to the risk of subglottic stenosis, and tracheostomy should be performed.

Emergent tracheostomy is indicated in patients with laryngotracheal separation or laryngeal fractures, in whom cricothyroidotomy may cause further damage or result in complete loss of the airway. This procedure is best performed in the operating room (OR) where there is optimal lighting and availability of advanced equipment (e.g., sternal saw). In these cases, often after a “clothesline” injury, direct visualization and instrumentation of the trachea usually is done through the traumatic anterior neck defect or after a generous collar skin incision (Fig. 7-2). If the trachea is completely transected, a nonpenetrating clamp should be placed on the distal aspect to prevent tracheal retraction into the mediastinum; this is particularly important before placement of the endotracheal tube.

Breathing and Ventilation. Once a secure airway is obtained, adequate oxygenation and ventilation must be ensured. All injured patients should receive supplemental oxygen and be monitored by pulse oximetry. The following conditions constitute an immediate threat to life due to inadequate ventilation and should be recognized during the primary survey: tension pneumothorax, open pneumothorax, flail chest with underlying pulmonary contusion, massive hemothorax, and major air leak due to a tracheobronchial injury.

Tension pneumothorax is presumed in any patient manifesting respiratory distress and hypotension in combination with any of the following physical signs: tracheal deviation away from the affected side, lack of or decreased breath sounds on

Figure 7-1. Cricothyroidotomy is recommended for emergent surgical establishment of a patent airway. A vertical skin incision avoids injury to the anterior jugular veins, which are located just lateral to the midline. Hemorrhage from these vessels obscures vision and prolongs the procedure. When a transverse incision is made in the cricothyroid membrane, the blade of the knife should be angled inferiorly to avoid injury to the vocal cords. A. Use of a tracheostomy hook stabilizes the thyroid cartilage and facilitates tube insertion. B. A 6.0 endotracheal tube is inserted after digital confirmation of airway access.

Figure 7-2. A “clothesline” injury can partially or completely transect the anterior neck structures, including the trachea. With complete tracheal transection, the endotracheal tube is placed directly into the distal aperture, with care taken not to push the trachea into the mediastinum.
the affected side, and subcutaneous emphysema on the affected side. Patients may have distended neck veins due to impedance of venous return, but the neck veins may be flat due to concurrent systemic hypovolemia. Tension pneumothorax and simple pneumothorax have similar signs, symptoms, and examination findings, but hypotension qualifies the pneumothorax as a tension pneumothorax. Although immediate needle thoracostomy decompression with a 14-gauge angiocatheter may be indicated in the field, tube thoracostomy in the midaxillary line should be performed immediately in the ED before a chest radiograph is obtained (Fig. 7-3). Recent studies suggest that preferred location for needle decompression may be the fifth intercostal space in the anterior axillary line due to body habitus. In cases of tension pneumothorax, the parenchymal tear in the lung acts as a one-way valve, with each inhalation allowing additional air to accumulate in the pleural space. The normally negative intrapleural pressure becomes positive, which depresses the ipsilateral hemidiaphragm and shifts the mediastinal structures into the contralateral chest. Subsequently, the contralateral lung is compressed and the heart rotates about the superior and inferior vena cava; this decreases venous return and ultimately cardiac output, which culminates in cardiovascular collapse.

An open pneumothorax or “sucking chest wound” occurs with full-thickness loss of the chest wall, permitting free communication between the pleural space and the atmosphere (Fig. 7-4). This compromises ventilation due to equilibration of atmospheric and pleural pressures, which prevents lung inflation and alveolar ventilation, and results in hypoxia and hypercarbia. Complete occlusion of the chest wall defect without a tube thoracostomy may convert an open pneumothorax to a tension pneumothorax. Temporary management of this injury includes covering the wound with an occlusive dressing that is taped on three sides, which allows accumulated air to escape from the pleural space and thus prevents a tension pneumothorax. Repair of the chest wall defect and tube thoracostomy remote from the wound is definitive treatment.

Flail chest occurs when three or more contiguous ribs are fractured in at least two locations. Paradoxical movement of this free-floating segment of chest wall is usually evident in patients with spontaneous ventilation, due to the negative intrapleural pressure of inspiration. The additional work of breathing and chest wall pain caused by the flail segment is rarely sufficient to compromise ventilation. Instead, it is the decreased compliance and increased shunt fraction caused by the associated pulmonary contusion that is the source of acute respiratory failure. Pulmonary contusions often progress during the first 12 hours. Resultant hypoventilation and hypoxemia may require intubation and mechanical ventilation. The patient’s initial chest...
radiograph often underestimates the extent of the pulmonary parenchymal damage (Fig. 7-5); close monitoring and frequent clinical reevaluation are warranted.

Major air leak occurs from tracheobronchial injuries. Type I injuries are those occurring within 2 cm of the carina.11,12 These may not be associated with a pneumothorax due to the envelopment in the mediastinal pleura. Type II injuries are more distal injuries within the tracheobronchial tree and hence manifest with a pneumothorax. Bronchoscopy confirms the extent of the injury and its location, and directs management.

Circulation With Hemorrhage Control. With a secure airway and adequate ventilation established, circulatory status is the next focus. An initial approximation of the patient’s cardiovascular status can be obtained by palpating peripheral pulses. In general, systolic blood pressure (SBP) must be 60 mmHg for the carotid pulse to be palpable, 70 mmHg for the femoral pulse, and 80 mmHg for the radial pulse. Any episode of hypotension (defined as a SBP <90 mmHg) is assumed to be caused by hemorrhage until proven otherwise. Patients with rapid massive blood loss may have paradoxical bradycardia.13 Blood pressure and pulse should be measured at least every 5 minutes in patients with significant blood loss until normal vital sign values are restored.

Intravenous (IV) access for fluid resuscitation and medication administration is obtained with two peripheral catheters, 16-gauge or larger in adults. For patients in whom peripheral angiocatheter access is difficult, intraosseous (IO) needles should be rapidly placed in the proximal humerus or tibia (Fig. 7-6).14,15 All medications administered IV may be administered in a similar dosage intraosseously. Although safe for emergent use, the needle should be removed once alternative access is established to prevent potential osteomyelitis. Blood should be drawn simultaneously for a bedside hemoglobin level and routine trauma laboratory tests. In the seriously injured patient arriving in shock, an arterial blood gas for base deficit (BD), cross-matching for possible blood component (RBC and plasma) transfusion, and a coagulation panel/viscoelastic hemostasis assay (e.g., TEG, ROTEM) should be obtained. In these patients, secondary large bore (7 to 9 Fr) cannulae should be obtained via the femoral or subclavian veins; Cordis introducer catheters are preferred over triple-lumen catheters. In general, initial access in trauma patients is best secured in the groin so that placement of the catheter will not interfere with the performance of other diagnostic and therapeutic thoracic procedures. A rule of thumb to consider for secondary access is placement of femoral access for thoracic trauma and jugular or subclavian access for abdominal trauma. Internal jugular or subclavian catheters provide a more reliable measurement of central venous pressure (CVP), which may be helpful in determining the volume status of the patient and in excluding cardiac tamponade. Saphenous vein cutdowns at the ankle can also provide excellent access (Fig. 7-7). The saphenous vein is reliably found 1 cm anterior and 1 cm superior to the medial malleolus. Standard 14-gauge catheters can be quickly placed, even in an exsanguinating patient with collapsed veins. In severely injured children younger than 6 years of age, the preferred venous access is peripheral intravenous catheters followed by an IO needle. Central venous catheter placement or saphenous vein cutdown may be considered as the third choice of access based upon provider experience. Inadvertent femoral artery cannulation, however, may result in limb-threatening arterial spasm.

External control of any visible hemorrhage should be achieved promptly while circulating volume is restored. For
open wounds with ongoing bleeding, manual compression should be done with a single 4 × 4 gauze and a gloved hand. Covering the wound with excessive dressings may permit ongoing unrecognized blood loss that is hidden underneath the dressing. Blind clamping of bleeding vessels should be avoided because of the risk to adjacent structures, including nerves. This is particularly true for penetrating injuries of the neck, thoracic outlet, and groin, where bleeding may be torrential and arising deep within the wound. In these situations, a gloved finger placed through the wound directly onto the bleeding vessel can apply enough pressure to control active bleeding. The surgeon performing this maneuver must then walk with the patient to the OR for definitive treatment. For bleeding of the extremities, it is tempting to apply tourniquets for hemorrhage control, but digital occlusion will usually control the bleeding; complete vascular occlusion with a tourniquet risks permanent neuromuscular impairment. Patients in shock have a lower tolerance to warm ischemia, and an occluded extremity is prone to small vessel thrombosis. For patients with open fractures, fracture reduction with stabilization via splints will limit bleeding both externally and into the subcutaneous tissues. Scalp lacerations through the galea aponeurotica tend to bleed profusely; these can be temporarily controlled with skin staples, Raney clips, or a full-thickness continuous running nylon stitch.

During the circulation section of the primary survey, four life-threatening injuries must be identified promptly: (a) massive hemothorax, (b) cardiac tamponade, (c) massive hemoperitoneum, and (d) mechanically unstable pelvic fractures with bleeding. Massive hemoperitoneum and mechanically unstable pelvic fractures are discussed in “Emergent Abdominal Exploration” and “Pelvic Fractures and Emergent Hemorrhage Control,” respectively. Critical tools used to differentiate these in the multisystem trauma patient are the chest and pelvis radiographs, and extended focused abdominal sonography for trauma (eFAST) (see “Regional Assessment and Special Diagnostic Tests”). A massive hemothorax (life-threatening injury number one) is defined as >1500 mL of blood or, in the pediatric population, >25% of the patient’s blood volume in the pleural space (Fig. 7-8). Although it may be estimated on chest radiograph, tube thoracostomy is the only reliable means to quantify the amount of hemothorax. After blunt trauma, a hemothorax is usually due to multiple rib fractures with severed intercostal vessels, but occasionally bleeding is from lacerated lung parenchyma, which is usually associated with an air leak. After penetrating trauma, a great vessel or pulmonary hilar vessel injury should be presumed. In either scenario, a massive hemothorax is an indication for operative intervention, but tube thoracostomy is critical to facilitate lung reexpansion, which may improve oxygenation and cardiac performance as well as tamponade venous bleeding. In patients arriving in shock with a high risk of pelvic fracture (e.g., autopedestrian accident), the pelvis should be presumptively stabilized with a sheet or binder.

![Figure 7-7](image-url) Saphenous vein cutdowns are excellent sites for fluid resuscitation access. A. The vein is consistently found 1 cm anterior and 1 cm superior to the medial malleolus. B. Proximal and distal traction sutures are placed with the distal suture ligated. C. A 14-gauge IV catheter is introduced and secured with sutures and tape to prevent dislodgment.

![Figure 7-8](image-url) More than 1500 mL of blood in the pleural space is considered a massive hemothorax. Chest film findings reflect the positioning of the patient. A. In the supine position, blood tracks along the entire posterior section of the chest and is most notable pushing the lung away from the chest wall. B. In the upright position, blood is visible dependently in the right pleural space.
Cardiac tamponade occurs most commonly after penetrating thoracic wounds, although occasionally blunt rupture of the heart, particularly the atrial appendage, is seen. Acutely, <100 mL of pericardial blood may cause pericardial tamponade. The classic Beck’s triad—dilated neck veins, muffled heart tones, and a decline in arterial pressure—is usually not appreciated in the trauma bay because of the noisy environment and associated hypovolemia. Because the pericardium is not acutely distensible, the pressure in the pericardial sac will rise to match that of the injured chamber. When this pressure exceeds that of the right atrium, right atrial filling is impaired and right ventricular preload is reduced. This ultimately leads to decreased right ventricular output. Additionally, increased intrapericardial pressure impedes myocardial blood flow, which leads to subendocardial ischemia and a further reduction in cardiac output.

Diagnosis of hemopericardium is best achieved by ultrasound of the pericardium (Fig. 7-9). Early in the course of tamponade, blood pressure and cardiac output will transiently improve with fluid administration due to increased central venous pressure. In patients with any hemodynamic disturbance, a pericardial drain can be placed using ultrasound guidance (Fig. 7-10). Removing as little as 15 to 20 mL of blood will often temporarily stabilize the patient’s hemodynamic status and alleviate the subendocardial ischemia that can be associated with lethal arrhythmias; this allows safe transport to the OR for sternotomy. Pericardiocentesis is successful in decompressing tamponade in approximately 80% of cases; the majority of failures are due to the presence of clotted blood within the pericardium. Patients with a persistent SBP <60 mmHg warrant resuscitative thoracotomy (RT) with opening of the pericardium for rapid decompression and control of bleeding.

The utility of RT has been debated for decades. Current indications are based on 40 years of prospective data (Table 7-2). RT is associated with the highest survival rate after isolated cardiac injury; 35% of patients presenting in shock and 20% without vital signs (i.e., no pulse or obtainable blood pressure) are salvaged after
isolated penetrating injury to the heart. For all penetrating wounds, survival rate is 15%. Conversely, patient outcome is limited when RT is done for blunt trauma, with 2% survival among patients in shock and <1% survival among those with no vital signs. Thus, patients undergoing cardiopulmonary resuscitation (CPR) upon arrival to the ED should undergo RT selectively based on injury and duration of CPR (Fig. 7-11). RT is best accomplished using a generous left anterolateral thoracotomy, with the skin incision started to the right of the sternum (Fig. 7-12). A longitudinal pericardiotomy anterior to the phrenic nerve is used to release cardiac tamponade and permits access to the heart for cardiac repair and open cardiac massage. The cardiac wound should be repaired prior to vigorous efforts of myocardial resuscitation (e.g., epinephrine, calcium). Cross-clamping of the aorta improves central circulation, augments cerebral and coronary blood flow, and limits further abdominal blood loss (Fig. 7-13). The patient must sustain a SBP of 70 mmHg after RT and associated interventions to be considered resuscitable, and hence transported to the OR.18,19

Disability and Exposure. The Glasgow Coma Scale (GCS) score should be determined for all injured patients (Table 7-3). It is calculated by adding the scores of the best motor response, best verbal response, and the best eye response. Scores range from 3 (the lowest) to 15 (normal). Scores of 13 to 15 indicate mild head injury, 9 to 12 moderate injury, and ≤8 severe injury. The GCS is a quantifiable determination of neurologic function that is useful for triage, treatment, and prognosis.

Neurologic evaluation, including spinal cord integrity, is critical before administration of neuromuscular blockade for intubation. Subtle changes in mental status can be caused by hypoxia, hypercarbia, or hypovolemia, or may be an early sign of increasing intracranial pressure. An abnormal mental status should prompt an immediate reevaluation of the patient’s ABCs and consideration of central nervous system injury. Deterioration in mental status may be subtle and may not progress in a predictable fashion. For example, previously calm, cooperative patients may become anxious and combative as they become hypoxic. However, a patient who is agitated and combative from drugs or alcohol may become somnolent if hypovolemic shock develops. Patients with neurogenic shock are typified by hypotension with relative bradycardia, and are often first recognized due to paralysis, decreased rectal tone, or priapism. Patients with high spinal cord disruption are at greatest risk for neurogenic shock due to physiologic disruption of sympathetic fibers; treatment consists of volume loading and a dopamine infusion, which is both inotropic and chronotropic, as well as a vasoconstrictor.

Seriously injured patients must have all of their clothing removed to avoid overlooking limb- or life-threatening injuries, but warmed blankets should be placed immediately to avoid hypothermia.

Shock Classification and Initial Fluid Resuscitation. Classic signs and symptoms of shock are tachycardia, hypotension, tachypnea, altered mental status, diaphoresis, and pallor

Figure 7-11. Algorithm directing the use of resuscitative thoracotomy (RT) in the injured patient undergoing cardiopulmonary resuscitation (CPR). OR = operating room; SBP = systolic blood pressure.
Figure 7-12. A. Resuscitative thoracotomy (RT) is performed through the fifth intercostal space using the anterolateral approach. B and C. The pericardium is opened anterior to the phrenic nerve, and the heart is rotated out for evaluation. D. Open cardiac massage should be performed with a hinged, clapping motion of the hands, with sequential closing from palms to fingers. The two-handed technique is strongly recommended because the one-handed massage technique poses the risk of myocardial perforation with the thumb.

Figure 7-13. A. Aortic cross-clamp is applied with the left lung retracted superiorly, below the inferior pulmonary ligament, just above the diaphragm. B. The flaccid aorta is identified as the first structure encountered on top of the spine when approached from the left chest.

(Table 7-4). In general, the quantity of acute blood loss correlates with physiologic abnormalities. For example, patients in class II shock are tachycardic, but they do not exhibit a reduction in blood pressure until over 1500 mL of blood loss, or class III shock. Physical findings should be used as an aid in the evaluation of the patient’s response to treatment. The goal of fluid resuscitation is to re-establish tissue perfusion. Fluid resuscitation usually begins with isotonic crystalloid, typically Ringer’s lactate. However, for patients arriving in shock (persistent SBP <90 mmHg in an adult), instead of crystalloid the current practice is to activate a massive transfusion protocol (MTP) in which red blood cells (RBC) and fresh frozen plasma (FFP) are administered. The details of a MTP are discussed later. Patients who have a good response to
fluid infusion (i.e., normalization of vital signs, clearing of the sensorium) and evidence of good peripheral perfusion (warm extremities with normal capillary refill) are presumed to have adequate overall perfusion. Urine output is a reliable indicator of organ perfusion but requires time to quantitate. Adequate urine output is 0.5 mL/kg per hour in an adult, 1 mL/kg per hour in a child, and 2 mL/kg per hour in an infant <1 year of age. Because measurement of this resuscitation-related variable is time dependent, it is generally more useful in the OR and intensive care unit (ICU) setting, than in initial evaluation in the trauma bay.

There are several caveats to be considered when evaluating the injured patient for shock. Tachycardia (HR >110 bpm) is often the earliest sign of ongoing blood loss, but the critical issue is change in HR over time. Individuals in good physical condition with a resting pulse rate in the 50s may manifest a relative tachycardia in the 90s; although clinically significant, this does not meet the standard definition of tachycardia. Conversely, patients on cardiac medications such as β-blockers may not be capable of increasing their heart rate to compensate for hypovolemia. Bradycardia can occur with rapid severe blood loss; this is an ominous sign, often heralding impending cardiovascular collapse. Other physiologic stresses, aside from hypovolemia, may produce tachycardia, such as hypoxia, pain, anxiety, and stimulant drugs (cocaine, amphetamines). As noted previously, decreased SBP is not a reliable early sign of hypovolemia because blood loss must exceed 30% before hypotension is evident. Additionally, younger patients may maintain their SBP due to sympathetic tone despite severe intravascular deficits until they are on the verge of cardiac arrest. Pregnant

BV = blood volume; CNS = central nervous system.
patients have a progressive increase in circulating blood volume over gestation; therefore, they must lose a relatively larger volume of blood before manifesting signs and symptoms of hypovolemia (see “Special Populations”).

Based on the initial response to fluid resuscitation, hypovolemic injured patients can be separated into three broad categories: responders, transient responders, and nonresponders. Individuals who are stable or have a good response to initial fluid therapy as evidenced by normalization of vital signs, mental status, and urine output are unlikely to have significant ongoing hemorrhage, and further diagnostic evaluation for occult injuries can proceed in an orderly fashion (see “Secondary Survey”). At the other end of the spectrum are patients classified as “nonresponders” who have persistent hypotension despite aggressive resuscitation. These patients mandate immediate identification of the source of hypotension with appropriate intervention to prevent a fatal outcome. Transient responders are those who respond initially to volume loading with improvement in vital signs, but subsequently deteriorate hemodynamically. This group of patients can be challenging to triage for definitive management.

**Persistent Hypotension.** Patients with ongoing hemodynamic instability, whether “nonresponders” or “transient responders,” require systematic evaluation and prompt intervention. The spectrum of disease in patients with persistent hypotension ranges from easily reversible problems such as a tension pneumothorax to multisystem injury with a number of sites of ongoing active hemorrhage. One must first consider the dominant categories of postinjury shock that may be the underlying cause: hemorrhagic, cardiogenic, and neurogenic. In patients with persistent hypotension and tachycardia, cardiogenic or hemorrhagic shock are the likely causes. Ultrasound evaluation of the pericardium, pleural cavities, and abdomen in combination with plain radiographs of the chest and pelvis will usually identify the source of shock. In patients with persistent hypotension following blunt trauma, the pelvis should be wrapped with a sheet for stabilization until radiography can be done; external blood loss should be controlled, and extremity fractures should be splinted to minimize further blood loss. Evaluation of the CVP or ultrasound of the IVC may further assist in distinguishing between cardiogenic and hypovolemic shock. Base deficit measurement is critical; a base deficit of >8 mmol/L implies ongoing cellular shock. Serum lactate also is used to monitor the patient’s physiologic response to resuscitation. Evolving technology, such as measurement of the critical reserve index, may provide noninvasive monitoring.

The differential diagnosis of cardiogenic shock in the trauma patient is: (a) tension pneumothorax, (b) pericardial tamponade, (c) blunt cardiac injury, (d) myocardial infarction, and (e) bronchovenous air embolism. Tension pneumothorax, the most frequent cause of cardiac failure, and pericardial tamponade have been discussed earlier. Although as many as one-third of patients sustaining significant blunt chest trauma experience some degree of blunt cardiac injury (BCI), few such injuries result in hemodynamic embarrassment. Patients with electrocardiographic (ECG) abnormalities or dysrhythmias require continuous ECG monitoring and antidyssrhythmic treatment as indicated. Unless myocardial infarction is suspected, there is no role for routine serial measurement of cardiac enzyme levels—they lack specificity and do not predict significant dysrhythmias. In patients with no identified injuries who are being considered for discharge from the ED, the combination of a normal EKG and troponin level rules out significant BCI. The patient with hemodynamic instability from BCI requires appropriate resuscitation and may benefit from hemodynamic monitoring to optimize preload and guide inotropic support. Echocardiography (ECHO) is performed to exclude valvular or septal injuries; the most common ECHO finding in BCI is right ventricular dyskinesia due to the anterior orientation of the right ventricle. Transsthoracic and transesophageal ECHO are now becoming routine in the trauma bay and surgical intensive care unit (SICU). Rarely, patients with refractory cardiogenic shock may require placement of an intra-aortic balloon pump to enhance coronary perfusion and decrease myocardial work. Acute myocardial infarction may be the cause of a motor vehicle collision or other trauma in older patients. Although optimal initial management includes treatment for the evolving infarction, such as thrombolytic therapy, anticoagulation, and emergent angioplasty, these decisions must be individualized in accordance with the patient’s other injuries.

Bronchovenous air embolism is a frequently overlooked lethal complication of pulmonary injury. Air emboli can occur after blunt or penetrating trauma, when air from an injured bronchus enters an adjacent injured pulmonary vein and returns air to the left heart. Air accumulation in the left ventricle impedes diastolic filling, and during systole air is pumped into the coronary arteries, disrupting coronary perfusion. The typical case is a patient with a penetrating thoracic injury who is hemodynamically stable but experiences sudden cardiac arrest after being intubated and placed on positive pressure ventilation. The patient should be placed immediately in Trendelenburg’s position to trap the air in the apex of the left ventricle. Emergency thoracotomy is followed by cross-clamping of the pulmonary hilum on the side of the injury to prevent further introduction of air (Fig. 7-14). Air is aspirated from the apex of the left ventricle and then the aortic root with an 18-gauge needle and 50-mL syringe. Vigorous massage is used to force the air bubbles through the coronary arteries; if this is unsuccessful, a tuberculin syringe is used to aspirate air bubbles from the coronary artery (most common is the right). Once circulation is restored, the patient should be kept in Trendelenburg’s position with the pulmonary hilum clamped until the pulmonary venous injury is controlled operatively.

Persistent hypotension due to uncontrolled hemorrhage is associated with high mortality. A rapid search for the source or sources of hemorrhage includes visual inspection with knowledge of the injury mechanism, eFAST, and chest and pelvic radiographs. During diagnostic evaluation, type O RBCs (O-negative for women of childbearing age) and thawed AB plasma should be administered at a ratio of 2:1. Type-specific RBCs should be administered as soon as available. The acute coagulopathy of trauma is now well recognized and underscores the importance of preemptive blood component administration. The resurgent interest in viscoelastic hemostatic assays (thrombelastography [TEG] and thrombelastometry [ROTEM]) has facilitated the appropriate and timely use of clotting adjuncts, including the prompt recognition of fibrinolysis. In patients with clear indications for operation, essential radiographs should be taken, and the patient should be transported to the OR immediately. Such patients include those with blunt trauma and massive hemorrhage, those with penetrating trauma and an initial chest tube output of >1 L, and those with abdominal trauma and ultrasound evidence of extensive hemoperitoneum. In patients with gunshot wounds to the chest or abdomen, a chest and
abdominal film, with radiopaque markers at the wound sites, should be obtained to determine the trajectory of the bullet or location of a retained fragment prior to transport to the OR. For example, a patient with a gunshot wound to the upper abdomen should have a chest radiograph to ensure that the bullet did not traverse the diaphragm causing intrathoracic injury. Similarly, a chest radiograph is important in a patient with a gunshot wound to the right chest to evaluate the left hemithorax. If a patient arrives with a penetrating weapon remaining in place, the weapon should not be removed in the ED because it could be tamponading a lacerated blood vessel (Fig. 7-15). The surgeon should extract the offending instrument in the controlled environment of the OR, ideally once an incision has been made with adequate exposure for vascular control. In situations where knives are embedded in the head or neck, preoperative imaging may be useful to anticipate arterial injuries.

In patients with persistent hypotension and no clear operative indications, one should systematically evaluate the five potential sources of blood loss: scalp, chest, abdomen, pelvis, and extremities. Significant bleeding at the scene may be reported by paramedics, but its quantification is unreliable. Examination should exclude active bleeding from a scalp laceration that may be readily controlled with clips or staples. Thoracoabdominal trauma should be evaluated with a combination of eFAST, chest radiograph, and pelvic radiograph. If the FAST results are negative and no other source of hypotension is obvious, diagnostic peritoneal aspiration should be entertained. Extremity examination and radiographs should be used to identify associated fractures. Fracture-related blood loss, when additive, may be a potential source of the patient’s hemodynamic instability. Each rib fracture can produce 100 to 200 mL of blood loss; for tibial fractures, 300 to 500 mL; for

Figure 7-14. A Satinsky clamp is used to clamp the pulmonary hilum to prevent further bronchovenous air embolism. B Sequential sites of aspiration include the left ventricle, the aortic root, and the right coronary artery.

Figure 7-15. If a weapon is still in place, it should be removed in the operating room because it could be tamponading a lacerated blood vessel.
femur fractures, 800 to 1000 mL; and for pelvic fractures >2000 mL. Although no single injury can account for the patient’s hemodynamic instability, the sum of the injuries may result in life-threatening blood loss. The diagnostic measures advocated earlier are those that can be easily performed in the trauma bay. Transport of a hypotensive patient out of the ED for CT scanning is hazardous; monitoring is compromised, and the environment is suboptimal for dealing with acute problems. Fast track CT scanning should be used in all patients manifesting evidence of shock. The surgeon must accompany the patient and be prepared to abort the CT scan with diversion to the OR. This dilemma is becoming less common in many trauma centers where CT scanning is available in the ED.

The concept of hypotensive resuscitation remains controversial, and it is primarily relevant for patients with penetrating vascular injuries. Experimental work suggests that an endogenous sealing clot of an injured artery may be disrupted at a SBP of >90 mmHg; thus, many believe that this should be the preoperative blood pressure target for patients with potential noncompressible arterial injuries. On the other hand, optimal management of traumatic brain injury (TBI) includes maintaining the SBP >100 mmHg and thus, hypotensive resuscitation is not appropriate for most blunt trauma patients.

Secondary Survey

Once the immediate threats to life have been addressed, a thorough history is obtained, and the patient is examined in a systematic fashion. The patient and surrogates should be queried to obtain an AMPLE history (Allergies, Medications, Past illnesses or Pregnancy, Last meal, and Events related to the injury). The physical examination should be literally head to toe, with special attention to the patient’s back, axillae, and perineum, because injuries here are easily overlooked. All seriously injured patients should undergo digital rectal examination to evaluate for sphincter tone, presence of blood, rectal perforation, or a high-riding prostate; this is particularly critical in patients with suspected spinal cord injury, pelvic fracture, or transpelvic gunshot wounds. Vaginal examination with a speculum should be performed in women with pelvic fractures to exclude an open fracture. Specific injuries, their associated signs and symptoms, diagnostic options, and treatments are discussed in detail later in this chapter.

Adjuncts to the physical examination include vital sign and ECG monitoring, nasogastric tube placement, Foley catheter placement, radiographs, hemoglobin, base deficit measurements, urinalysis, and repeat FAST exam. A nasogastric tube should be inserted in all intubated patients to decrease the risk of gastric aspiration, but it may not be necessary in the awake patient. Nasogastric tube placement in patients with complex mid-facial fractures is contraindicated; rather, a tube should be placed orally if required. Nasogastric tube evaluation of stomach contents for blood may suggest occult gastroduodenal injury, or the errant path of the nasogastric tube on a chest film may indicate a left diaphragm injury. A Foley catheter should be inserted in patients unable to void to decompress the bladder, obtain a urine specimen, and monitor urine output. Gross hematuria demands evaluation of the genitourinary system for injury. Foley catheter placement may be deferred until urologic evaluation in patients with signs of urethral injury: blood at the meatus, perineal or scrotal hematomas, or a high-riding prostate. Although policies vary at individual institutions, most agree that patients in extremis should undergo one attempt at Foley catheter placement; if the catheter does not pass easily, a suprapubic cystostomy should be considered.

Selective radiography and laboratory tests are done early in the evaluation after the primary survey. For patients with severe blunt trauma, chest and pelvic radiographs should be obtained. Historically, a lateral cervical spine radiograph was also obtained, hence the reference to the big three films, but currently patients preferentially undergo CT scanning of the spine rather than plain film radiography. For patients with truncal gunshot wounds, anteroposterior and at times lateral radiographs of the chest and abdomen are warranted. It is important to mark the entrance and exit sites of penetrating wounds with ECG pads, metallic clips, or staples so that the trajectory of the missile can be estimated. Limited one-shot extremity radiographs may also be appropriate to assist in application of a splint. In critically injured patients, blood samples for a routine trauma panel (type and crossmatch, complete blood count, blood chemistries, coagulation studies, and arterial blood gas analysis) should be sent to the laboratory. For less severely injured patients, only a complete blood count and urinalysis may be required. Because older patients may present in subclinical shock, even with minor injuries, routine analysis of an arterial blood gas in patients over the age of 55 should be considered. Repeat FAST is mandatory if there are any signs of abdominal injury or unexplained blood loss.

Many trauma patients cannot provide specific information about the mechanism of their injury. Emergency medical service personnel and police are trained to evaluate an injury scene and should be questioned while they are present in the ED. For automobile collisions, the speed of the vehicles involved, angle of impact, location of the patient within the vehicle, use of restraints, airbag deployment, condition of the steering wheel and windshield, amount of intrusion, ejection of the patient from the vehicle, and fate of other passengers should be ascertained. For other injury mechanisms, critical information includes such things as height of a fall, surface impact, helmet use, and weight of an object by which the patient was crushed. In patients sustaining gunshot wounds, bullet characteristics, distance, and presumed path of the bullet are important, if known. For patients with stab wounds, the length and type of object is helpful. Finally, some patients experience a combination of blunt and penetrating trauma. Do not assume that someone who was stabbed was not also assaulted; the patient may have a multitude of injuries and cannot be presumed to have only injuries associated with the more obvious penetrating wound. In short, these details of information are critical to the clinician to determine overall mechanism of injury and anticipate associated injury patterns.

Mechanisms and Patterns of Injury

In general, more energy is transferred over a wider area during blunt trauma than from a penetrating wound. As a result, blunt trauma is associated with multiple widely distributed injuries, whereas in penetrating wounds the damage is localized to the path of the bullet or knife. In blunt trauma, organs that cannot yield to impact by elastic deformation are most likely to be injured, namely, the solid organs (liver, spleen, and kidneys). For penetrating trauma, organs with the largest surface area are most prone to injury (small bowel, liver, and colon). Additionally, because bullets and knives usually follow straight lines, adjacent structures are commonly injured.

Patients who have sustained blunt trauma separate them into categories according to their risk for multiple injuries: those
sustaining high energy transfer injuries and those sustaining low energy transfer injuries. Injuries involving high energy transfer include auto-pedestrian accidents, motor vehicle collisions in which the car’s change of velocity (ΔV) exceeds 20 mph or in which the patient has been ejected, motorcycle collisions, and falls from heights >20 ft. In fact, for motor vehicle collisions the variables strongly associated with life-threatening injuries, and hence reflective of the magnitude of the mechanism, are death of another occupant in the vehicle, extrication time of >20 minutes, ΔV >20 mph, lack of restraint use, and lateral impact. Low-energy trauma, such as being struck with a club or falling from a bicycle, usually does not result in widely distributed injuries. However, potentially lethal injuries of internal organs can occur because the net energy transfer to any given location may be substantial.

In blunt trauma, particular constellations of injury or injury patterns are associated with specific injury mechanisms. For example, when an unrestrained driver sustains a frontal impact, the head strikes the windshield, the chest and upper abdomen hit the steering column, and the legs or knees contact the dashboard. The resultant injuries can include facial fractures, cervical spine fractures, injury of the descending thoracic aorta, myocardial contusion, injury to the spleen and liver, and fractures of the pelvis and lower extremities. When such patients are evaluated, the discovery of one of these injuries should prompt a search for the others. Collisions with side impact also carry the risk of cervical spine and thoracic trauma, diaphragm rupture, and crush injuries of the pelvic ring, but solid organ injury usually is limited to either the liver or spleen based on the direction of impact. However, patients ejected from a vehicle or thrown a significant distance from a motorcycle have the risk of any injury pattern.

Penetrating injuries are classified according to the wounding agent (i.e., stab wound, gunshot wound, or shotgun wound). Gunshot wounds are subdivided further into high- and low-velocity injuries because the speed of the bullet is much more important than its weight in determining potential kinetic energy transfer. High-velocity gunshot wounds (bullet speed >2000 ft/s) are infrequent in the civilian setting. Shotgun injuries are divided into close-range (<20 feet) and long-range wounds. Close-range shotgun wounds are tantamount to high-velocity wounds because the entire energy of the load is delivered to a small area, often with devastating results. In contrast, long-range shotgun blasts result in a diffuse pellet pattern in which many pellets miss the victim, and those that do strike are dispersed and are of comparatively low energy.

Regional Assessment and Special Diagnostic Tests

Based on mechanism, location of injuries identified on physical examination, screening radiographs, and the patient’s overall condition, additional diagnostic studies often are indicated. However, the seriously injured patient is in constant jeopardy when undergoing special diagnostic testing; therefore, the surgeon must be in attendance and must be prepared to alter plans as circumstances demand. Hemodynamic, respiratory, and mental status will determine the most appropriate course of action. With these issues in mind, additional diagnostic tests are discussed on an anatomic basis.

Head. Evaluation of the head includes examination for injuries to the scalp, eyes, ears, nose, mouth, facial bones, and intracranial structures. Palpation of the head is done to identify scalp lacerations, which should be evaluated for depth, and presence of associated depressed or open skull fractures. The eye examination includes not only pupillary size and reactivity, but also examination for visual acuity and for hemorrhage within the globe. Ocular entrapment, caused by orbital fractures with impingement of the ocular muscles, is evident when the patient cannot move his or her eyes through an entire range of motion. It is important to perform the eye examination early because significant orbital swelling may prevent later evaluation. A lateral canthotomy may be needed to relieve periorbital pressure. The tympanic membrane is examined to identify hematotympanum, otorrhea, or rupture, which may signal an underlying head injury. Otorrhea, rhinorrhea, raccoon eyes, and Battle’s sign (ecchymosis behind the ear) suggest a basilar skull fracture. Although such fractures may not require treatment, there is an association with blunt cerebrovascular injuries, cranial nerve injuries, and risk of meningitis.

Anterior facial structures should be examined to rule out fractures. This entails palpating for bony step-off of the facial bones and instability of the midface (by grasping the upper palate and seeing if this moves separately from the patient’s head). A good question to ask awake patients is whether their bite feels normal to them; abnormal dental closure suggests malalignment of facial bones and the possibility for a mandible or maxillary fracture. Nasal fractures, which may be evident on direct inspection or palpation, typically bleed vigorously. This may result in the patient having airway compromise due to blood running down the posterior pharynx, or there may be vomiting provoked by swallowed blood. Nasal packing or balloon tamponade may be necessary to control bleeding. Examination of the oral cavity includes inspection for open fractures, loose or fractured teeth, and sublingual hematomas.

All patients with a significant closed head injury (GCS score <14) should undergo CT scanning of the head. Additionally, elderly patients or those patients on antiplatelet agents or anticoagulation should be imaged despite a GCS of 15. For penetrating injuries, plain skull films may be helpful in the trauma bay to determine the trajectory of the bullet. The presence of lateralizing findings (e.g., a unilateral dilated pupil unreactive to light, asymmetric movement of the extremities either spontaneously or in response to noxious stimuli, or unilateral Babinski’s reflex) suggests an intracranial mass lesion or major structural damage.

Such intracranial lesions following trauma include hematomas, contusions, hemorrhage into ventricular and subarachnoid spaces, and diffuse axonal injury (DAI). Epidural hematomas occur when blood accumulates between the skull and dura, and are caused by disruption of the middle meningeal artery or other small arteries in that potential space, typically after a skull fracture (Fig. 7-16). Subdural hematomas occur between the dura and cortex and are caused by venous disruption or laceration of the parenchyma of the brain. Due to associated parenchymal injury, subdural hematomas have a much worse prognosis than epidural collections. Hemorrhage into the subarachnoid space may cause vasospasm and further reduce cerebral blood flow. Intraparenchymal hematomas and contusions can occur anywhere within the brain. DAI results from high-speed deceleration injury and represents direct axonal damage from shear effects. CT scan may demonstrate blurring of the gray and white matter interface and multiple small punctate hemorrhages, but magnetic resonance imaging is a more accurate test. Although prognosis for these injuries is extremely variable, early evidence of DAI is associated with a poor outcome. Stroke syndromes should prompt a search for carotid or vertebral artery injury using multislice CTA (Fig. 7-17).
Significant intracranial penetrating injuries usually are produced by bullets from handguns, but an array of other weapons or instruments can injure the cerebrum via the orbit or through the thinner temporal region of the skull. Although the diagnosis usually is obvious, in some instances wounds in the auditory canal, mouth, and nose can be elusive. Prognosis is variable, but virtually all supratentorial wounds that injure both hemispheres are fatal.

**Neck.** All blunt trauma patients should be assumed to have cervical spine injuries until proven otherwise. During the physical examination, one must maintain cervical spine precautions and in-line stabilization. Due to the devastating consequences of quadriplegia, a diligent evaluation for occult cervical spine injuries is mandatory. In the awake patient, the presence of posterior midline pain or tenderness should provoke a thorough radiologic evaluation. Additionally, intubated patients, patients with distracting injuries, significant mechanism, or another identified spine fracture should undergo CT imaging. A ligamentous injury may not be visible with standard imaging techniques. Flexion and extension views or magnetic resonance imaging (MRI) are obtained to further evaluate patients at risk or those with persistent symptoms.

Spinal cord injuries can vary in severity. Complete injuries cause either quadriplegia or paraplegia, depending on the level of injury. These patients have a complete loss of motor function and sensation two or more levels below the bony injury. Patients with high spinal cord disruption are at risk for shock due to physiologic disruption of sympathetic fibers. Significant neurologic recovery is rare. However, there are several partial or incomplete spinal cord injury syndromes where the prognosis is better. Central cord syndrome typically occurs in older persons who experience hyperextension injuries. Motor function, pain, and temperature sensation are preserved in the lower extremities but diminished in the upper extremities. Some functional

---

**Figure 7-16.** Epidural hematomas (A) have a distinctive convex shape on computed tomographic scan, whereas subdural hematomas (B) are concave along the surface of the brain.

**Figure 7-17.** A. A right middle cerebral infarct noted on a computed tomographic scan of the head. Such a finding should prompt imaging to rule out an associated extracranial cerebrovascular injury. B. An internal carotid artery pseudoaneurysm documented by angiography.
recovery usually occurs, but is often not a return to normal. Anterior cord syndrome is characterized by diminished motor function, pain, and temperature sensation below the level of the injury, but position sensing, vibratory sensation, and crude touch are maintained. Prognosis for recovery is poor. Brown-Séquard syndrome is usually the result of a penetrating injury in which one-half of the spinal cord is transected. This lesion is characterized by the ipsilateral loss of motor function, proprioception, and vibratory sensation, whereas pain and temperature sensation are lost on the contralateral side.

During the primary survey, identification of injuries to the neck with exsanguination, expanding hematomas, airway obstruction, or aerodigestive injuries is a priority. A more subtle injury that may not be identified is a fracture of the larynx due to blunt trauma. Signs and symptoms include hoarseness, subcutaneous emphysema (Fig. 7-18), or a palpable fracture. Penetrating injuries of the anterior neck that violate the platysma are potentially life-threatening because of the density of critical structures in this region. Although operative exploration is appropriate for overt injuries, selective nonoperative management has been proven safe (Fig. 7-19).

Indications for immediate operative intervention for penetrating cervical injury include hemodynamic instability, significant external hemorrhage, or evidence of aerodigestive injury. The management algorithm for hemodynamically stable patients is based on the presenting symptoms and anatomic location of injury, with the neck being divided into three distinct zones (Fig. 7-20). Zone I is inferior to the clavicles encompassing the thoracic outlet structures, zone II is between the thoracic outlet and the angle of the mandible, and zone III is above the angle of the mandible. Due to technical difficulties of injury exposure and varying operative approaches, a precise preoperative diagnosis is desirable for symptomatic zone I and III injuries. Therefore, these patients should ideally undergo diagnostic imaging before operation if they remain hemodynamically stable. Management of patients is further divided into those who are symptomatic and those who are not (see Fig 7-19). Specific symptoms or signs that should be identified include dysphagia, hoarseness, hematoma, venous bleeding, minor hemoptysis, and

---

**Figure 7-18.** A laryngeal fracture results in air tracking around the trachea along the prevertebral space (arrows).

**Figure 7-19.** Algorithm for the management of penetrating neck injuries. CTA = computed tomographic angiography; GSW = gunshot wound.
subcutaneous emphysema. Symptomatic patients, without overt injuries, should undergo CTA with further evaluation or operation based upon the imaging findings. Overall, less than 15% of penetrating cervical trauma requires neck exploration. Asymptomatic patients are typically observed for 6 to 12 hours. The one caveat is asymptomatic patients with a transcervical gunshot wound; these patients should undergo CTA to determine the trajectory of the bullet; further studies are performed based on proximity to major structures. Such additional imaging includes angiography, soluble contrast esophagram followed by barium esophagogram, esophagoscopy, or bronchoscopy. Angiographic diagnosis, particularly of zone III injuries, can then be managed by selective angioembolization.

Chest. Blunt trauma to the chest may involve the chest wall, thoracic spine, heart, lungs, thoracic aorta and great vessels, and rarely the esophagus. Most of these injuries can be evaluated by physical examination and chest radiography, with supplemental CT scanning to exclude vascular injury. Any patient who undergoes an intervention in the ED—endotracheal intubation, central line placement, tube thoracostomy—needs a repeat chest radiograph to document the adequacy of the procedure. This is particularly true in patients undergoing tube thoracostomy for a pneumothorax or hemothorax. Patients with persistent pneumothorax, large air leaks after tube thoracostomy, or difficulty ventilating should undergo fiber-optic bronchoscopy to exclude a tracheobronchial injury or presence of a foreign body. Patients with hemothorax must have a chest radiograph documenting complete evacuation of the chest; a persistent hemothorax that is not drained by two chest tubes is termed a caked hemothorax and mandates immediate thoracotomy.

Figure 7-20. For the purpose of evaluating penetrating injuries, the neck is divided into three zones. Zone I is to the level of the clavicular heads and is also known as the thoracic outlet. Zone II is located between the clavicles and the angle of the mandible. Zone III is above the angle of the mandible.

Occult thoracic vascular injury must be diligently sought due to the high mortality of a missed lesion. Widening of the mediastinum on initial anteroposterior chest radiograph, caused by a hematoma around an injured vessel that is contained by the mediastinal pleura, suggests an injury of the great vessels. The mediastinal abnormality may suggest the location of the arterial injury (i.e., left-sided hematomas are associated with descending blunt aortic injuries [BAI], whereas right-sided hematomas are seen with innominate injuries) (Fig. 7-22). Posterior rib fractures, sternal fractures with laceration of small vessels, and mediastinal venous bleeding also can produce similar hematomas. Other chest radiographic findings suggestive of a BAI are summarized in Table 7-5 (Fig. 7-23). However, at least 7% of patients with a descending BAI have a normal chest radiograph. Therefore, screening CTA is performed based on the mechanism of injury: high-energy deceleration motor vehicle collision with frontal or lateral impact (>30 mph frontal impact and >23 mph lateral impact), motor vehicle collision with ejection, falls of >25 ft, or direct impact (horse kick to chest, snowmobile, or ski collision with tree). In >95% of patients who survive to reach the ED, the BAI occurs just distal to the left subclavian artery, where it is tethered by the ligamentum arteriosum (Fig. 7-24). In 2% to 5% of patients the injury occurs in the ascending aorta, in the transverse arch, or at the diaphragm. Reconstructions with multislice CTA obviate the need for invasive arteriography.

For penetrating thoracic trauma, physical examination, plain posteroanterior and lateral chest radiographs with metallic markings of wounds, and pericardial ultrasound will identify the majority of injuries. Injuries of the esophagus and trachea are the exceptions. Bronchoscopy should be performed to evaluate the trachea in patients with a persistent air leak from the chest tube or mediastinal air. Patients at risk for an esophageal injury should undergo bedside esophagoscopy or soluble contrast esophagography followed by barium examination to look for extravasation of contrast. As with neck injuries,
hemodynamically stable patients with transmediastinal gunshot wounds should undergo CT scanning to determine the path of the bullet; trajectory in proximity to vascular or visceral structures dictates the need for angiography, endoscopy, or operative plan. If there is a suspicion of a subclavian artery injury, brachial-brachial indices should be measured, but >60% of patients with an injury may not have a pulse deficit. Therefore, CTA should be performed based on injury proximity to intrathoracic vasculature. Finally, with GSWs identified on the chest, penetrating trauma should not be presumed to be isolated to the thorax. Injury to contiguous body cavities (i.e., the abdomen and neck) must be excluded; plain radiographs are a rapid, effective screening modality to identify retained bullet fragments.

**Abdomen.** The abdomen is a diagnostic black box. Fortunately, with few exceptions, it is not necessary to determine in the ED which intra-abdominal organs are injured, only whether an exploratory laparotomy is necessary. However, physical examination of the abdomen can be unreliable in making this determination, and drugs, alcohol, and head and spinal cord injuries can complicate the clinical evaluation. The presence of abdominal rigidity and hemodynamic compromise is an undisputed indication

for prompt surgical exploration. For the remainder of patients, a variety of diagnostic adjuncts are used to identify abdominal injury.

The diagnostic approach differs for penetrating trauma and blunt abdominal trauma. As a rule, laparotomy is warranted for gunshot or shotgun wounds that penetrate the peritoneal cavity because most have significant internal injuries. The standard has been that anterior truncal gunshot wounds between the fourth intercostal space and the pubic symphysis whose trajectory as determined by radiograph or wound location indicates peritoneal penetration should undergo laparotomy (Fig. 7-25). However, there has been increased use of CT scanning to facilitate nonoperative management of abdominal GSWs. The exception is penetrating trauma isolated to the right upper quadrant; in hemodynamically stable patients with trajectory confined to the liver by CT scan, nonoperative observation may be reasonable. In obese patients, if the gunshot wound is thought to be tangential through the subcutaneous tissues, CT scan can delineate the track and exclude peritoneal violation. Laparoscopy is another option to assess peritoneal penetration for tangential wounds it should not be done in unstable patients. In the scenario of tangential high energy GSWs, however, it is possible to sustain a transmitted intraperitoneal hollow visceral injury due to a blast insult. Gunshot wounds to the back or flank are more difficult to evaluate because of the retroperitoneal location of the injured abdominal organs. Triple-contrast CT scan can delineate the trajectory of the bullet and identify peritoneal violation or retroperitoneal entry, and associated injuries.

In contrast to gunshot wounds, stab wounds that penetrate the peritoneal cavity are less likely to injure intra-abdominal organs. Anterior abdominal stab wounds (from costal margin to inguinal ligament and bilateral midaxillary lines) should be explored under local anesthesia in the ED to determine if the fascia has been violated. Injuries that do not penetrate the peritoneal cavity do not require further evaluation, and the patient...
may be discharged from the ED. Patients with fascial penetration must be further evaluated for intra-abdominal injury because there is up to a 50% chance of requiring laparotomy. Debate remains over whether the optimal diagnostic approach is serial examination, diagnostic peritoneal lavage (DPL), or CT scanning. The most recent evidence supports serial examination and laboratory evaluation. Patients with stab wounds to the right upper quadrant can undergo CT scanning to determine trajectory and confinement to the liver for potential nonoperative care. Those with stab wounds to the flank and back should undergo contrasted CT to assess for the potential risk of retroperitoneal injuries of the colon, duodenum, and urinary tract.

Penetrating thoracoabdominal wounds may cause occult injury to the diaphragm. Patients with gunshot or stab wounds to the left lower chest should be evaluated with diagnostic laparoscopy or DPL to exclude diaphragmatic injury. In general, penetrating right diaphragm injury is ignored unless there is a major underlying liver injury with a risk of bilio-pleural fistula. Diagnostic laparoscopy may be preferred in patients with a positive chest radiograph (hemothorax or pneumothorax) or in those who would not tolerate a DPL. For patients undergoing DPL evaluation, laboratory value cutoffs to rule out diaphragm injury are different from traditional values formerly used for abdominal stab wounds (Table 7-6). An RBC count of >10,000/μL is considered a positive finding and an indication for abdominal evaluation; patients with a DPL RBC count between 1000/μL and 10,000/μL should undergo laparoscopy or thoracoscopy.

Blunt abdominal trauma is now evaluated initially by FAST examination, and this has supplanted DPL (Fig. 7-26). FAST is not 100% sensitive, however, so diagnostic peritoneal aspiration is warranted in hemodynamically unstable patients without a defined source of blood loss to rule out abdominal hemorrhage. FAST is used to identify free intraperitoneal fluid (Fig. 7-27) in Morrison’s pouch, the left upper quadrant, and the pelvis. Although this method is sensitive for detecting

intrapertioneal fluid of >250 mL, it does not reliably determine the source of hemorrhage nor grade solid organ injuries.\textsuperscript{51} Patients with fluid on FAST examination, considered a “positive FAST,” who do not have immediate indications for laparotomy (hemodynamically stable, no evidence of peritonitis) undergo CT scanning to quantify their injuries. Injury grading using the American Association for the Surgery of Trauma (AAST) grading scale (Table 7-7) is an important component of nonoperative management of solid organ injuries. Additional findings that should be noted on CT scan in patients with solid organ injury include contrast extravasation (i.e., a “blush”), the amount of intra-abdominal hemorrhage, and presence of pseudoaneurysms (Fig. 7-28). CT also is indicated for hemodynamically stable patients for whom the physical examination is unreliable. Despite the increasing diagnostic accuracy of multidetector CT scanners, identification of intestinal injuries remains a limitation. Bowel injury is suggested by findings of thickened bowel wall, “streaking” in the mesentery, free fluid without associated solid organ injury, or free intrapertioneal air.\textsuperscript{52,53} Patients with free intra-abdominal fluid without solid organ injury are closely monitored for evolving signs of peritonitis; if patients have a significant closed head injury or cannot be serially examined, DPL should be performed to exclude bowel injury. If DPL is pursued, an intraumbilical approach is used (Fig. 7-29). After placement of the catheter, a 10-mL syringe is connected and the abdominal contents aspirated (termed a diagnostic peritoneal aspiration). The aspirate is considered positive if >10 mL of blood is aspirated. If <10 mL is withdrawn, a liter of normal saline is instilled. The effluent is withdrawn via siphoning and sent to the laboratory for RBC count, white blood cell (WBC) count, and determination of amylase, bilirubin, and alkaline phosphatase levels. Values representing positive findings are summarized in Table 7-6.

**Pelvis.** Blunt injury to the pelvis may produce mechanically unstable fractures with major hemorrhage (Fig. 7-30). Plain radiographs will reveal gross abnormalities, but CT scanning is necessary to determine the precise geometry. Sharp spicules of bone can lacerate the bladder, rectum, or vagina. Alternatively, bladder rupture may result from a direct blow to the torso if the bladder is full. CT cystography is performed if the urinalysis demonstrates RBCs. Urethral injuries are suspected if examination reveals blood at the meatus, scrotal or perineal hematomas, or a high-riding prostate on rectal examination. Urethrograms should be obtained for stable patients before placing a Foley catheter to avoid false passage and subsequent stricture. Major vascular injuries of the external iliacs causing bleeding are uncommon in blunt pelvic trauma; however, thrombosis of either the arteries or veins in the iliofemoral system may occur, and CTA should be performed for evaluation if there is a pulse differential. Life-threatening hemorrhage can be associated with pelvic fractures and may initially
Figure 7-29. Diagnostic peritoneal lavage is performed through an infraumbilical incision unless the patient has a pelvic fracture or is pregnant. A. The linea alba is sharply incised, and the catheter is directed into the pelvis. B. The abdominal contents should initially be aspirated using a 10-mL syringe.

preclude definitive imaging. Treatment algorithms for patients with complex pelvic fractures and hemodynamic instability are presented later in the chapter.

**Extremities.** Blunt or penetrating trauma to the extremities requires an evaluation for fractures, ligamentous disruption, and neurovascular injury. Plain radiographs are used to evaluate fractures, whereas ligamentous injuries, particularly those of the knee and shoulder, can be imaged with magnetic resonance imaging. Physical examination identifies the majority of arterial injuries, and findings are classified as either hard signs or soft signs of vascular injury (Table 7-8). In general, hard signs constitute indications for operative exploration, whereas soft signs are indications for further testing or observation. Bony fractures or knee dislocations should be realigned before definitive vascular examination. In management of vascular trauma, controversy exists regarding the treatment of patients with soft signs of injury, particularly those with injuries in proximity to major vessels. It is known that some of these patients will have arterial injuries that require repair. The most common approach has been to measure SBP using Doppler ultrasonography and compare the value for the injured side with that for the uninjured side, termed the A-A index. If the pressures are within 10% of each other, a significant injury is unlikely, and no further evaluation is performed. If the difference is >10%, CTA or arteriography is indicated. Others argue that there are occult injuries, such as pseudoaneurysms or injuries of the profunda femoris or peroneal arteries, which may not be detected with this technique. If hemorrhage occurs from these injuries, compartment syndrome and limb loss may occur. Although busy trauma centers continue to debate this issue, the surgeon who is obliged to treat the occasional injured patient may be better served by performing CTA in selected patients with soft signs. In patients with hard signs of vascular injury, on-table angiography may be useful to localize the arterial injury and thus, limit tissue dissection. For example, a patient with an absent popliteal pulse and femoral shaft fracture due to a bullet that entered the lateral hip and exited below the medial knee could have injured either the femoral or popliteal artery anywhere along its course (Fig. 7-31).

**GENERAL PRINCIPLES OF MANAGEMENT**

Over the past 25 years there has been a remarkable change in management practices and operative approach for the injured patient. With the advent of CT scanning, nonoperative management of solid organ injuries has replaced routine operative exploration. Those patients who do require operation may be treated with less radical resection techniques, such as splenorrhaphy or partial nephrectomy. Colonic injuries, previously mandating colostomy, are now repaired primarily in virtually all cases. Additionally, the type of anastomosis has shifted from a double-layer closure to a continuous running single-layer closure; this method is technically equivalent to and faster than the interrupted multilayer techniques. Adoption of damage control surgical techniques in physiologically deranged patients has resulted in limited initial operative time, with definitive injury repair delayed until after resuscitation in the surgical intensive care unit (SICU) with physiologic restoration. Abdominal drains, once considered mandatory for parenchymal injuries and some anastomoses, have disappeared; fluid collections are managed by percutaneous techniques. Newer endovascular
techniques such as stenting of arterial injuries and angioembolization are routine adjuncts. Blunt cerebrovascular injuries have been recognized as a significant, preventable source of neurologic morbidity and mortality. The use of preperitoneal pelvic packing for unstable pelvic fractures as well as early fracture immobilization with external fixators are paradigm shifts in management. Recently resuscitative endovascular balloon occlusion (REBOA) has been added to the armamentarium for life-threatening pelvic fracture bleeding\textsuperscript{57,58} (Fig. 7-32). Finally, the institution of massive transfusion protocols balances the benefit of blood component therapy against immunologic risk. Viscoelastic hemostatic assays (TEG and ROTEM) have been shown to be superior to traditional laboratory tests and have been central to the evolving concept of goal-directed hemoostasis.\textsuperscript{59} These many conceptual changes have significantly improved survival of critically injured patients; they have been promoted and critically reviewed by academic trauma centers via forums such as the American College of Surgeons Committee on Trauma, the American Association for the Surgery of Trauma, the International Association of Trauma Surgery and Intensive Care, the Pan-American Trauma Congress, and other surgical organizations.

**Transfusion Practices**

Injured patients with life-threatening hemorrhage develop acute coagulopathy of trauma (ACOT).\textsuperscript{60,61} The mechanism for inadequate clot formation remains uncertain, but it is believed to involve activation of protein C, which impairs Va and VIIa, glycocalyx breakdown, which releases heparin sulfate, immune

activation with the releases of DAMPs, DNA, histone, polyphosphate, and PMN elastase, and complement activation. Fibrinolysis is an important component of the ACOT; hyperfibrinolysis and fibrinolysis shutdown are both associated with increased mortality. Fresh whole blood, arguably the optimal replacement, has not been available in the United States since the early 1980s. Rather, its component parts, packed red blood cells (PRBCs), fresh frozen plasma, platelets, and cryoprecipitate, are administered. Specific transfusion triggers for individual blood components remain debated. Although current critical care guidelines indicate that PRBC transfusion should occur once the patient’s hemoglobin level is <7 g/dL, in the acute phase of resuscitation a hemoglobin of 10 g/dL is suggested to facilitate hemostasis via platelet margination. The traditional thresholds for blood component replacement in the patient manifesting a coagulopathy have been INR >1.5, PTT >1.5 normal, platelet count >50,000/μL, and fibrinogen >100 mg/dL. However, these guidelines have been replaced by TEG and ROTEM criteria in many trauma centers. Such guidelines are designed to limit the transfusion of immunologically active blood components and decrease the risk of transfusion-associated lung injury and secondary multiple organ failure.

In the critically injured patient requiring large amounts of blood component therapy, a massive transfusion protocol should be followed (Fig. 7-33). This approach calls for administration of various components in a specific ratio during transfusion to achieve restoration of blood volume to reverse shock and correct coagulopathy. Although the optimal ratio is unknown, current evidence suggests a presumptive 1:2 red cell:plasma ratio in patients at risk for massive transfusion (10 units of PRBCs in 6 hours). Because complete typing and cross-matching takes up to 45 minutes, patients requiring emergent transfusions are given type O-negative RBCs. Similarly, without time for blood typing, AB plasma is the universal donor, although A plasma appears to be a safe option. Blood typing, and to a lesser extent cross-matching, is essential to avoid life-threatening intravascular hemolytic transfusion reactions. Trauma centers and their associated blood banks must have the capability of transfusing tremendous quantities of blood components because it is not unusual to have >50 component units transfused during one procedure and have the patient survive. Massive transfusion protocols, established preemptively, permit coordination of the activities of surgeons, anesthesiologists, and blood bankers to facilitate transfusion of the appropriate blood products.

Postinjury coagulopathy due to shock is aggravated by core hypothermia and metabolic acidosis, termed the bloody vicious cycle, and now commonly referred to as the lethal triad. The pathophysiology is multifactorial and includes inhibition of temperature-dependent enzyme-activated coagulation cascades, platelet dysfunction, endothelial abnormalities, and fibrinolytic activity. Such coagulopathy may be insidious, so the surgeon must be cognizant of subtle signs such as excessive bleeding from the cut edges of skin. Point-of-care viscoelastic assays (TEG and ROTEM), which provide a comprehensive assessment of clot capacity and fibrinolysis, can provide useful information within 15 minutes. In contrast, traditional laboratory tests of coagulation capability (i.e., INR, PTT, fibrinogen levels, and platelet count) requires at least 45 minutes. Using damage control techniques to limit operative time and provide physiologic restoration in the SICU can be lifesaving (see “Damage Control Surgery”).
Prophylactic Measures

All injured patients undergoing an operation should receive preoperative antibiotics. The type of antibiotic is determined by the anticipated source of contamination in the abdomen or other operative region; additional doses should be administered during the procedure based on blood loss and the half-life of the antibiotic. Extended postoperative antibiotic therapy is administered only for contaminated open fractures. Tetanus prophylaxis is administered to all patients according to published guidelines.

Trauma patients are at risk for venous thromboembolism and its associated morbidity and mortality. In fact, pulmonary embolus can occur much earlier in the patient’s hospital course than previously believed. Patients at higher risk for venous thromboembolism are those with multiple fractures of the pelvis and lower extremities, those with TBI or spinal cord injury, and those requiring ligation of large veins in the abdomen and lower extremities. Morbidly obese patients and those over 55 years of age are at additional risk. Administration of low molecular weight heparin (LMWH) is initiated as soon as possible.
as bleeding has been controlled and there is stable intracranial pathology. In high-risk patients, antiplatelet therapy should be added.\textsuperscript{74} Removable inferior vena caval filters should be considered if there are prolonged contraindications to administration of LMWH. Additionally, pulsatile compression stockings (also termed \textit{sequential compression devices}) are used routinely unless there is a fractured lower extremity or vascular injury.

A final prophylactic measure that is usually not considered is thermal protection. Hemorrhagic shock impairs perfusion and metabolic activity throughout the body, with resultant decrease in heat production and body temperature. Removing the patient’s clothes causes a second thermal insult, and infusion of cold PRBCs or room temperature crystalloid exacerbates the problem. As a result, injured patients can become hypothermic, with temperatures below 34°C (93.2°F) upon arrival in the OR. Hypothermia aggravates coagulopathy and provokes myocardial irritability. Therefore, prevention must begin in the ED by maintaining a comfortable ambient temperature, covering patients with warm blankets, and administering warmed IV fluids and blood products. Additionally, in the OR a Bair Hugger\textsuperscript{®} warmer (the upper body or lower body blanket) and heated inhalation via the ventilatory circuit is instituted. For cases of severe hypothermia (temperature <30°C [86°F]), arteriovenous rewarming should be considered.

**Operative Approaches and Exposure**

**Cervical Exposure.** Operative exposure for midline structures of the neck (e.g., trachea, thyroid, bilateral carotid sheaths) is obtained through a collar incision; this is typically performed two finger breadths above the sternal notch, but can be varied based on the level of anticipated injury. After subplatysmal flap elevation, the strap muscles are divided in the midline to gain access to the central neck compartment. More superior and lateral structures are accessed by extending the collar incision upward along the sternocleidomastoid muscle; this may be done bilaterally if necessary. For unilateral injuries, neck exploration is done through an incision extending from the mastoid down to the clavicle, along the anterior border of the sternocleidomastoid muscle (Fig. 7-34).

---

**Figure 7-34.** A. Unilateral neck exploration is performed through an incision along the anterior border of the sternocleidomastoid muscle; exposure of the carotid artery requires early division of the facial vein. B. The distal internal carotid artery is exposed by dividing the ansa cervicalis, which permits mobilization of the hypoglossal nerve. C. Further exposure is facilitated by resection of the posterior belly of the digastric muscle.
BASIC CONSIDERATIONS

PART I

**Figure 7-36.** A. A “clamshell” thoracotomy provides exposure to bilateral thoracic cavities. B. Sternal transection requires individual ligation of both the proximal and distal internal mammary arteries on the undersurface of the sternum.

The carotid sheath, containing the carotid artery, jugular vein, and vagus nerve, is opened widely to examine these structures. The facial vein, which marks the carotid bifurcation, is usually ligated for exposure of the internal carotid artery and the hypoglossal nerve is the next structure encountered.

Exposure of the distal carotid artery in zone III is difficult (see Fig. 7-34). The first step is division of the ansa cervicalis to facilitate mobilization of the hypoglossal nerve. Next, the posterior portion of the digastric muscle, which overlies the internal carotid, is transected. The glosopharyngeal and vagus nerves are also mobilized and retracted as necessary. If accessible, the styloid process and attached muscles are removed. In desperate situations, anterior displacement of the mandible (subluxation) may be helpful or the vertical ramus of the mandible may be divided. However, the latter maneuver often entails resection of the parotid gland, and the facial nerve is at risk of injury.

**Thoracic Incisions.** An anterolateral thoracotomy, with the patient placed supine, is the most versatile incision for emergent thoracic exploration. The location of the incision is in the fifth interspace, in the inframammary line (Fig. 7-35). If access is needed to both pleural cavities, the original incision can be extended across the sternum with a Lebsche knife, into a “clamshell” thoracotomy (Fig. 7-36). If the sternum is divided, the internal mammary arteries should be ligated to prevent blood loss. The heart, lungs, descending aorta, pulmonary hilum, and esophagus are accessible with this approach. For control of the great vessels, the superior portion of the sternum may be divided vertically with extension of the incision into the neck considered. A method advocated for access to the proximal left subclavian artery is through a fourth interspace anterolateral thoracotomy, superior sternal extension, and left supraclavicular incision (“trap door” thoracotomy). Although the trap door procedure is appropriate after resuscitative thoracotomy, the proximal left subclavian artery can be accessed more easily via a sternotomy with a supraclavicular extension. If the left subclavian artery is injured outside the thoracic outlet, vascular control can be obtained via the sternotomy and definitive repair done through the supraclavicular incision. Emergent median sternotomy is optimal for anterior stab wounds to the heart. Typically, these patients have pericardial tamponade and may undergo placement of a pericardial drain before a semiurgent median sternotomy is performed. Patients in extremis, however, should undergo anterolateral thoracotomy.

Median sternotomy with cervical extension is used for rapid exposure in patients with presumed proximal subclavian, innominate, or proximal carotid artery injuries. Care must be taken to avoid injury to the phrenic and vagus nerves that pass over the subclavian artery and to the recurrent laryngeal nerve passing posteriorly. Posterolateral thoracotomies are used for exposure of injuries to the trachea or main stem bronchi near the carina or the upper esophagus (right posterolateral thoracotomy) and tears of the descending thoracic aorta or lower esophagus (left posterolateral thoracotomy).

**Emergent Abdominal Exploration.** Abdominal exploration in adults is performed using a midline incision because of its versatility. For children under the age of 6, a transverse incision may be advantageous. Making the incision is faster with a scalpel than with an electrosurgical unit; incisional abdominal wall bleeding should be ignored until intra-abdominal sources of hemorrhage are controlled. Liquid and clotted blood are
evacuated with multiple laparotomy pads to identify the major source(s) of active bleeding. After blunt trauma, the spleen and liver should be palpated first and packed if fractured, and the infracolic mesentery should be inspected for zone I vascular injury. In contrast, after a penetrating wound the search for bleeding should pursue the trajectory of the penetrating device. If the patient has an SBP of <70 mmHg when the abdomen is opened, digital pressure or a clamp should be placed on the aorta at the diaphragmatic hiatus. After the source of hemorrhage is localized, direct digital occlusion (vascular injury) or laparotomy pad packing (solid organ injury) is used to control bleeding (Fig. 7-37). If the liver is the source in a hemodynamically unstable patient, additional control of bleeding is obtained by clamping the hepatic pedicle with a vascular clamp or Rummel tourniquet (termed the Pringle maneuver) (Fig. 7-38). Similarly, clamping the splenic hilum may be required for hilar bleeding. When the spleen is mobilized, it should be gently rotated medially to expose the lateral peritoneum; this peritoneum and endoabdominal fascia are incised, which allows blunt dissection of the spleen and pancreas as a composite from the retroperitoneum anterior to Gerota’s fascia (Fig. 7-39).

Rapid exposure of the intra-abdominal vasculature can prove challenging in the face of exsanguinating hemorrhage. Proximal control of the aorta is obtained at the diaphragmatic hiatus; if an aortic injury is supraceliac, transecting the left crus of diaphragm or extending the laparotomy via a left thoracotomy may be necessary.

Figure 7-37. A sagittal view of packs placed to control hepatic hemorrhage. LAP = laparotomy.

Figure 7-38. The Pringle maneuver, performed with a vascular clamp, occludes the hepatic pedicle containing the portal vein, hepatic artery, and common bile duct.

Figure 7-39. To mobilize the spleen, an incision is made into the endoabdominal fascia 1 cm lateral to the reflection of the peritoneum onto the spleen (A). While the spleen is gently rotated medially, a plane is developed between the pancreas and left kidney (B). With complete mobilization, the spleen can reach the level of the abdominal incision.
An alternative for a contained hematoma is placement of a trans-femoral REBOA into zone I. The first decision is whether the patient has a supracolic or an infracolic vascular injury. Supracolic injuries (aorta, celiac axis, proximal superior mesenteric artery [SMA], and left renal arteries) are best approached via a left medial visceral rotation (Fig. 7-40). This is done by incising the lateral peritoneal reflection (white line of Toldt) beginning at the distal descending colon and extending the incision along the colonic splenic flexure, around the posterior aspect of the spleen, and behind the gastric fundus, ending at the esophagus. The left colon, spleen, pancreas, and stomach are then rotated toward the midline. The authors prefer to leave the kidney in situ when mobilizing the viscera because this exaggerates the separation of the renal vessels from the SMA. The operative approach for SMA injuries is based on the level of injury. Fullen zone I SMA injuries, located posterior to the pancreas, are best exposed by a left medial visceral rotation. Fullen zone II SMA injuries, extending from the pancreatic edge to the middle colic branch, on the other hand, are approached via the lesser sac along the inferior edge of the pancreas at the base of the transverse mesocolon; the pancreatic body may be divided to gain proximal vascular access. More distal SMA injuries, Fullen zones III and IV, are approached directly within the mesentery. A venous injury behind the pancreas, from the junction of the superior mesenteric, splenic, and portal veins, is accessed by dividing the neck of the pancreas. Inferior vena cava injuries are approached by a right medial visceral rotation (Fig. 7-41). Proximal control is obtained just above the iliac bifurcation with direct pressure via a sponge stick; the injury is identified by cephalad dissection along the anterior surface of the inferior vena cava. A Satinsky clamp can be used to control anterior caval wounds.

Injuries of the iliac vessels pose a unique problem for emergent vascular control due to the number of vessels, their close proximity, and cross circulation. Proximal control at the infrarenal aorta arrests the arterial bleeding and avoids splanchnic and renal ischemia; however, venous injuries are not controlled with aortic clamping. Tamponade with digital pressure or with a folded laparotomy pad held directly over the bleeding site usually will establish hemostasis sufficient to prevent exsanguination. If hemostasis is not adequate to expose the vessel proximal and distal to the injury, sponge sticks can be strategically placed on either side of the injury and carefully adjusted to improve hemostasis. Alternatively, complete pelvic vascular isolation (Fig. 7-42) may be required to control hemorrhage for adequate visualization of the injuries. The right common iliac artery obscures the bifurcation of the vena cava and the right iliac vein; the iliac artery may require division to expose venous injuries in this area (Fig. 7-43). The artery must be repaired after the venous injury is treated, however, because of limb-threatening ischemia.

Once overt hemorrhage is controlled, sources of enteric contamination are identified by serially running along the small and large bowel, looking at all surfaces. Associated hematomas should be unroofed to rule out adjacent bowel injury. The anterior and posterior aspects of the stomach should be inspected, which requires opening the lesser sac for complete visualization. Duodenal injuries should be evaluated with a wide Kocher maneuver. During exploration of the lesser sac, visualization and palpation of the pancreas is done to exclude injury. Palpating the anterior surface is not sufficient because the investing

Figure 7-40. A left medial visceral rotation is used to expose the abdominal aorta.

Figure 7-41. A right medial visceral rotation is used to expose the infrahepatic vena cava.
fascia may mask a pancreatic injury; mobilization, including evaluation of the posterior aspect, is critical. After injuries are identified, whether to use damage control techniques or perform primary repair of injuries is based on the patient’s intraoperative physiologic status (see “Damage Control Surgery” and “Treatment of Specific Injuries”). In a patient with multisystem trauma, enteral access via gastrostomy or jejunostomy tube should be considered. If abdominal closure is indicated after the patient’s injuries are addressed, the abdomen is irrigated with warm saline and the midline fascia is closed with a running heavy absorbable suture. The skin is closed selectively based on the amount of intra-abdominal contamination.

Vascular Repair Techniques. Initial control of vascular injuries is accomplished digitally by applying enough direct pressure to stop the hemorrhage. Sharp dissection is used to define the injury and mobilize sufficient length for proximal and distal control. Fogarty thromboembolectomy should be done proximally and distally to optimize collateral blood flow. Heparinized saline (50 units/mL) is then injected into the proximal and distal ends of the injured vessel to prevent small clot formation on the exposed intima and media. Ragged edges of the injury site should be debrided using sharp dissection. Intravascular shunts are used when there are multiple life-threatening injuries or the arterial injury is anticipated to require saphenous vein interposition reconstruction.

Options for the treatment of vascular injuries are listed in Table 7-9. Arterial repair should always be done for the aorta, carotid, innominate, brachial, superior mesenteric, proper hepatic, renal, iliac, femoral, and popliteal arteries. Named arteries that usually tolerate ligation include the right or left hepatic artery and the celiac artery. In the lower extremities, at least one artery with distal runoff should be salvaged. Arterial injuries that may be treated nonoperatively include small pseudoaneurysms, intimal dissections, small intimal flaps, and small arteriovenous

Figure 7-42. Pelvic vascular isolation. A. Initially, clamps are placed on the aorta, inferior vena cava, and bilateral external iliac vessels. B. With continued dissection, the clamps can be moved progressively closer to the vascular injury to limit unwarranted ischemia.

Figure 7-43. The right common iliac artery can be divided to expose the bifurcation of the inferior vena cava and the right common iliac vein.
fistulas in the extremities. Follow-up imaging is performed 1 to 2 weeks after injury to confirm healing. Venous repair should be performed for injuries of the superior vena cava, the inferior vena cava proximal to the renal veins, and the portal vein, although the portal vein may be ligated in extreme cases. The SMV should be repaired optimally, but >80% of patients will survive following ligation. Similarly, the left renal vein can usually be ligated adjacent to the IVC due to collateral decompression.

The type of operative repair for a vascular injury is based on the extent and location of injury. Lateral suture repair is preferred for arterial injuries with minimal loss of tissue. End-to-end primary anastomosis is performed if the vessel can be repaired without tension. Arterial defects of 1 to 2 cm often can be bridged by mobilizing the severed ends of the vessel after ligating small branches. The aorta, subclavian artery, brachial artery, and popliteal artery however, are difficult to mobilize for additional length. To avoid postoperative stenosis, particularly in smaller arteries, beveling or spatulation should be used so that the completed anastomosis is slightly larger in diameter than the native artery (Fig. 7-44). The authors emphasize the parachute technique to ensure precision placement of the posterior suture line (Fig. 7-45). If this technique is used, traction must be maintained on both ends of the suture, or leakage from the posterior aspect of the suture line may occur.

Interposition grafts are used when end-to-end anastomosis cannot be accomplished without tension despite mobilization. For vessels <6 mm in diameter (e.g., internal carotid, brachial, superficial femoral, and popliteal arteries), autogenous greater saphenous vein (GSV) from the contralateral groin should be used because polytetrafluoroethylene (PTFE) grafts of <6 mm have a prohibitive rate of thrombosis. When GSV is not available, autologous options include the cephalic and basilic veins. Larger arteries (e.g., subclavian, innominate, aorta, common iliac) are bridged by PTFE grafts. PTFE is preferred over Dacron because of the reported decreased risk of infection. Aortic or iliac arterial injuries may be complicated by enteric contamination from colon or small bowel injuries. There is a natural reluctance to place artificial grafts in such circumstances, but graft infections are rare, and the time required to perform an axillofemoral bypass is excessive. Therefore, after the control of hemorrhage, bowel contamination is contained and the abdomen irrigated before placing PTFE grafts. After placement of the graft, it is covered with peritoneum or omentum before definitive treatment of the enteric injuries.

Transposition procedures can be used when an artery has a bifurcation and one vessel can be ligated safely. Injuries of the proximal internal carotid can be treated by mobilizing the adjacent external carotid, dividing it distal to the internal injury, and performing an end-to-end anastomosis between it and the distal internal carotid (Fig. 7-46). The proximal stump of the internal carotid is oversewn, with care taken to avoid a blind pocket where a clot may form. Injuries of the common and external iliac arteries can be handled in a similar fashion (Fig. 7-47), while maintaining flow in at least one internal iliac artery.

Venous injuries should be repaired when technically feasible. Small injuries without loss of tissue can be treated with lateral suture repair. More complex repairs with interposition grafts may thrombose, but this typically occurs gradually over 1 to 2 weeks. During this time adequate collateral circulation develops, which is sufficient to avoid acute venous hypertension. Therefore, it is reasonable to use ringed PTFE for venous interposition grafting and accept a gradual, but eventual, thrombosis while allowing time for collateral circulation to develop. Such an approach is reasonable for venous injuries of the superior vena cava, suprarenal vena cava, SMV, and popliteal vein because ligation of these is associated with significant morbidity. In the remainder of venous injuries, the vein may be ligated. In such patients, chronic venous hypertensive complications in the lower extremities often can be avoided by (a) temporary use of elastic bandages (Ace wraps) applied from the toes to the hips at the end of the procedure, and (b) judicious elevation of the lower extremities. These measures should be maintained for

---

**Figure 7-44.** Small arteries repaired with an end-to-end anastomosis are prone to stricture. Enlarging the anastomosis by beveling the cut ends of the injured vessel can minimize this problem. A curved hemostat is a useful adjunct to create the curve.

**Figure 7-45.** The parachute technique is helpful for accurate placement of the posterior sutures of an anastomosis when the arterial end is fixed and an interposition graft is necessary. Traction must be maintained on both ends of the suture to prevent loosening and leakage of blood. Six stitches should be placed before the graft is pulled down to the artery.
Carotid transposition is an effective approach for treating injuries of the proximal internal carotid artery.

Figure 7-46. Carotid transposition is an effective approach for treating injuries of the proximal internal carotid artery.

Transposition procedures can be used for iliac artery injuries to eliminate the dilemma of placing an interposition polytetrafluoroethylene graft in the presence of enteric contamination. A. Right common iliac artery transposed to left common iliac artery. B. Left internal iliac artery transposed to the distal right common iliac artery. C. Right internal iliac artery transposed to the right external iliac artery.

1 week; if the patient has no peripheral edema with ambulation, these maneuvers are no longer required.

**Damage Control Surgery**

The recognition of the bloody vicious cycle and the introduction of damage control surgery (DCS) have improved the survival of critically injured patients. Conceptually, the bloody vicious cycle, first described in 1981, is the lethal combination of coagulopathy, hypothermia, and metabolic acidosis (Fig. 7-48). Hypothermia from evaporative and conductive heat loss and diminished heat production occurs despite the use of warming blankets and blood warmers. The metabolic acidosis of shock is exacerbated by aortic clamping, administration of vasopressors, massive RBC transfusions, and impaired myocardial performance. The ACOT, described previously, is compounded by hemodilution, hypothermia, and acidosis. Once the cycle starts, each component magnifies the other, which leads to a downward spiral and ultimately a fatal arrhythmia. The purpose of DCS is to limit operative time so that the patient can be returned to the SICU for physiologic restoration and the cycle thereby broken. Indications to limit the initial operation and institute DCS techniques include a combination of refractory hypothermia (temperature <35°C), profound acidosis (arterial pH <7.2, base deficit >15 mmol/L), and refractory coagulopathy. The decision to abbreviate a trauma laparotomy is made intraoperatively as the patient’s clinical course becomes clearer and laboratory values become available.

The goal of DCS is to control surgical bleeding and limit GI spillage. The operative techniques used are temporary measures, with definitive repair of injuries delayed until the patient is physiologically replete. Controlling surgical bleeding while preventing ischemia is of utmost importance during DCS. Aortic injuries must be repaired using an interposition PTFE
graft. Although celiac artery injuries may be ligated, the SMA must maintain flow, and the early insertion of an intravascular shunt is advocated. Similarly, perfusion of the iliac system and infrainguinal vessels can be restored with a vascular shunt, with interposition graft placement delayed. Arterial reconstruction following shunt placement should be done optimally within 6 hours. Venous injuries are preferentially treated with ligation in damage control situations, except for the suprarenal inferior vena cava and popliteal vein. For extensive solid organ injuries to the spleen or one kidney, excision is indicated rather than an attempt at operative repair. For hepatic injuries, perihepatic packing of the liver will usually tamponade bleeding (see Fig. 7-37). Translobar gunshot wounds of the liver are best controlled with balloon catheter tamponade, whereas deep lacerations can be controlled with Foley catheter inflation deep within the injury track (Fig. 7-49). For thoracic injuries requiring DCS several options exist. For bleeding peripheral pulmonary injuries, wedge resection using a stapler is performed. In penetrating injuries, pulmonary tractotomy is used to divide the parenchyma (Fig. 7-50); individual vessels and bronchi are then ligated using a 3-0 polydioxanone suture (PDS), and the track is left open. Patients who sustain more proximal injuries may require formal pulmonary resection, but pneumonectomy is poorly tolerated. Recent experimental work suggests inhaled nitric oxide (NO) will reduce right heart failure following pneumonectomy. Cardiac injuries may be temporarily controlled using a running 3-0 nonabsorbable polypropylene suture or skin staples. Pledged repair should be performed for the relatively thin right ventricle.

The second key component of DCS is limiting enteric content spillage. Small GI injuries (stomach, duodenum, small intestine, and colon) may be controlled using a rapid whipstitch of 3-0 PDS. Complete transection of the bowel or segmental damage is controlled using a GIA stapler, often with resection of the injured segment. Alternatively, open ends of the bowel may be ligated using umbilical tapes to limit spillage. Pancreatic injuries, regardless of location, are packed and the evaluation of ductal integrity postponed. Urologic injuries may require catheter diversion. Before the patient is returned to the SICU, the abdomen must be closed temporarily. Temporary closure of the abdomen is accomplished using an antimicrobial surgical incise drape (Ioban, 3M Health Care, St Paul, MN) (Fig. 7-51). In this technique, the bowel is covered with a fenestrated subfascial sterile drape (45 × 60 cm Steri-Drape 3M Health Care), and two Jackson-Pratt drains are placed along the fascial edges; this is

**Figure 7-48.** The bloody vicious cycle. FFP = fresh frozen plasma; RBC = red blood cell.
then covered using an Ioban drape, which allows closed suction to control reperfusion-related ascitic fluid egress while providing adequate space for bowel expansion to prevent abdominal compartment syndrome. During the initial DCS stage, the subfascial sterile drape is not covered by a blue towel so that the status of the bowel and hemorrhage control can be assessed. The use of direct peritoneal resuscitation following DCS should be considered; 18 Fr round Blake drains may be placed intraoperatively for the instillation of the dialysate solution. Return to the OR within 24 hours is planned once the patient clinically improves, as evidenced by normothermia, normalization of coagulation test results, and correction of acidosis.

**TREATMENT OF SPECIFIC INJURIES**

**Head Injuries**

**Intracranial Injuries.** CT scanning, performed on all patients with a significant closed head injury (GCS score <14), identifies and quantitates intracranial lesions as well as intracranial hypertension. Patients with intracranial hemorrhage, including epidural hematoma, subdural hematoma, subarachnoid hemorrhage, intracerebral hematoma or contusion, and diffuse axonal injury, are admitted to the SICU. In patients with abnormal findings on CT scans and GCS scores of ≤8, intracranial pressure (ICP) should be monitored using fiber-optic intraparenchymal devices or intraventricular catheters. Although an ICP of 10 mmHg is the upper limit of normal, therapy is targeted to maintain an ICP of <20 mmHg. The newest neurosurgery guidelines additionally recommend maintaining the cerebral perfusion pressure (CPP) at >60 mmHg. Indications for operative intervention to remove space-occupying hematomas are based on the clot volume, amount of midline shift, location of the clot, GCS score, and ICP. A shift of >5 mm typically is considered an indication for evacuation, but this is not an absolute rule. Smaller hematomas that are in treacherous locations, such as the posterior fossa, may require drainage due to brain stem compression or impending herniation. Removal of small hematomas may also improve ICP and cerebral perfusion in patients with elevated ICP that is refractory to medical therapy. Patients with diffuse cerebral edema resulting in excessive ICP may require a decompressive craniectomy, although a recent AAST multicenter trial questioned the benefits. Patients with open or depressed skull fractures, with or without sinus involvement, may require operative intervention. Penetrating injuries to the head may require operative intervention for hemorrhage control, evacuation of blood, skull fracture fixation, or debridement.

General surgeons in communities without emergency neurosurgical coverage should have a working knowledge of burr hole placement in the event that emergent evacuation is required for a life-threatening epidural hematoma (Fig. 7-52). The typical clinical course of an epidural hematoma is an initial loss of consciousness, a lucid interval, and recurrent loss of consciousness with an ipsilateral fixed and dilated pupil. While decompression of subdural hematomas may be delayed, epidural hematomas require evacuation within 70 minutes. The final stages of this sequence are caused by blood accumulation that forces the temporal lobe medially, with resultant compression of the third cranial nerve and eventually the brain stem. The burr hole is made on the side of the dilated pupil to decompress the intracranial space. After stabilization, the patient is transferred to a facility with neurosurgical capability for formal craniotomy.

In addition to operative intervention, postinjury care directed at limiting secondary injury to the brain is critical. The goal of resuscitation and management in patients with head injuries is to avoid hypotension (SBP of <100 mmHg) and hypoxia (partial pressure of arterial oxygen of <60 or arterial oxygen saturation of <90%). Attention, therefore, is focused on maintaining cerebral perfusion rather than merely lowering
ICP. Resuscitation efforts aim for a euvolemic state and a SBP of >100 mmHg. Cerebral perfusion pressure (CPP) is equal to the mean arterial pressure minus the ICP, with a target range of >60 mmHg. CPP can be increased by either lowering ICP or raising mean arterial pressure. Sedation, osmotic diuresis, paralysis, ventricular drainage, and barbiturate coma are used in sequence, with coma induction being the last resort. The role of decompressive craniectomy for refractory ICH remains controversial. The partial pressure of carbon dioxide (PCO₂) should be maintained in a normal range (35–40 mmHg), but for temporary management of acute intracranial hypertension, inducing cerebral vasoconstriction by hyperventilation to a PCO₂ of

Figure 7-51. Temporary closure of the abdomen entails covering the bowel with a fenestrated subfascial 45 × 60 cm sterile drape (A), placing Jackson-Pratt drains along the fascial edge (B), and then occluding with an Ioban drape (C, D).
TRAUMA

CHAPTER 7

<30 mmHg is occasionally warranted. Moderate hypothermia (32°–33°C [89.6°–91.4°F]) has been shown experimentally to improve neurologic outcomes, but clinical studies have not validated this concept.33,85,86 Patients with intracranial hemorrhage should be monitored for postinjury seizures, and prophylactic anticonvulsant therapy is indicated for 7 days after injury.33

Maxillofacial Injuries. Maxillofacial injuries are common with multisystem trauma and require coordinated management by the trauma surgeon and the specialists in otolaryngology, plastic surgery, ophthalmology, and oral and maxillofacial surgery. Delay in addressing these systems that control vision, hearing, smelling, breathing, eating, and phonation may produce dysfunction and disfigurement with serious psychological impact. The maxillofacial complex is divided into three regions; the upper face containing the frontal sinus and brain; the midface containing the orbits, nose, and zygomaticomaxillary complex; and the lower face containing the mandible. High-impact kinetic energy is required to fracture the frontal sinus, orbital rims, and mandible, whereas low-impact forces will injure the nasal bones and zygoma.

The most common scenario, which at times may be life-threatening, is bleeding from facial fractures.87 Temporizing measures include nasal packing, Foley catheter tamponade of posterior nasal bleeding, and oropharyngeal packing. Prompt angioembolization will halt exsanguinating hemorrhage. Fractures of tooth-bearing bone are considered open fractures and require antibiotic therapy and semiurgent repair to preserve the airway as well as the functional integrity of the occlusion (bite) and the aesthetics of the face. Orbital fractures may compromise vision, produce muscle injury causing diplopia, or change orbital volume to produce a sunken appearance to the orbit. Nose and nasoethmoidal fractures should be assessed carefully to identify damage to the lacrimal drainage system or to the cribiform plate producing cerebrospinal fluid rhinorrhea. After initial stabilization, a systematic physical examination of the head and neck should be performed that also includes cranial nerve examination and three-dimensional CT scanning of the maxillofacial complex (Fig. 7-53).

Cervical Injuries

Spine. Treatment of injuries to the cervical spine is based on the level of injury, the stability of the spine, the presence of subluxation, the extent of angulation, the level of neurologic deficit, and the overall condition of the patient. In general, physician-supervised axial traction, via cervical tongs or the more commonly used halo vest, is used to reduce subluxations and stabilize the injury. Immobilization of injuries also is achieved with spinal orthoses (braces), particularly in those with associated thoracolumbar injuries. Surgical fusion typically is performed in patients with neurologic deficit, those with angulation of >11° or translation of >3.5 mm, and those who remain unstable after halo placement. Indications for immediate operative intervention are deterioration in neurologic function and fractures or dislocations with incomplete deficit. Historically, methylprednisolone was administered to patients with acute spinal cord injury after blunt injury, with clinical data suggesting a small benefit to initiating a 24-hour infusion if started within 3 hours and a 48-hour infusion if started within 3 to 8 hours.88 Current guidelines, however, no longer recommend steroids for acute injuries.89 The role and timing of operative surgical decompression after acute spinal cord injury is debated, and
the concept of damage control has been suggested. However, evidence supports urgent decompression of bilateral locked facets in patients with incomplete tetraplegia or with neurologic deterioration. Performing surgery within 24 hours may decrease length of stay and complications. Complete injuries of the spinal cord remain essentially untreatable. Yet, approximately 3% of patients who present with flaccid quadriplegia have concussive injuries, and these patients represent the very few who seem to have miraculous recoveries.

**Vascular.** Cervical vascular injuries due to either blunt or penetrating trauma can result in devastating neurologic sequelae or exsanguination. Penetrating injuries to the carotid artery and internal jugular vein usually are obvious on operative neck exploration. The principles of vascular repair techniques (discussed previously) apply to carotid injuries, and options for repair include end-to-end primary repair (often possible with mobilization of the common carotid), graft interposition, and transposition procedures. All carotid injuries should be repaired except in patients who present in coma with a delay in transport. Prompt revascularization of the internal carotid artery, using a temporary Pruitt-Inahara shunt, should be considered in patients arriving in profound shock. Otherwise, carotid shunting should be done selectively as in elective carotid endarterectomy, but the patient should be systemically anticoagulated. Currently, we administer heparin with an ACT target of 250 sec. Tangential wounds of the internal jugular vein should be repaired by lateral venorrhaphy, but extensive wounds are efficiently addressed by ligation. However, it is not advisable to ligate both jugular veins due to potential intracranial hypertension. Vertebral artery injuries due to penetrating trauma are difficult to control operatively because of the artery’s protected location within the foramen transversarium. Although exposure from an anterior approach can be accomplished by removing the anterior elements of the bony canal and the tough fascia covering the artery between the elements, typically the most efficacious control of such injuries is angioembolization. Fogarty catheter balloon occlusion, however, is useful for controlling acute bleeding if encountered during neck exploration.

Blunt injury to the carotid or vertebral arteries may cause dissection, thrombosis, or pseudoaneurysm, typically in the surgically inaccessible distal internal carotid (Fig. 7-54). Early recognition and management of these injuries is paramount because patients treated with antithrombotics have a stroke rate of <1% compared with stroke rates of 20% in untreated patients. Because treatment must be instituted during the latent period between injury and onset of neurologic sequelae, diagnostic imaging is performed based on identified risk factors (Fig. 7-55). After identification of an injury, antithrombotics are administered if the patient does not have contraindications (intracranial hemorrhage, falling hemoglobin level with solid organ injury or complex pelvic fractures). Heparin, started without a loading dose at 15 units/kg per hour, is titrated to achieve a PTT between 40 and 50 seconds or antiplatelet agents are initiated (aspirin 325 mg/d or clopidogrel 75 mg/d). The types of

Figure 7-54. The Denver grading scale for blunt cerebrovascular injuries. Grade I: irregularity of the vessel wall, dissection/intramural hematoma with <25% luminal stenosis. Grade II: visualized intraluminal thrombus or raised intimal flap, or dissection/intramural hematoma with 25% or more luminal narrowing. Grade III: pseudoaneurysm. Grade IV: vessel occlusion. CAI = carotid artery injury; VAI = vertebral artery injury.
antithrombotic treatment appear equivalent in published studies to date, and the duration of treatment is empirically recommended to be 6 months.93,94 The role of carotid stenting for grade II or III internal carotid artery injuries remain controversial; current literature suggests stenting be reserved for symptomatic patients or markedly enlarging pseudoaneurysms.95 Thrombosis of the internal jugular veins caused by blunt trauma can occur unilaterally or bilaterally and is often discovered incidentally because most patients are asymptomatic. Bilateral thrombosis can aggravate cerebral edema in patients with serious head injuries; stent placement should be considered in such patients if ICP remains elevated.

Figure 7-55. Screening and treatment algorithm for blunt cerebrovascular injuries (BCVIs). Aerodigestive. Fractures of the larynx and trachea may manifest as cervical emphysema. Fractures documented by CT scan are usually repaired. Common injuries include thyroid cartilage fractures, rupture of the thyroepiglottic ligament, disruption of the arytenoids or vocal cord tears, and cricoid fractures. After debridement of devitalized tissue, tracheal injuries are repaired end-to-end using a single layer of interrupted absorbable sutures. Associated injuries of the esophagus are common in penetrating injuries due to its close proximity. After debridement and repair, vascularized tissue is interposed between the repaired esophagus and trachea, and a closed suction drain is placed. The sternocleidomastoid muscle or strap muscles are useful for interposition and help prevent postoperative fistulas.

Chest Injuries
The most common injuries from both blunt and penetrating thoracic trauma are hemothorax and pneumothorax. More than 85% of patients can be definitively treated with a chest tube. The indications for thoracotomy include significant initial or ongoing hemorrhage from the tube thoracostomy and specific imaging-identified diagnoses (Table 7-10). One caveat concerns the patient who presents after a delay. Even when the initial chest tube output is 1.5 L, if the output ceases and the lung is reexpanded, the patient may be managed nonoperatively if hemodynamically stable.

Great Vessels. Over 90% of thoracic great vessel injuries are due to penetrating trauma, although blunt injury to the innominate, subclavian, or descending aorta may cause a pseudoaneurysm or frank rupture. Simple lacerations of the ascending or transverse aortic arch can be repaired with lateral aortorrhaphy. Repair of posterior aortic injuries, complex ascending or transverse injuries, or those requiring interposition grafting of the arch, require full cardiopulmonary bypass. Innominate artery injuries are repaired using the bypass exclusion technique, which avoids the need for cardiopulmonary bypass. Bypass grafting from the proximal aorta to the distal innominate with a prosthetic tube graft is performed before the postinjury hematoma is entered. The PTFE graft is anastomosed end-to-side from the proximal undamaged aorta and anastomosed end-to-end to the innominate artery (Fig. 7-56). The origin of the innominate is then oversewn at its base to exclude the pseudoaneurysm or other injury. Subclavian artery injuries can be repaired using lateral aortorrhaphy or PTFE graft interposition; due to its multiple branches and tethering of the artery, end-to-end primary anastomosis is not advocated if there is a significant segmental loss.

Descending BAI may require urgent intervention. However, operative intervention for intracranial or intra-abdominal hemorrhage or unstable pelvic fractures takes precedence. To prevent aortic rupture, pharmacologic therapy with a selective $\beta_1$-antagonist, esmolol, should be instituted in the trauma bay, with a target SBP of <100 mmHg and heart rate of <100/min. Endovascular stenting is now the mainstay of treatment.

While endograft sizing has improved, the major question is long-term outcome in younger patients. Open repair of the descending aorta is accomplished using partial left heart bypass to prevent spinal cord and splanchnic ischemia and reduce left ventricular afterload (Fig. 7-57). Nonoperative management for grade I

**Figure 7-56.**

A. Angiography reveals a 1-cm pseudoaneurysm of the innominate artery origin. B. In the first stage of the bypass exclusion technique, a 12-mm polytetrafluoroethylene graft is anastomosed end to side from the proximal undamaged aorta, tunneled under the vein, and anastomosed end to end to the innominate artery. C. The origin of the innominate is then oversewn at its base to exclude the pseudoaneurysm.
When repairing a tear of the descending thoracic aorta, perfusion of the spinal cord while the aorta is clamped is achieved by using partial left heart bypass. The venous cannula is inserted into the left superior pulmonary vein because it is less prone to tearing than the left atrium (LA).

intimal aortic injuries is accomplished with antiplatelet agents and blood pressure control.

Heart. Blunt and penetrating cardiac injuries have widely differing presentations and therefore disparate treatments. Survivable penetrating cardiac injuries consist of wounds that can be repaired operatively; most are stab wounds. Before repair of the injury is attempted, hemorrhage should be controlled; injuries to the atria can be clamped with a Satinsky vascular clamp, whereas digital pressure is used to occlude the majority of ventricular wounds. Foley catheter occlusion of larger stellate lesions is described, but even minimal traction may enlarge the original injury. Temporary control of hemorrhage, and at times definitive repair, may be accomplished with skin staples for left ventricular lacerations; the myocardial edges of the laceration must coapt in diastole for stapling to be technically feasible.

Definitive repair of cardiac injuries is performed with either running 3-0 polypropylene suture or interrupted, pledgeted 2-0 polypropylene suture (Fig. 7-58). Use of pledgets may be particularly important in the right ventricle to prevent sutures from pulling through the thinner myocardium. Injuries adjacent to coronary arteries should be repaired using horizontal mattress sutures because use of running sutures results in coronary occlusion and distal infarction. Gunshot wounds may result in stellate lesions or contused, extremely friable myocardium adjacent to the wound. When the edges of such complex wounds cannot be fully approximated and hence the repair is not hemostatic, the authors have used surgical adhesive (BioGlue) to achieve hemostasis. Occasionally, interior structures of the heart may be damaged. Intraoperative auscultation or postoperative hemodynamic assessment usually identifies such injuries. ECHO can diagnose the injury and quantitate its effect on cardiac output. Immediate repair of valvular damage or septal defects rarely is necessary and would require cardiopulmonary bypass, but structural intracardiac lesions may progress, and thus patients must have a follow-up ECHO.

Patients with blunt cardiac injury typically present with persistent tachycardia or conduction disturbances, but occasionally present with tamponade due to atrial or right ventricular rupture. There are no pathognomonic ECG findings, and cardiac enzyme levels do not correlate with the risk of cardiac complications. Therefore, patients for whom there is high clinical suspicion of cardiac contusion and who are hemodynamically stable should be monitored for dysrhythmias for 24 hours by telemetry. Patients with hemodynamic instability should undergo ECHO to evaluate for wall motion abnormalities (particularly hypokinesis of the right ventricle), pericardial fluid, valvular dysfunction, chordae rupture, or diminished ejection fraction. If such findings are noted or if vasoactive agents are required, cardiac function can be continuously monitored using a pulmonary artery catheter and serial SICU trans-thoracic or transesophageal ECHO.

Trachea, Bronchi, and Lung Parenchyma. Less than 1% of all injured patients sustain intrathoracic tracheobronchial
injuries, and only a small number require operative intervention. Although penetrating injuries may occur throughout the tracheobronchial system, blunt injuries most commonly occur within 2.5 cm of the carina. For patients with a massive air leak requiring emergent exploration, initial control of the injury to provide effective ventilation is obtained by passing an endotracheal tube either beyond the injury or into the contralateral mainstem bronchus. Principles of repair are similar to those for repair of cervical tracheal injuries. Devitalized tissue is debrided, and primary end-to-end anastomosis with 3-0 PDS suture is performed. Dissection should be limited to the area of injury to prevent disruption of surrounding bronchial vasculature and ensuing ischemia and stricture. Suture lines should be encircled with vascularized tissue, either pericardium, intercostal muscle, or pleura. Expectant management is employed for bronchial injuries that are less than one-third the circumference of the airway and have no evidence of a persistent major air leak.11 In patients with peripheral bronchial injuries, indicated by persistent air leaks from the chest tube and documented by endoscopy, bronchoscopically directed fibrin glue sealing may be useful.

The majority of pulmonary parenchymal injuries are suspected based upon identification of a pneumothorax; the vast majority can be managed with a tube thoracostomy. Identified parenchymal injuries encountered during thoracic exploration for a massive hemorthax are managed without resection as much as possible. Bronchovenuous fistula is a constant threat and should be minimized by prompt control of a major air leak. Peripheral lacerations with persistent bleeding can be managed with stapled wedge resection. For central injuries, the current treatment is pulmonary tractotomy, which permits selective ligation of individual bronchioles and bleeder, prevents the development of an intraparenchymal hematoma or air embolism, and reduces the need for formal lobar resection (see Fig. 7-50).106,107 A stapling device, preferably the longest stapler available (e.g., GIA-100), is inserted directly into the injury track and positioned along the thinnest section of overlapping parenchyma. The injury track is thus filleted open, which allows direct access to the bleeding vessels and leaking bronchi. The majority of injuries are definitively managed with selective ligation, and the defect is left open. Occasionally, tractotomy reveals a more proximal vascular on bronchial injury that must be treated with formal lobectomy. Injuries severe enough to mandate pneumonectomy usually are fatal because of right heart decompensation.108

One parenchymal injury that may be discovered during thoracic imaging is a posttraumatic pulmonary pseudocyst, colloquially termed a pneumatocele.109 Traumatic pneumatoceles typically follow a benign clinical course and are treated with aggressive pain management, pulmonary toilet, and serial chest radiography to monitor for resolution of the lesion. If the patient has persistent fever or leukocytosis, however, chest CT is done to evaluate for an evolving abscess because pneumatoceles may become infected. CT-guided catheter drainage may be required in such cases because 25% of patients do not respond to antibiotic therapy alone. Surgery, ranging from partial resection to anatomic lobectomy, is indicated for unresolved complex pneumatoceles or infected lesions refractory to antibiotic therapy and drainage.

The most common complication after thoracic injury is development of an empyema. Management is based on CT diagnostic criteria.110 Percutaneous drainage is indicated for a single loculation without appreciable rind. While fibrinolytics are often used for empyema, there is a paucity of data to support their use. Early decortication via video-assisted thoracic surgery should be done promptly in patients with multiple loculations or a pleural rind of >1 cm.111 Antibiotic treatment is based on definitive culture results, but presumptive antibiotics should cover MRSA in the SICU.

**Esophagus.** Due to the proximity of the structures, esophageal injuries often occur with tracheobronchial injuries, particularly in cases of penetrating trauma. Operative options are based on the extent and location of esophageal injury. With sufficient mobilization, a primary single-layer end-to-end anastomosis may be performed after appropriate debridement. As with cervical repairs, if there are two suture lines in close approximation (trachea or bronchi and esophagus) interposition of a vascularized pedicle is warranted to prevent fistula formation. Perforations at the gastroesophageal junction may be treated with repair and Nissan fundoplication or, for destructive injuries, segmental resection and gastric pull-up. Small esophageal injuries can be managed with stenting. With large destructive injuries or delayed presentation of injuries, esophageal exclusion with wide drainage, diverting loop esophagostomy, and placement of a gastrostomy tube should be considered.

**Chest Wall and Diaphragm.** Virtually all chest wall injuries, consisting of rib fractures and laceration of intercostal vessels, are treated nonoperatively with pain control, pulmonary toilet or ventilatory management, and drainage of the pleural space as indicated. Early institution of effective pain control is essential. The authors advocate preemptive rib blocks with 0.25% bupivacaine hydrochlo-
ride (Marcaine) in the trauma bay, followed by thoracic wall pain catheters.112 Epidural anesthesia is reserved for multiple segmental fractures. Persistent hemorrhage from a chest tube after blunt trauma most often is due to injured intercostal arteries; for unusual persistent bleeding (see Table 7-10), thoracotomy with direct ligation or angioembolization may be required to arrest hemorrhage. In cases of extensive flail chest segments, markedly displaced biconical rib fractures, or loss of 20% of the thoracic volume, open reduction and internal fixation of the fracture with plates may be warranted. Chest wall defects, particularly those seen with open pneumothorax, are repaired using local approximation of tissues or tissue transfer for coverage. Scapular and sternal fractures rarely require operative intervention but are markers for significant thoracoabdominal force during injury; significant displacement may benefit from sternal plating (Fig. 7-59). Careful examination and imaging should exclude associated injuries, including blunt cardiac injury and descending BAL. On the other hand, clavicle fractures are often isolated injuries and should be managed with pain control and immobilization. The exception is posterior dislocation of the clavicular head, which may injure the subclavian vessels.

Blunt diaphragmatic injuries usually result in a linear tear, and most injuries are large, whereas penetrating injuries are variable in size and location depending on the agent of injury. Regardless of the etiology, acute injuries are usually repaired through an abdominal approach to manage potential associated visceral injury. After delineation of the injury, the chest should be evacuated of all blood and particulate matter, and a thoracostomy tube placed if not previously done. Allis clamps are used to approximate the diaphragmatic edges, and the defect is closed with a running No. 1 polypropylene suture. Occasionally, large avulsions or shotgun wounds with extensive tissue loss will require polypropylene or biologic mesh to bridge the defect.
Alternatively, transposition of the diaphragm cephalad one to two intercostal spaces may allow repair without undue tension.73

**Abdominal Injuries**

**Liver and Extrahepatic Biliary Tract.** The liver’s large size makes it the organ most susceptible to blunt trauma, and it is frequently involved in upper torso penetrating wounds. Nonoperative management of solid organ injuries is pursued in hemodynamically stable patients who do not have overt peritonitis or other indications for laparotomy. Patients with >grade II injuries should be admitted to the SICU with frequent hemodynamic monitoring, determination of hemoglobin, and abdominal examination. The only absolute contraindication to nonoperative management is hemodynamic instability from intraperitoneal hemorrhage. Factors such as high injury grade, large hemoperitoneum, contrast extravasation, or pseudoaneurysms may predict complications or failure of nonoperative management. Angioembolization and endoscopic retrograde cholangiopancreatography (ERCP) are useful adjuncts that can improve the success rate of nonoperative management.113,114 The indication for angiography to control hepatic hemorrhage is transfusion of 4 units of RBCs in 6 hours or 6 units of RBCs in 24 hours attributable to the liver.

In the 15% of patients for whom emergent laparotomy is mandated, the primary goal is to arrest hemorrhage. Initial control of hemorrhage is best accomplished using perihpatic packing and manual compression. The edges of the liver laceration should be opposed for local pressure control of bleeding. Hemorrhage from most major hepatic injuries can be controlled with effective perihpatic packing. The right costal margin is elevated, and the pads are strategically placed over and around the bleeding site (see Fig. 7-37). Additional pads should be placed between the liver, diaphragm, and anterior chest wall until the bleeding has been controlled. Sometimes 10 to 15 pads may be required to control the hemorrhage from an extensive right lobar injury. Packing of injuries of the left lobe is not as effective because there is insufficient abdominal and thoracic wall anterior to the left lobe to provide adequate compression with the abdomen open. Fortunately, hemorrhage from the left lobe usually can be controlled by mobilizing the lobe and compressing it between the surgeon’s hands. With extensive injuries and major hemorrhage, a Pringle maneuver should be done immediately. Intermittent release of the Pringle is helpful to attenuate hepatic cellular loss.

If the patient has persistent bleeding despite packing, injuries to the hepatic artery, portal vein, and retrohepatic vasculature should be considered. A Pringle maneuver can help delineate the source of hemorrhage. Hemorrhage from hepatic artery and portal vein injuries will halt with the application of a vascular clamp across the portal triad, whereas bleeding from the hepatic veins and the retrohepatic vena cava will continue despite a Pringle maneuver.

Injuries of the portal triad vasculature should be addressed immediately. In general, ligation from the celiac axis to the level of the common hepatic artery at the gastroduodenal arterial branch is tolerated due to extensive collaterals, but the proper hepatic artery should be repaired. The right or left hepatic artery, or in urgent situations the portal vein, may be selectively ligated; occasionally, lobar necrosis will necessitate delayed anatomic resection. If the right hepatic artery is ligated, cholecystectomy also should be performed. If the vascular injury is a stab wound with clean transection of the vessels, primary end-to-end repair is done. If the injury is destructive, temporary shunting should be performed followed by interposition reversed saphenous vein graft (RSVG). Blunt avulsions of the portal structures are particularly problematic if located at the hepatic plate, flush with the liver; hemorrhage control at the liver can be attempted with directed packing or Fogarty catheters. If injury to the portal triad vasculature is more proximal, at the superior border of the pancreatic body or even retropancreatic, the pancreas must be transected to gain access for hemorrhage control and repair.

If massive venous hemorrhage is seen from behind the liver despite use of the Pringle maneuver, the patient likely has a hepatic vein or retrohepatic vena cava injury. If bleeding can be controlled with perihpatic packing, the packing should be left undisturbed and the patient observed in the SICU. Placement of a hepatic vein stent by interventional radiology may be considered. If bleeding continues despite repeated attempts at packing, then direct repair, with or without hepatic vascular isolation, should be attempted. Three techniques have been used to accomplish hepatic vascular isolation: (a) direct repair with suprahpatic and infrahepatic clamping of the vena cava and stapled assisted parenchymal resection115; (b) temporary shunting of the retrohepatic vena cava; and (c) venovenous bypass (Fig. 7-60).116

A number of methods for the definitive control of hepatic parenchymal hemorrhage have been developed. Minor lacerations may be controlled with manual compression applied directly to the injury site. Topical hemostatic techniques include

---

**Figure 7-59.** Significant sternal displacement (A; arrows) can be reduced and stabilized with sternal plating (B).
the use of an electrocautery (with the device set at 100 watts), argon beam coagulator, microcrystalline collagen, thrombin-soaked gelatin foam sponge, fibrin glue, and BioGlue. Suturing of the hepatic parenchyma with a blunt tipped 0 chronic suture (e.g., a “liver suture”) can be an effective hemostatic technique. A running suture is used to approximate the edges of shallow lacerations, whereas deeper lacerations are approximated using interrupted horizontal mattress sutures placed parallel to the edge of the laceration. When the suture is tied, tension is adequate when visible hemorrhage ceases or the liver blanches around the suture. Caution must be used to prevent hepatic necrosis. This technique of placing large liver sutures controls bleeding through reapproximation of the liver laceration rather than direct ligation of bleeding vessels. Aggressive finger fracture to identify bleeding vessels followed by individual clip or suture ligation was advocated previously but currently has a limited role in hemostasis. Hepatic lobar arterial ligation may be appropriate for patients with recalcitrant arterial hemorrhage from deep within the liver and is a reasonable alternative to a deep hepatotomy, particularly in unstable patients. Omentum can be used to fill large defects in the liver. The tongue of omentum not only obliterates potential dead space with viable tissue but also provides an excellent source of macrophages. Additionally, the omentum can provide buttressing support for parenchymal sutures.

Translobar penetrating injuries are particularly challenging because of the extent of the injury cannot be fully visualized. As discussed in “Damage Control Surgery,” options include intraparenchymal tamponade with a Foley catheter or balloon occlusion (see Fig. 7-49). If tamponade is successful with either modality, the balloon is left inflated for 24 to 48 hours followed by sequential deflation and removal at a second laparotomy. Hepatotomy with ligation of individual bleeders occasionally may be required; however, division of the overlying viable hepatic tissue may cause considerable blood loss in the coagulopathic patient. Finally, angioembolization is an effective adjunct in any of these scenarios and should be considered early in the course of treatment.

Several centers have reported patients with devastating hepatic injuries or necrosis of the entire liver who have undergone successful hepatic transplantation. Clearly this is dramatic therapy, and the patient must have all other injuries delineated, particularly those of the central nervous system, and have an excellent chance of survival excluding the hepatic injury. Because donor availability will limit such procedures, hepatic transplantation for trauma will continue to be performed only in extraordinary circumstances.

Cholecystectomy is performed for injuries of the gallbladder and after operative ligation of the right hepatic artery. Injuries of the extrahepatic bile ducts are a challenge due to their small size and thin walls. Because of the proximity of other portal structures and the vena cava, associated vascular injuries are common. These factors may preclude primary repair. Small lacerations with no accompanying loss or devitalization of adjacent tissue can be treated by the insertion of a T-tube through the wound or by lateral suturing using 6-0 monofilament absorbable suture. Virtually all transections and any injury associated with significant tissue loss will require a Roux-en-Y choledochojjunostomy. The anastomosis is performed using a single-layer interrupted technique with 5-0 monofilament absorbable suture. To reduce anastomotic tension, the jejunum should be sutured to the areolar tissue of the hepatic pedicle or porta hepatis. Injuries of the hepatic ducts are almost impossible to satisfactorily repair under emergent circumstances. One approach is to intubate the duct for external drainage and attempt a repair when the patient recovers or attempt stenting via ERC. Alternatively, the duct can be ligated if the opposite lobe is normal and uninjured.

Patients undergoing perihepatic packing for extensive liver injuries typically are returned to the OR for pack removal 24 hours after initial injury. Earlier exploration may be indicated in patients with evidence of ongoing hemorrhage. Signs of rebleeding are usually conspicuous, and include a falling hemoglobin, accumulation of blood clots under the temporary abdominal closure device, and bloody output from drains; the magnitude of hemorrhage is reflected in ongoing hemodynamic instability and metabolic monitoring. Postoperative hemorrhage should be reevaluated in the OR once the patient’s coagulopathy is corrected. Alternatively, angioembolization is appropriate for complex injuries. Patients with hepatic ischemia due to prolonged intraoperative use of the Pringle maneuver have an expected elevation but subsequent resolution of transaminase levels, whereas patients requiring hepatic artery ligation may have frank hepatic necrosis. Although febrile patients should be evaluated for infectious complications, patients with complex hepatic injuries typically have intermittent “liver fever” for the first 5 days after injury.

Aside from hemorrhage and hepatic necrosis, additional complications after significant hepatic trauma include bilomas, arterial pseudoaneurysms, and biliary fistulas (Fig. 7-61). Bilomas are loculated collections of bile, which may or may not be infected. If infected, they should be treated like an abscess via percutaneous drainage. Although small, sterile bilomas
Complications after hepatic trauma include bilomas (A; arrow), hepatic duct injuries (B), and hepatic necrosis after hepatic artery ligation or embolization (C). Eventually will be reabsorbed, larger fluid collections should be drained. Biliary ascites, due to the disruption of a major bile duct, often requires reoperation and wide drainage. Primary repair of the injured intrahepatic duct is unlikely to be successful. Resectional debridement is indicated for the removal of peripheral portions of nonviable hepatic parenchyma.

Pseudoaneurysms and biliary fistulas are rare complications in patients with hepatic injuries. Because hemorrhage from hepatic injuries often is treated without isolating individual bleeding vessels, arterial pseudoaneurysms may develop, with the potential for rupture. Rupture into a bile duct results in hemobilia, which is characterized by intermittent episodes of right upper quadrant pain, upper GI hemorrhage, and jaundice. If the aneurysm ruptures into a portal vein, portal venous hypertension with bleeding esophageal varices may occur. Either scenario is best managed with hepatic arteriography and embolization. Biliovenous fistulas, causing jaundice due to rapid increases in serum bilirubin levels, should be treated with ERCP and sphincterotomy. Rarely, a biliary fistulous communication will form with intrathoracic structures in patients with associated diaphragm injuries, resulting in a bronchobiliary or pleurobiliary fistula. Due to the pressure differential between the biliary tract (positive) and the pleural cavity (negative), the majority require operative closure. Occasionally, endoscopic sphincterotomy with stent placement will be required to address the pressure differential, and the pleurobiliary fistula will close spontaneously.

Spleen. Until the 1970s, splenectomy was considered mandatory for all splenic injuries. Recognition of the immune function of the spleen refocused efforts on operative splenic salvage in the 1980s. After demonstrated success in pediatric patients, nonoperative management has become the preferred means of splenic salvage for all patients. The identification of contrast extravasation as a risk factor for failure of nonoperative management led to liberal use of angioembolization. The role of selective angioembolization (SAE) continues to be defined, but appears warranted in high grade injuries, particularly those with contrast blush. It is clear, however, that up to 15% to 20% of patients with splenic trauma warrant early splenectomy and that failure of nonoperative management often represents inappropriate patient selection. Indications for early intervention in adults include initiation of blood transfusion within the first 12 hours and hemodynamic instability. Unlike hepatic injuries, which usually rebleed within 48 hours, delayed hemorrhage or rupture of the spleen can occur up to weeks after injury.

Splenic injuries are managed operatively by splenectomy, partial splenectomy, or splenic repair (splenorrhaphy), based on the extent of the injury and the physiologic condition of the patient. Splenectomy is indicated for significant hilar injuries, pulverized splenic parenchyma, or any >grade II injury in a patient with coagulopathy or multiple life-threatening injuries. The authors use autotransplantation of splenic implants (Fig. 7-62) to achieve partial immunocompetence in younger patients who do not have an associated enteric injury. Drains are not used. Partial splenectomy can be employed in patients in whom only the superior or inferior pole has been injured. Hemorrhage from the raw splenic edge is controlled with horizontal mattress sutures, with gentle compression of the parenchyma (Fig. 7-63). During splenorrhaphy hemostasis is achieved by topical methods (electrocautery; argon beam coagulation; application of thrombin-soaked gelatin foam sponges, fibrin glue, or BioGlue), envelopment of the injured spleen in absorbable mesh, and pledgeted suture repair.

After splenectomy or splenorrhaphy, postoperative hemorrhage may be due to an improperly ligated or unrecognized short gastric artery, or recurrent bleeding from the splenic parenchyma if splenic repair was used. An immediate postsplenectomy
increase in platelets and WBCs is normal; however, beyond postoperative day 5, a WBC count above 15,000/mm³ and a platelet/WBC ratio of <20 are associated with sepsis and should prompt a thorough search for underlying infection. A common infectious complication after splenectomy is a subphrenic abscess, which should be managed with percutaneous drainage. Additional sources of morbidity include a concurrent or unrecognized iatrogenic injury to the pancreatic tail during rapid splenectomy resulting in pancreatic ascites or fistula, or gastric perforation during short gastric vessel ligation. Enthusiasm for splenic salvage was driven by the rare, but often fatal, complication of overwhelming postsplenectomy sepsis. Overwhelming postsplenectomy sepsis is caused by encapsulated bacteria, *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*, which are resistant to antimicrobial treatment. In patients undergoing splenectomy, prophylaxis against these bacteria is provided via vaccines administered optimally at >14 days postinjury.

**Stomach and Small Intestine.** Little controversy exists regarding the repair of injuries to the stomach or small bowel because of a rich blood supply. Gastric wounds can be oversewn with a running single-layer suture line or closed with a stapler. If a single-layer closure is chosen, full-thickness bites should be taken to ensure hemostasis from the well-vascularized gastric wall. The most commonly missed gastric injury is the posterior wound of a through and through penetrating injury. Injuries also can be overlooked if the wound is located within the mesentry of the lesser curvature or high in the fundus. To delineate a questionable injury, the stomach can be digitally occluded at the pylorus while methylene blue-colored saline is instilled via a nasogastric (NG) tube. Alternatively, air can be introduced via the NG tube with the abdomen filled with saline. Partial gastrectomy may be required for destructive injuries, with resection of the distal antrum or pylorus reconstructed using a Billroth procedure. Patients with injuries that damage both Latarjet nerves or vagi should undergo a drainage procedure (see Chapter 26). Small intestine injuries can be repaired using a transverse running 3-0 PDS suture if the injury is less than one-third the circumference of the bowel. Destructive injuries or multiple penetrating injuries occurring close together are treated with segmental resection followed by end-to-end anastomosis using a continuous, single-layer 3-0 polypropylene suture. Mesenteric injuries may result in an ischemic segment of intestine, which mandates resection.

Following repair of GI tract injuries, patients may develop a postoperative ileus. Return of bowel function is indicated by a decrease in gastrostomy or nasogastric tube output. The topic of nutrition is well covered in other chapters (see Chapter 2), but a few issues warrant mention. Multiple studies have confirmed the importance of early total enteral nutrition (TEN) in the trauma population, particularly its impact in reducing septic complications. The route of enteral feedings (stomach vs. small bowel) tends to be less important because gut tolerance appears equivalent unless there is upper GI tract pathology. Although early enteral nutrition is the goal, evidence of bowel function should be apparent before advancing to goal tube feedings. Overzealous jejunal feeding can lead to small bowel necrosis in the patient recovering from profound shock. Patients undergoing monitoring for nonoperative management of grade III or higher solid organ injuries should receive nothing by mouth for at least 48 hours in case they require an operation. Although there is general reluctance to initiate TEN in patients with an open abdomen, a recent multicenter trial demonstrates that TEN in the postinjury open abdomen is feasible. For those patients without a bowel injury, TEN was associated with higher fascial closure rates, decreased
complications, and decreased mortality. TEN in patients with bowel injuries does not appear to alter fascial closure rates, complications, or mortality; hence, EN appears to be neither advantageous nor detrimental in these patients. Once resuscitation is complete, initiation of TEN, even at trophic levels (20 mL/h), should be considered in all injured patients with an open abdomen.

**Duodenum and Pancreas.** The spectrum of injuries to the duodenum includes hematomas, perforation (blunt blow-outs, lacerations from stab wounds, or blast injury from gunshot wounds), and combined pancreaticoduodenal injuries. The majority of duodenal hematomas are managed nonoperatively with nasogastric suction and parenteral nutrition. Patients with suspected associated perforation, suggested by clinical deterioration or imaging with retroperitoneal free air or contrast extravasation, should undergo operative exploration. A marked drop in nasogastric tube output heralds resolution of the hematoma, which typically occurs within 2 weeks; repeat imaging to confirm these clinical findings is optional. If the patient shows no clinical or radiographic improvement within 3 weeks, operative evaluation is warranted.

Small duodenal perforations or lacerations should be treated by primary repair using a running single-layer suture of 3-0 monofilament. The wound should be closed in a direction that results in the largest residual lumen. Challenges arise when there is a substantial loss of duodenal tissue. Extensive injuries of the first portion of the duodenum (proximal to the duct of Santorini) can be repaired by debridement and end-to-end anastomosis because of the mobility and rich blood supply of the distal gastric atrium and pylorus. In contrast, the second portion is tethered to the head of the pancreas by its blood supply and the ducts of Wirsung and Santorini; therefore, no more than 1 cm of duodenum can be mobilized away from the pancreas. Moreover, suture repair using an end-to-end anastomosis in the second portion often results in an unacceptably narrow lumen. Therefore, defects in the second portion of the duodenum should be “patched” with a Roux-en-Y duodenojejunostomy. Duodenal injuries with tissue loss distal to the papilla of Vater and proximal to the superior mesenteric vessels are best treated by Roux-en-Y duodenojejunostomy with the distal portion of the duodenum oversewn (Fig. 7-64). In particular, injuries in the distal third and fourth portions of the duodenum (behind the mesenteric vessels) should be resected, and a duodenojejunostomy should be performed on the D3 side of the superior mesenteric vessels.

Optimal management of pancreatic trauma is determined by where the parenchymal damage is located and whether the intrapancreatic common bile duct and main pancreatic duct remain intact. Patients with pancreatic contusions (defined as injuries that leave the ductal system intact) can be treated nonoperatively or with closed suction drainage if undergoing laparotomy for other indications. Patients with proximal pancreatic injuries, defined as those that lie to the right of the superior mesenteric vessels, are also managed with closed suction drainage. In contrast, distal pancreatic injuries are managed based upon ductal integrity. Pancreatic duct disruption can be identified through direct exploration of the parenchymal laceration, operative pancreatography, ERCP, or magnetic resonance cholangiopancreatography. Patients with distal ductal disruption undergo distal pancreatectomy, preferably with splenic preservation.

Injuries to the pancreatic head add substantial complexity because the intrapancreatic portion of the common bile duct traverses this area and often converges with the pancreatic duct. In contrast to diagnosis of pancreatic duct injuries, identification of intrapancreatic common bile duct disruption is relatively simple. The first method is to squeeze the gallbladder and look for bile leaking from the pancreatic wound. Otherwise, cholangiography, optimally via the cystic duct, is diagnostic. Definitive treatment of this injury entails division of the common bile duct superior to the first portion of the duodenum, with ligation of the distal duct and reconstruction with a Roux-en-Y choledochojejunostomy. For injuries to the head of the pancreas that involve the main pancreatic duct but not the intrapancreatic bile duct, there are few options. Distal pancreatectomy alone is rarely indicated due to the extended resection of normal gland and the resultant risk of pancreatic insufficiency. Central pancreatectomy preserves the common bile duct, and mobilization of the pancreatic body permits drainage into a posterior wall pancreaticogastrostomy or a Roux-en-Y pancreaticojejunostomy (Fig. 7-65). Although this approach avoids a pancreaticoduodenectomy (Whipple procedure), the complexity may make the pancreaticoduodenectomy more appropriate in patients with multiple injuries and is usually done in a damage control scenario. Some injuries of the pancreatic head do not involve either the pancreatic or common bile duct; if no clear ductal injury is present, drains are placed. Rarely, patients sustain destructive injuries to the head of the pancreas or combined pancreaticoduodenal injuries that require pancreaticoduodenectomy. Examples of such injuries include transection of both the intrapancreatic bile duct and the main pancreatic duct in the head of the pancreas, avulsion of the papilla of Vater from the duodenum, and destruction
of the entire second portion of the duodenum. In these cases of extensive injuries, damage control principles are often employed.

In contrast to proximal injuries, pancreatic resection continues to be advocated for major ductal disruption in the more distal pancreas. Several options exist for treating injuries of the pancreatic body and tail. In stable patients, spleen-preserving distal pancreatectomy should be performed. An alternative, which preserves both the spleen and distal transected end of the pancreas, is either a Roux-en-Y pancreaticojejunostomy or pancreaticogastrostomy. If the patient is physiologically compromised, distal pancreatectomy with splenectomy is the preferred approach. Regardless of the choice of definitive procedure, the pancreatic duct in the proximal edge of transected pancreas should be individually ligated or occluded with a TA stapler. Application of fibrin glue over the stump may be advantageous.

Pyloric exclusion may be used to divert the GI stream after high-risk, complex duodenal repairs, particularly with adjacent pancreatic injuries (Fig. 7-66). If the duodenal repair breaks down, the resultant fistula is an end fistula, which is easier to manage and more likely to close than a lateral fistula. To perform a pyloric exclusion, first a gastrostomy is made on the greater curvature near the pylorus. The pylorus is then grasped with a Babcock clamp, via the gastrostomy, and oversewn with an O polypropylene suture. A gastrojejunostomy restores GI tract continuity. Vagotomy is not necessary because a risk of marginal ulceration has not been documented. Perhaps surprisingly, the sutures maintain diversion for only 3 to 4 weeks. Alternatively, the most durable pyloric closure is a double external staple line across the pylorus using a TA stapler.

Complications should be expected after major pancreaticoduodenal injuries. Delayed hemorrhage is rare but may occur with pancreatic necrosis or abdominal infection; this usually can be managed by angioembolization. If closed suction drains have been inserted for major pancreatic trauma, these should remain in place until the patient is tolerating an oral diet or enteral nutrition. Pancreatic fistula is diagnosed after postoperative day 5 in patients with drain output of ≥30 mL/d and a drain amylase level three times the serum value. Pancreatic fistula develops in over 20% of patients with combined injuries and should be managed similar to fistulas after elective surgery (see Chapter 33). Similarly, a duodenal fistula, presumptively an end fistula if a pyloric exclusion has been done, will typically heal in 6 to 8 weeks with adequate drainage and control of intra-abdominal sepsis. Pancreatic pseudocysts in patients managed nonoperatively suggest a missed injury, and ERCP should be done to evaluate the integrity of the pancreatic duct. Late pseudocysts may be a complication of operative management and are treated much like those in patients with pancreatitis (see Chapter 33). Intra-abdominal abscesses are common and routinely managed with percutaneous drainage.

Colon and Rectum. Currently, three methods for treating colonic injuries are used: primary repair, end colostomy, and primary repair with diverting loop ileostomy. Primary repairs include lateral suture repair or resection of the damaged segment with reconstruction by ileocolostomy or colocolostomy. All suturing and anastomoses are performed using a running single-layer technique (Fig. 7-67). The advantage of definitive treatment must be balanced against the possibility of anastomotic leakage if suture lines are created under suboptimal conditions. Alternatively, although use of an end colostomy requires a second operation, an unprotected suture line with
**Figure 7-66.** A. Pyloric exclusion is used to treat combined injuries of the duodenum and the head of the pancreas as well as isolated duodenal injuries when the duodenal repair is less than optimal. B and C. The pylorus is oversewn through a gastrotomy, which is subsequently used to create a gastrojejunostomy. The authors frequently use operatively placed feeding jejunostomy tube feedings for these patients.

**Figure 7-67.** Technique for bowel repair and anastomosis. A. The running, single-layer suture is started at the mesenteric border. B. Stitches are spaced 3 to 4 mm from the edge of the bowel and advanced 3 to 4 mm, including all layers except the mucosa. C. The continuous suture is tied near the antimesenteric border.
Rectal injuries are similar to colonic injuries with respect to the ecology of the luminal contents, overall structure, and blood supply of the wall, but access to extraperitoneal injuries is limited due to the surrounding bony pelvis. Therefore, indirect treatment with intestinal diversion usually is required. The current options are loop ileostomy and sigmoid loop colostomy. The latter is preferred because it is quick and easy to perform, and provides essentially total fecal diversion. For sigmoid colostomy, technical elements include: (a) adequate mobilization of the sigmoid colon so that the loop will rest on the abdominal wall without tension, (b) maintenance of the spur of the colostomy (the common wall of the proximal and distal limbs after maturation) above the level of the skin with a one-half-inch Penrose drain or similar device, (c) longitudinal incision in the tenia coli, and (d) immediate maturation in the OR (Fig. 7-68). If the injury is accessible (e.g., in the posterior intraperitoneal portion of the rectum), repair of the injury should also be attempted. However, it is not necessary to explore the extraperitoneal rectum to repair a distal perforation. If the rectal injury is extensive, another option is to divide the rectum at the level of the injury, oversew or staple the distal rectal pouch if possible, and create an end colostomy (Hartmann’s procedure). Extensive injuries may warrant presacral drainage with Penrose drains placed along Waldeyer’s fascia via a perianal incision (see Fig. 7-68), but routine presacral drainage and rectal washout is no longer practiced. In rare instances in which destructive injuries are present, an abdominoperineal resection may be necessary to avert lethal pelvic sepsis.

Complications related to colorectal injuries include intra-abdominal abscess, fecal fistula, wound infection, and stomal complications. Intra-abdominal abscesses occur in approximately 10% of patients, and most are managed with percutaneous drainage. Fistulas occur in 1% to 3% of patients and usually present as an abscess or wound infection with subsequent continuous drainage of fecal output; the majority will heal spontaneously with routine care (see Chapter 29). Stomal complications (necrosis, stenosis, obstruction, and prolapse) occur in 5% of patients and may require either immediate or delayed reoperation. Stomal necrosis should be carefully monitored because spread beyond the mucosa may result in septic complications, including necrotizing fasciitis of the abdominal wall. Penetrating injuries that involve both the rectum and adjacent bony structures are prone to development of osteomyelitis. Bone biopsy is performed for diagnosis and bacteriologic analysis, and treatment entails long-term IV antibiotic therapy and occasionally debridement.

**Abdominal and Pelvic Vasculature.** Injury to the major arteries and veins in the abdomen can be a technical challenge. Although penetrating trauma indiscriminately affects all blood vessels, blunt trauma most commonly involves renal vasculature and occasionally the abdominal aorta. Patients with a penetrating aortic wound who survive to reach the OR frequently have a contained hematoma within the retroperitoneum. Due to lack of mobility of the abdominal aorta, few injuries are amenable to primary repair. Supraceliac aortic wounds are particularly challenging due to the need for proximal control. Small lateral perforations may be controlled with 4-0 polypropylene suture or a PTFE patch, but end-to-end interposition grafting with a PTFE tube graft is the most common repair. Blunt injuries are typically extensive intimal tears of the infrarenal aorta with resultant thrombosis, and are exposed via a direct approach; most require an interposition graft. To avoid future vascular-enteric fistulas, the vascular suture lines should be covered with omentum.

---

**Figure 7-68.** Loop colostomy will completely divert the fecal flow, allowing the low rectal injury to heal. For extensive wounds, presacral drains are inserted through a perianal incision (box) and advanced along Waldeyer’s fascia (dashed line).
Penetrating wounds to the superior mesenteric artery (SMA) are typically encountered after exploration for a gunshot wound, with “black bowel” and associated supramesocolic hematoma being pathognomonic. Blunt avulsions of the SMA are rare but should be considered in patients with a seat belt sign who have midepigastric pain or tenderness and associated hypotension. For injuries of the SMA, temporary damage control with a Pruitt-Inahara shunt can prevent extensive bowel necrosis. For definitive repair, end-to-end interposition RSVG from the proximal SMA to the SMA past the point of injury can be performed if there is no associated pancreatic injury. Alternatively, if the patient has an associated pancreatic injury, the graft should be tunnelled from the distal aorta beneath the duodenum to the distal SMA. For proximal SMV injuries, digital compression for hemorrhage control is followed by attempted venorrhaphy; ligation is an option in a life-threatening situation, but the resultant bowel edema requires aggressive fluid resuscitation. Temporary abdominal closure and a second-look operation to evaluate bowel viability should be done.

Transpelvic gunshot wounds or blunt injuries with associated pelvic fractures are the most common scenarios in patients with iliac artery injuries. As with abdominal vascular injuries, a Pruitt-Inahara shunt can be used for temporary shunting of the vessel for damage control. Definitive interposition grafting with excision of the injured segment is appropriate (see “Vascular Repair Techniques”). Careful monitoring for distal embolic events and reperfusion injury necessitating fasciotomy is imperative.

In general, outcome after pelvic vascular injuries is related to (a) the technical success of the vascular reconstruction and (b) associated soft tissue and nerve injuries. Vascular repairs rarely fail after the first 12 hours, whereas soft tissue infection is a limb threat for several weeks. Following aortic interposition grafting, the patient’s SBP should not exceed 120 mmHg for at least the first 72 hours postoperatively. Patients requiring ligation of an inferior vena cava injury often develop marked bilateral lower extremity edema. To limit the associated morbidity, the patient’s legs should be wrapped with elastic bandages from the toes to the hips and elevated. For superior mesenteric vein injuries, either ligation or thrombosis after venorrhaphy results in marked bowel edema; fluid resuscitation should be aggressive and abdominal pressure monitoring routine in these patients. Prosthetic graft infections are rare complications, but prevention of bacteremia is imperative; administration of antibiotics perioperatively and treatment of secondary infections is indicated. Long-term arterial graft complications such as stenosis or pseudoaneurysms are uncommon, and routine graft surveillance rarely is performed. Consequently, long-term administration of antiplatelet agents or antithrombotics is not routine.

**Genitourinary Tract.** Historically, when undergoing laparotomy for trauma, all penetrating wounds to the kidneys were explored; recently, routine exploration of Gerota’s fascia has been questioned. Parenchymal renal injuries are treated with hemostatic and reconstructive techniques similar to those used for injuries of the liver and spleen: topical methods (electrocautery; argon beam coagulation; application of thrombin-soaked gelatin foam sponge, fibrin glue, or BioGlue) and pledged suture repair. However, two caveats are recognized: the collecting system should be closed separately, and the renal capsule should be preserved to close over the repair of the collecting system (Fig. 7-69). Renal vascular injuries are common after penetrating trauma and may be deceptive due to tamponade by Gerota’s

---

**Figure 7-69.** When renorrhaphy is undertaken, effective repair is assisted by attention to several key points: **A.** Vascular occlusion controls bleeding and permits adequate visualization. **B.** The renal capsule is carefully preserved. **C.** The collecting system is closed separately with absorbable suture. **D.** The preserved capsule is closed over the collecting system repair.
fascia, which results in delayed hemorrhage. Arterial reconstruction using graft interposition should be attempted within 5 hours of injury for renal preservation. For destructive parenchymal or irreparable renovascular injuries, nephrectomy may be the only option; a normal contralateral kidney must be palpated because unilateral renal agenesis occurs in 0.1% of patients.

Over 90% of blunt renal injuries are treated nonoperatively. Hematuria typically resolves within a few days with bed rest, although rarely bleeding is so persistent that bladder irrigation to displace blood clots is warranted. Persistent gross hematuria may require embolization, whereas urinomas can be drained percutaneously. Operative intervention after blunt trauma is limited to renovascular injuries and destructive parenchymal injuries that result in hypotension. The renal arteries and veins are uniquely susceptible to traction injury caused by blunt trauma. As the artery is stretched, the inelastic intima and media may rupture, which causes thrombus formation and resultant stenosis or occlusion. The success rate for renal artery repair is limited, but an attempt is reasonable if the injury is <5 hours old or if the patient has a solitary kidney or bilateral injuries.140 Image-guided endoluminal stent placement is now employed for many of these injuries recognized by CT scanning. Reconstruction after blunt renal injuries may be difficult, however, because the injury is typically at the level of the aorta. If repair is not possible within this time frame, leaving the kidney in situ does not necessarily lead to the late sequelae of hypertension or abscess formation. The renal vein may be torn or completely avulsed from the vena cava due to blunt trauma. Typically, the large hematoma causes hypotension, which leads to operative intervention. During laparotomy for blunt trauma, expanding or pulsatile perinephric hematomas should be explored. If necessary, emergent vascular control can be obtained by placing a curved vascular clamp across the hilum from an inferior approach. Techniques of repair and hemostasis are similar to those described earlier.

Injuries to the ureters are uncommon but may occur in patients with pelvic fractures and penetrating trauma. An injury may not be identified until a complication (i.e., a urinoma) becomes apparent. If an injury is suspected during operative exploration but is not clearly identified, methylene blue or indigo carmine is administered IV with observation for extravasation. Injuries are repaired using 5-0 absorbable monofilament, and mobilization of the kidney may reduce tension on the anastomosis. Distal ureteral injuries can be treated by reimplantation facilitated with a psoas hitch and/or Boari flap. In damage control circumstances, the ureter can be ligated on both sides of the injury and a nephrostomy tube placed.

Bladder injuries are subdivided into those with intraperitoneal extravasation and those with extraperitoneal extravasation. Ruptures or lacerations of the intraperitoneal bladder are operatively closed with a running, single-layer, 3-0 absorbable monofilament suture. Laparoscopic repair is becoming common in patients not requiring laparotomy for other injuries. Extraperitoneal ruptures are treated nonoperatively with bladder decompression for 2 weeks. Urethral injuries are managed by bridging the defect with a Foley catheter, with or without direct suture repair. Strictures are not uncommon but can be managed electively.

**Female Reproductive Tract.** Gynecologic injuries are rare. Occasionally the vaginal wall will be lacerated by a bone fragment from a pelvic fracture. Although repair is not mandated, it should be performed if physiologically feasible. More important, however, is recognition of the open fracture, need for possible drainage, and potential for pelvic sepsis. Penetrating injuries to the vagina, uterus, fallopian tubes, and ovaries are also uncommon, and routine hemostatic techniques are used. Repair of a transected fallopian tube can be attempted but probably is unjustified because a suboptimal repair will increase the risk of tubal pregnancy. Transection at the injury site with proximal ligation and distal salpingectomy is a more prudent approach.

**Pelvic Fracture Hemorrhage Control**

Patients with pelvic fractures who are hemodynamically unstable are a diagnostic and therapeutic challenge for the trauma team. These injuries often occur in conjunction with other life-threatening injuries, and there is no universal agreement among clinicians on management. Current management algorithms in the United States incorporate variable time frames for bony stabilization and fixation, as well as hemorrhage control by preperitoneal pelvic packing and/or angiembolization. Early institution of a multidisciplinary approach with the involvement of trauma surgeons, orthopedic surgeons, interventional radiologists, the director of the blood bank, and anesthesiologists is imperative due to high associated mortality rates (Fig. 7-70).

Evaluation in the ED focuses on identification of injuries mandating operative intervention (e.g., massive hemothorax or hemoperitoneum) and injuries related to the pelvic fracture that alter management (e.g., injuries to the iliac artery, rectum, urethra, or bladder). Immediate temporary stabilization with sheeting of the pelvis or application of commercially available compression devices should be performed in hemodynamically unstable patients. In patients with profound shock who are at high risk based upon mechanism (e.g., autopedestrian accident), pelvic stabilization should be done before radiographic confirmation. If the patient’s primary source of bleeding is the fracture-related pelvic hematoma, several options exist for hemorrhage control. Because 85% of bleeding due to pelvic fractures is venous or bony in origin, the authors advocate immediate external fixation and preperitoneal pelvic packing.141 Anterior external fixation decreases pelvic volume, which promotes tamponade of venous bleeding and prevents secondary hemorrhage from the shifting of bony elements. Pelvic packing, in which six laparotomy pads (four in children) are placed directly into the paravesical space through a small anterior suprapubic incision, provides tamponade for the bleeding (Fig. 7-71). Pelvic packing also eliminates the often difficult decision by the trauma surgeon: OR vs. interventional radiology? All patients can be rapidly transported to the OR, and packing can be accomplished in under 30 minutes. In the authors’ experience, this results in hemodynamic stability and abrupt cessation of the need for ongoing blood transfusion in the majority of cases.141 Patients also can undergo additional procedures such as laparotomy, thoracotomy, external fixation of extremity fractures, fasciotomy, revascularization, or craniotomy. Following pelvic packing, angiography is reserved for patients with evidence of ongoing pelvic bleeding after admission to the SICU (>4 units of RBCs in the first 12 postoperative hours after the coagulopathy is corrected). Patients undergo standard posttrauma resuscitative SICU care, and the pelvic packs are removed within 48 hours; prior to unpacking, however, the patient’s coagulopathy should be corrected to prevent the need for repacking of the pelvic space. Repacking of the pelvic space is associated with an infection rate of 47% and should be avoided; directed hemostasis with topical agents, suture repair, or electrocauterity at pelvic pack removal should be performed.

Another clinical challenge is the open pelvic fracture. In many instances, the wounds are located in the perineum, and the risk of pelvic sepsis and osteomyelitis is high. To reduce
the risk of infection, performance of a diverting sigmoid colostomy is recommended. The pelvic wound is manually debrided and then irrigated daily with a high-pressure pulsatile irrigation system until granulation tissue covers the wound. The wound is then left to heal by secondary intention with a wound vacuum-assisted wound closure (VAC) device.

Extremity Vascular Injuries, Fractures, and Compartment Syndromes

Patients with injured extremities often require a multidisciplinary approach with involvement of trauma, orthopedic, and plastic surgeons to address vascular injuries, fractures, soft tissue injuries, and compartment syndromes. Immediate stabilization of fractures or unstable joints is done in the ED using Hare traction, knee immobilizers, or plaster splints. In patients with open fractures, the wound should be covered with povidone-iodine (Betadine)-soaked gauze and antibiotics administered. Options for fracture fixation include external fixation or open reduction and internal fixation with plates or intramedullary nails. Vascular injuries, either isolated or in combination with fractures, require emergent repair. Common combined injuries include clavicle/first rib fractures and subclavian artery injuries, dislocated shoulder/proximal humeral fractures and axillary artery injuries, supracondylar fractures/elbow dislocations and brachial artery injuries, femur fracture and superficial femoral artery injuries, and knee dislocation and popliteal vessel injuries. On-table angiography in the OR facilitates rapid intervention and is warranted in patients with evidence of limb threat on arrival. Arterial access for on-table lower extremity angiography can be obtained percutaneously at the femoral vessels with a standard arterial catheter, via femoral vessel exposure and direct cannulation, or with superficial femoral artery (SFA) exposure just above the medial knee. Controversy exists regarding which should be done first, fracture fixation or arterial repair. The authors prefer placement of temporary intravascular shunts first to reestablish arterial flow and minimize ischemia during fracture treatment, with definitive vascular repair following. Rarely, immediate amputation may be considered due to the severity of orthopedic and neurovascular injuries. This is particularly true if primary nerve transection is present in addition to fracture and arterial injury. Collaborative decision making by the trauma, orthopedic, and plastic/reconstructive team is essential.

Figure 7-70. Management algorithm for patients with pelvic fractures with hemodynamic instability. CT = computed tomography; ED = emergency department; FAST = focused abdominal sonography for trauma; HD = hemodynamic; PLT = platelets; PRBCs = packed red blood cells; SICU = surgical intensive care unit.
Operative intervention for vascular injuries should follow standard principles of repair (see “Vascular Repair Techniques”). For subclavian or axillary artery repairs, 6-mm PTFE graft or RSVG are used depending on the location. Because associated injuries of the brachial plexus are common, a thorough neurologic examination of the extremity is mandated before operative intervention. Operative approach for a brachial artery injury is via a medial upper extremity longitudinal incision; proximal control may be obtained at the axillary artery, and an S-shaped extension through the antecubital fossa provides access to the distal brachial artery. The injured vessel segment is excised, and an end-to-end interposition RSVG graft is performed. Upper extremity fasciotomy is rarely required because of the rich collateral perfusion via the profunda. For SFA injuries, external fixation of the femur typically is performed, followed by end-to-end RSVG of the injured SFA segment. Close monitoring for calf compartment syndrome is mandatory. Preferred access to the popliteal space for an acute injury is the medial, one-incision approach with detachment of the semitendinosus, semimembranosus, and gracilis muscles (Fig. 7-72). Another option is a medial approach

Figure 7-71. A. Pelvic packing is performed through a 6- to 8-cm midline incision made from the pubic symphysis cephalad, with division of the midline fascia. B. The pelvic hematoma often dissects the preperitoneal and paravesical space down to the presacral region, which facilitates packing; alternatively, blunt digital dissection opens the preperitoneal space for packing. C. Three standard surgical laparotomy pads are placed on each side of the bladder, deep within the preperitoneal space; the fascia is closed with an O polydioxanone monofilament suture and the skin with staples.

Figure 7-72. A. The popliteal space is commonly accessed using a single medial incision (the detached semitendinosus, semimembranosus, and gracilis muscles are identified by different suture types). B. Alternatively, a medial approach with two incisions may be used. Insertion of a Pruitt-Inahara shunt (arrow) provides temporary restoration of blood flow, which prevents ischemia during fracture treatment.
with two incisions using a longer RSVG, but this requires interval ligation of the popliteal artery and geniculate branches. Rarely, with open wounds a straight posterior approach with an S-shaped incision can be used. If the patient has an associated popliteal vein injury, this should be repaired first with a PTFE interposition graft while the artery is shunted. For an isolated popliteal artery injury, RSVG is performed with an end-to-end anastomosis. Compartment syndrome is common, and presumptive four-compartment fasciotomies are warranted in patients with combined arterial and venous injury. Once the vessel is repaired and restoration of arterial flow documented, completion angiography should be done in the OR if there is no palpable distal pulse. Vasoparalysis with verapamil, nitroglycerin, and papaverine may be used to treat vasoconstriction (Table 7-11).

Compartment syndromes, which can occur anywhere in the extremities, involve an acute increase in pressure inside a closed space, which impairs blood flow to the structures within. Causes of compartment syndrome include arterial hemorrhage into a compartment, venous ligation or thrombosis, crush injuries, and reperfusion injury. In conscious patients, pain is the prominent symptom, and active or passive motion of muscles in the involved compartment increases the pain. Paresthesias may also be described. In the lower extremity, numbness between the first and second toes is the hallmark of early compartment syndrome in the exquisitely sensitive anterior compartment and its enveloped deep peroneal nerve. Progression to paralysis can occur, and loss of pulses is a late sign. In comatose or obtunded patients, the diagnosis is more difficult to secure. In patients with a compatible history and a tense extremity, compartment pressures should be measured with a hand-held Stryker device. Fasciotomy is indicated in patients with a gradient of <30 mmHg (gradient = diastolic pressure – compartment pressure), an absolute compartment pressure >30 mmHg, ischemic periods of >6 hours, or combined arterial and venous injuries. The lower extremity is most frequently involved, and compartment release is performed using a two-incision, four-compartment fasciotomy (Fig. 7-73). Of note, the soleus muscle must be detached from the tibia to decompress the deep flexor compartment.

### SURGICAL INTENSIVE CARE MANAGEMENT

#### Postinjury Resuscitation

ICU management of the trauma patient, either with direct admission from the ED or after emergent operative intervention, is considered in distinct phases because there are differing goals and priorities. The period of acute resuscitation, typically lasting for the first 12 to 24 hours after injury, combines several key principles: optimizing tissue perfusion, ensuring normothermia, and restoring coagulation status. There are a multitude of management algorithms aimed at accomplishing these goals, the majority of which involve goal-directed resuscitation with initial volume loading to attain adequate preload, followed by judicious use of inotropic agents or vasopressors. Although the optimal hemoglobin level remains debated, during shock resuscitation a hemoglobin level of >10 g/dL is generally accepted to optimize hemostasis and ensure adequate oxygen delivery. After the first 24 hours of resuscitation, a more judicious transfusion trigger of a hemoglobin level of <7 g/dL in the euvolemic patient limits the adverse inflammatory effects of stored RBCs. Recent trends have focused on limiting crystalloid loading. In fact, optimizing crystalloid administration is a challenging aspect of early care (i.e., balancing cardiac performance against generation of an abdominal compartment syndrome and generalized tissue edema). Although early colloid administration is appealing, evidence to date does not support this concept.

Invasive monitoring with pulmonary artery catheters has been supplanted with specialized catheters that measure arterial pulse contour analysis; in mechanically ventilated patients, stroke volume (SV) and continuous cardiac output can be measured. A patient’s volume status may be ascertained by measuring the SV following either 10 cc/kg volume bolus or following a passive leg raise, which augments preload by 250 to 500 mL. A change in SV of ≥10% suggests preload responsiveness, and additional resuscitation fluid should be given. Although norepinephrine is the agent of choice for patients with low systemic vascular resistance who are unable to maintain a mean arterial pressure of >60 mmHg, patients may have an element of myocardial dysfunction requiring inotropic support. The role of relative adrenal insufficiency is another controversial area.

Optimal early resuscitation is mandatory and determines when the patient can (a) undergo additional necessary imaging, and (b) be returned to the OR after initial damage control surgery for definitive repair of injuries. Specific goals of resuscitation before repeated “semi-elective” transport include a core temperature of >35°C (95°F), base deficit of <6 mmol/L, and normal coagulation indices. Although correction of metabolic acidosis is desirable, how quickly this should be accomplished requires careful consideration. Adverse sequelae of excessive crystalloid resuscitation include increased intracranial pressure, worsening pulmonary edema, and intra-abdominal visceral and retroperitoneal edema resulting in secondary abdominal compartment syndrome. Therefore, it should be the overall trend of the resuscitation rather than a rapid reduction of the base deficit that is the goal. The goal is to normalize lactate within 24 hours.

In general, wounds sustained from trauma should be examined daily for progression of healing and signs of infection. Complex soft tissue wounds of the abdomen, such as degloving injuries after blunt trauma (termed Morel-Lavallée lesions), shotgun wounds, and other destructive blast injuries, are particularly difficult to manage. Following initial debridement of devitalized tissue, wound care includes wet-to-dry dressing changes twice daily or application of a VAC device. Repeated operative debridement may be necessary, and early involvement of the reconstructive surgery service for possible flap coverage is advised. Midline laparotomy wounds are inspected 48 hours postoperatively by removing the sterile surgical dressing. If an ileostomy or colostomy is required, one should inspect it...
daily to ensure that it is viable. If the patient develops a high-grade fever, the wound should be inspected sooner to exclude an early necrotizing infection. If a wound infection is identified— as evidenced by erythema, pain along the wound, or purulent drainage—the wound should be widely opened by removing skin staples. After ensuring that the midline fascia is intact with digital palpation, the wound is initially managed with wet-to-dry dressing changes. The most common intra-abdominal complications are anastomotic failure and abscess. The choice between percutaneous and operative therapy is based on the location, timing, and extent of the collection.

**Abdominal Compartment Syndrome**

The abdominal compartment syndrome is classified as pathologic intra-abdominal hypertension due to intra-abdominal injury (primary) or splanchnic reperfusion after massive resuscitation (secondary). Secondary abdominal compartment syndrome may result from any condition requiring extensive crystalloid resuscitation, including extremity trauma, chest trauma, or even postinjury sepsis. The sources of increased intra-abdominal pressure include bowel edema, ascites, bleeding, and packs. A diagnosis of intra-abdominal hypertension cannot reliably be made by physical examination; therefore, it is obtained by measuring the intraperitoneal pressure. The most common technique is to measure the patient’s bladder pressure. Fifty milliliters of saline is instilled into the bladder via the aspiration port of the Foley catheter with the drainage tube clamped, and a three-way stopcock and water manometer is placed at the level of the pubic symphysis. Bladder pressure is then measured on the manometer in centimeters of water (Table 7-12) and

Figure 7-73. A. The anterior and lateral compartments are approached from a lateral incision, with identification of the fascial raphe between the two compartments. Care must be taken to avoid the superficial peroneal nerve running along the raphe. B. To decompress the deep flexor compartment, which contains the tibial nerve and two of the three arteries to the foot, the soleus muscle must be detached from the tibia.

Increased abdominal pressure affects multiple organ systems (Fig. 7-74). Abdominal compartment syndrome, as noted earlier, is defined as intra-abdominal hypertension sufficient to produce physiologic deterioration and manifests via such end-organ sequelae as decreased urine output, increased pulmonary inspiratory pressures, decreased cardiac preload, and decreased cardiac output. Because any of these clinical symptoms of abdominal compartment syndrome may be attributed to the primary injury, a heightened awareness of this syndrome must be maintained. Organ failure can occur over a wide range of recorded bladder pressures. Generally, no specific bladder pressure prompts therapeutic intervention, except when the pressure is >35 mmHg. Rather, emergent decompression is carried out when intra-abdominal hypertension reaches a level at which end-organ dysfunction occurs. Mortality is directly affected by the timing of decompression, with 70% mortality in patients with a delay in decompression, and nearly uniform mortality in those not undergoing decompression. Decompression is usually performed operatively, either in the ICU if the patient is hemodynamically unstable or in the OR. ICU bedside laparotomy is easily accomplished, avoids transport of hemodynamically compromised patients, and requires minimal equipment (e.g., scalpel, suction device, cautery, and dressings for temporary abdominal closure). In patients with significant intra-abdominal fluid as the primary component of abdominal compartment syndrome, rather than bowel or retroperitoneal edema, decompression can be accomplished effectively via a percutaneous drain. These patients are identified by bedside ultrasound, and the morbidity of a laparotomy is avoided. When operative decompression is required with egress of the abdominal contents, temporary coverage is obtained using a fenestrated subfascial 45 × 60 cm sterile drape and Ioban application (see Fig. 7-49).

The performance of damage control surgery and recognition of abdominal compartment syndrome have dramatically improved patient survival, but at the cost of an open abdomen. Several management points deserve attention. Despite having a widely open abdomen, patients can develop recurrent abdominal compartment syndrome, which increases their morbidity and mortality; therefore, bladder pressure should be monitored every 4 hours, with significant increases in pressures alerting the clinician to the possible need for repeat operative decompression. Patients with an open abdomen lose between 500 and 2500 mL per day of abdominal effluent. Appropriate volume compensation for this albumin-rich fluid remains controversial, with regard to both the amount administered (replacement based on clinical indices vs. routine 0.5 mL replacement for every milliliter lost) as well as the type of replacement (crystalloid vs. colloid).

Following resuscitation and management of specific injuries, the goal of the operative team is to close the abdomen as quickly as possible. Multiple techniques have been introduced to obtain fascial closure of the open abdomen to minimize morbidity and cost of care. Historically, for patients who could not be closed at repeat operation, approximation of the fascia with mesh (prosthetic or biologic) was used, with planned reoperation. Another option was split-thickness skin grafts applied directly to the exposed bowel for coverage; removal of the skin...
grids was planned 9 to 12 months after the initial surgery, with definitive repair of the hernia by component separation. However, delayed abdominal wall reconstruction was resource intensive, with considerable patient morbidity. The advent of VAC technology has revolutionized fascial closure. The authors currently use a sequential closure technique with the wound VAC device that is based on constant fascial tension and return to the OR every 48 hours until closure is complete (Fig. 7-75). The authors’ success rate with this approach exceeds 95%. This is important because among patients not attaining fascial closure, 20% suffer GI tract complications that prolong their hospital course. These include intra-abdominal abscess, enteric fistula, and bowel perforations (Fig. 7-76). Management requires frequent operative or percutaneous drainage of abscesses, control of fistulas, and prolonged nutritional support.

**SPECIAL POPULATIONS**

**Pregnant Patients**

During pregnancy, 7% of women are injured. Motor vehicle collisions and falls are the leading causes of injury, accounting for 70% of cases. Fetal death after trauma most frequently occurs after motor vehicle collisions, but only 11% of fetal deaths are due to the death of the mother; therefore, early trauma resuscitation and management is directed not only at the mother but also at the fetus. Domestic violence is also common, affecting between 10% and 30% of pregnant women and resulting in fetal mortality of 5%.

Pregnancy results in physiologic changes that may impact postinjury evaluation (Table 7-13). Heart rate increases by 10 to 15 beats per minute during the first trimester and remains elevated until delivery. Blood pressure diminishes during the first two trimesters due to a decrease in systemic vascular resistance and rises again slightly during the third trimester (mean values: first = 105/60, second = 102/55, third = 108/67). Intra-vascular volume is increased by up to 8 L, which results in a relative anemia but also a relative hypervolemia. Consequently, a pregnant woman may lose 35% of her blood volume before exhibiting signs of shock. Pregnant patients have an increase in tidal volume and minute ventilation but a decreased functional residual capacity; this results in a diminished PCO₂ and respiratory alkalosis. Also, pregnant patients may desaturate more rapidly, particularly in the supine position and during intubation. Supplemental oxygen is always warranted in the trauma patient but is particularly critical in the injured pregnant patient because the oxygen dissociation curve is shifted to the left for the fetus compared to the mother (i.e., small changes in maternal oxygenation result in larger changes for the fetus because the fetus is operating in the steep portion of the dissociation curve). Anatomic changes contribute to these pulmonary functional alterations and are relevant in terms of procedures. With the gravid uterus enlarged, DPL should be performed in a supraumbilical site with the catheter directed cephalad. In addition, the upward pressure on the diaphragm calls for caution when placing a thoracostomy tube; standard positioning may result in an infra-abdominal location or perforation of the diaphragm.

Other physiologic changes during pregnancy affect the GI, renal, and hematologic systems. The lower esophageal sphincter has decreased competency, which increases the risk for aspiration. Liver function test values increase, with the alkaline phosphatase level nearly doubling. The high levels of progesterone impair gallbladder contractions, which results in bile stasis and an increased incidence of gallstone formation; this may not affect the trauma bay evaluation but becomes important in a prolonged ICU stay. Plasma albumin level decreases from a normal of around 4.3 g/dL to an average of 3.0 g/dL. Renal blood flow increases by 30% during pregnancy, which causes a decrease in serum level of blood urea nitrogen and creatinine. The uterus may also compress the ureters and bladder, causing hydronephrosis and hydroureter. Finally, as noted earlier there is a relative anemia during pregnancy, but a hemoglobin level of <11 g/dL is considered abnormal. Additional hematologic changes include a moderate leukocytosis (up to 20,000 mm³) and a relative hypercoagulable state due to increased levels of factors VII, VIII, IX, X, and XII and decreased fibrinolytic activity.

During evaluation in the ED, the primary and secondary surveys commence, with mindfulness that the mother always receives priority while conditions are still optimized for the fetus. This management includes provision of supplemental oxygen (to prevent maternal and fetal hypoxia), fluid resuscitation (the hypervolemia of pregnancy may mask signs of shock), and placement of the patient in the left lateral decubitus position (or tilting of the backboard to the left) to avoid caval compression. Assessment of the fetal heart rate is the most valuable information regarding fetal viability. Fetal monitoring should initially be assessed with bedside FAST ultrasound to document the heart rate of the fetus; subsequent monitoring should be performed with a cardiotocographic device that measures both contractions and fetal heart tones (FHTs). Because change in heart rate is the primary response of the fetus to hypoxia or hypotension, anything above an FHT of 160 is a concern, whereas bradycardia (FHT of <120) is considered fetal distress. Indications for emergent cesarean section include: (a) severe maternal shock or impending death (if the fetus is delivered within 5 minutes, survival is estimated at 70%), (b) uterine injury or significant fetal distress (anticipated survival rates of >70% if FHTs are present and fetal gestational age is >28 weeks).

If possible, a member of the obstetrics team should be present during initial evaluation. Vaginal bleeding can signal early cervical dilation and labor, abruptio placentae, or placenta previa. Amniotic sac rupture can result in prolapse of the umbilical cord with fetal compromise. Strong contractions are associated with true labor and should prompt consideration of delivery and resuscitation of the neonate. Focused prenatal history-taking should elicit a history of pregnancy-induced hypertension, gestational diabetes, congenital heart disease, preterm labor, or placental abnormalities. Asking the patient when the baby first moved and if she is currently experiencing movement of the fetus is important. Determining fetal age is key for considerations of viability. Gestational age may be estimated by noting fundal height, with the fundus approximating the umbilicus at 20 weeks and the costal margin at 40 weeks. Discrepancy in dates and size may be due to uterine rupture or hemorrhage.

Initial evaluation for abdominopelvic trauma in pregnant patients should proceed in the standard manner. Ultrasound (FAST) of the abdomen should evaluate the four windows (pericardial, right and left upper quadrant, and bladder) and additionally assess FHTs, fetal movement, and sufficiency of amniotic fluid. DPL can be performed in pregnant women via a supraumbilical, open technique. Trauma radiography of pregnant patients presents a conundrum. Radiation damage has three distinct phases of damage and effect: preimplantation, during the period of organogenesis from 3 to 16 weeks, and after 16 weeks. Generally, it is accepted that “safe” doses of radiation
Figure 7-75. The authors’ sequential closure technique for the open abdomen. A. Multiple white sponges (solid arrow), stapled together, are placed on top of the bowel underneath the fascia. Interrupted No. 1 polydioxanone sutures are placed approximately 5 cm apart (dashed arrow), which puts the fascia under moderate tension over the white sponge. B. After the sticky clear plastic vacuum-assisted closure (VAC) dressing is placed over the white sponges and adjacent 5 cm of skin, the central portion is removed by cutting along the wound edges. C and D. Black VAC sponges are placed on top of the white sponges and plastic-protected skin with standard occlusive dressing and suction. E. On return to the operating room (OR) 48 hours later, fascial sutures are placed from both the superior and inferior directions until tension precludes further closure; skin is closed over the fascial closure with skin staples. F. White sponges (fewer in number) are again applied and fascial retention sutures are placed with planned return to the OR in 48 hours.
Complications after split-thickness skin graft closure of the abdomen include enterocutaneous fistulas (intubated here with a red rubber catheter) (A; arrow), rupture of the graft with exposure of the bowel mucosa (B), enteroatmospheric fistulas with a large ventral hernia and loss of abdominal domain (C).

Figure 7-76. Complications after split-thickness skin graft closure of the abdomen include enterocutaneous fistulas (intubated here with a red rubber catheter) (A; arrow), rupture of the graft with exposure of the bowel mucosa (B), enteroatmospheric fistulas with a large ventral hernia and loss of abdominal domain (C).

loss may be related to both maternal shock and direct injury to the uterus or fetal head. Penetrating injuries in this patient population also carry a high risk. The gravid uterus is a large target, and any penetrating injury to the abdomen may result in fetal injury depending on trajectory and uterine size. Gunshot wounds to the abdomen are associated with a 70% injury rate to the uterus and 35% mortality rate of the fetus. If the bullet traverses the uterus and the fetus is viable, cesarean section should be performed. On the other hand, stab wounds do not often penetrate the thick wall of the uterus.

Any patient with a viable pregnancy should be monitored after trauma, with the length of monitoring determined by the injury mechanism and patient physiology. Patients who are
symptomatic, defined by the presence of uterine irritability or contractions, abdominal tenderness, vaginal bleeding, or blood pressure instability, should be monitored in the hospital for at least 24 hours. In addition, patients at high risk for fetal loss (those experiencing vehicle ejection or involved in motorcycle or pedestrian collisions and those with maternal tachycardia, Injury Severity Score of >9, gestational period of >35 weeks, or history of prior assault) also warrant careful monitoring. Patients without these risk factors who are asymptomatic can be monitored for 6 hours in the ED and sent home if no problems develop. They should be counseled regarding warning signs that mandate prompt return to the ED.

Geriatric Patients
Elderly trauma patients (>65 years of age) are hospitalized twice as often as those in any other age group, and this population accounts for one quarter of all trauma admissions. Although the physiology of aging separates older trauma patients from the younger generation (Table 7-14), treatment must remain individualized (some octogenarians look and physiologically act 50 years old, whereas others appear closer to 100 years). No chronologic age is associated with a higher morbidity or mortality, but a patient’s comorbidities do impact the individual’s postinjury course and outcome. For example, recognition that a patient is taking β-blockers affects the physician’s evaluation of vital signs in the ED and impacts treatment course in the ICU. Early monitoring of arterial blood gas values will identify occult shock. A base deficit of >6 mmol/L is associated with a twofold higher risk of mortality in patients over the age of 55 than in younger patients (67% vs. 30%).

Although the published literature on geriatric traumatic brain injury is relatively sparse and uncontrolled with regard to management, some interesting points are noted. First, as anticipated, outcomes are worse in this age group than in their younger counterparts. Based on data from the Traumatic Coma Databank, mortality in patients with severe head injury more than doubles after the age of 55. Moreover, 25% of patients with a normal GCS score of 15 had intracranial bleeding, with an associated mortality of 50%. Just as there is no absolute age that predicts outcome, admission GCS score is a poor predictor of individual outcome. Therefore, the majority of trauma centers advocate an initial aggressive approach with reevaluation at the 72-hour mark to determine subsequent care.

One of the most common sequelae of blunt thoracic trauma is rib fractures. In the aging population, perhaps due to osteoporosis, less force is required to cause a fracture. In fact, in one study, 50% of patients >65 years old sustained rib fractures from a fall of <6 ft, compared with only 1% of patients <65 years of age. Concurrent pulmonary contusion is noted in up to 35% of patients, and pneumonia complicates the injuries in 10% to 30% of patients with rib fractures, not surprisingly leading to longer ICU stays. Additionally, mortality increases linearly with the number of rib fractures. Patients who sustain more than six rib fractures have pulmonary morbidity rates of >50% and overall mortality rates of >20%.

Chronologic age is not the best predictor of outcome, but the presence of preexisting conditions, which affect a patient’s physiologic age, is associated with increased mortality rates. Injury Severity Score is probably the best overall predictor of patient outcome in the elderly; however, for any given individual its sensitivity may not be precise, and there is a time delay in obtaining sufficient information to calculate the final score. In addition to preexisting conditions and severity of injury, the occurrence of complications compounds the risk for mortality.

### Table 7-13
**Physiologic effects of pregnancy**

**Cardiovascular**
- Increase in heart rate by 10–15 bpm
  - (a) Decreased systemic vascular resistance resulting in:
  - (b) Increased intravascular volume
- Decreased blood pressure during the first two trimesters

**Pulmonary**
- Elevated diaphragm
- Increased tidal volume
- Increased minute ventilation
- Decreased functional residual capacity

**Hematopoietic**
- Relative anemia
- Leukocytosis

**Hypercoagulability**
- (a) Increased levels of factors VII, VIII, IX, X, XII
- (b) Decreased fibrinolytic activity

**Other**
- Decreased competency of lower esophageal sphincter
- Increased enzyme levels on liver function tests
- Impaired gallbladder contractions
- Decreased plasma albumin level
- Decreased blood urea nitrogen and creatinine levels
- Hydronephrosis and hydroureter

### Table 7-14
**Physiologic effects of aging**

**Cardiovascular**
- Atherosclerotic disease that limits cardiac response to stress
- Progressive stiffening and loss of elasticity of the myocardium
- Diminished stroke volume, systolic contraction, and diastolic relaxation
- Decrease in cardiac output of 0.5% per year
- Thickening and calcification of the cardiac valves, which results in valvular incompetence

**Pulmonary**
- Loss of compliance
- Progressive loss of alveolar size and surface area
- Air trapping and atelectasis

**Intracranial**
- Loss of cerebral volume, resulting in:
  - (a) Increased risk of tearing of bridging veins with smaller injuries
  - (b) Accumulation of a significant amount of blood before symptoms occur
  - (c) Muscle loss
- Senescence of the senses

**Other**
- Decline in creatinine clearance by 80%–90%
- Osteoporosis, which causes a greater susceptibility to fractures
Pediatric Patients
Twenty million children, or almost one in four children, are injured each year, with an associated cost of treating the injured child of $16 billion per year. Injury is the leading cause of death among children over the age of 1 year, with 15,000 to 25,000 pediatric deaths per year. Disability after traumatic injury is more devastating, with rates 3 to 10 times that of the death rate. Pediatric trauma involves different mechanisms, different constellations of injury, and the potential for long-term problems related to growth and development. As with adult trauma, over 85% of pediatric trauma has a blunt mechanism, with boys injured twice as often as girls.155 Falls are the most common cause of injury in infants and toddlers. In children, bicycle mishaps are the most common cause of severe injury, whereas motor vehicle-related injury predominates in adolescence. Although unintentional injuries are by far the most common type of injuries in childhood, the number of intentional injuries, such as firearm-related injury and child abuse, is increasing.

ED preparation for the pediatric trauma patient includes assembling age-appropriate equipment (e.g., intubation equipment; IV catheters, including intravenous needles and 4F single-lumen lines), laying out the Broselow Pediatric Emergency Tape (which allows effective approximation of the patient’s weight, medication doses, size of endotracheal tube, and chest tube size), and turning on heat lamps. Upon the pediatric patient’s arrival, the basic tenets of the ABCs apply, with some caveats. In children, the airway is smaller and more cephalad in position compared with that of adults, and in children younger than 10 years, the larynx is funnel shaped rather than cylindrical as in adults. Additionally, the child’s tongue is much larger in relation to the oropharynx. Therefore, a small amount of edema or obstruction can significantly reduce the diameter of the airway (thus increasing the work of breathing), and the tongue may posteriorly obstruct the airway, causing intubation to be difficult. During intubation, a Miller (straight) blade rather than a Macintosh (curved) blade may be more effective due to the acute angle of the cephalad, funnel-shaped larynx. Administration of atropine before rapid-sequence intubation will prevent bradycardia. Adequate ventilation is critical because oxygen consumption in infants and young children is twice that in adults; onset of hypoxemia, followed by cardiac arrest, may be precipitous. Because gastric distension can inhibit adequate ventilation, placement of a nasogastric tube may facilitate effective gas exchange. Approximately one-third of preventable deaths in children are related to airway management; therefore, if airway control cannot be obtained using a standard endotracheal method, surgical establishment of an airway should be considered. In children older than 11 years, standard cricothyroidotomy is performed. Due to the increased incidence of subglottic stenosis in younger patients, needle cricothyroidotomy with either a 14- or 16-gauge catheter is advocated, although it is rarely used. Alternatively, tracheostomy may be performed. In children, the standard physiologic response to hypovolemia is peripheral vasoconstriction and reflex tachycardia; this may mask significant hemorrhagic injury because children can compensate for up to a 25% loss of circulating blood volume with minimal external signs. “Normal” values for vital signs should not necessarily make one feel more secure about the child’s volume status. Volume restoration is based on the child’s weight; two to three boluses of 20 mL/kg of crystalloid is appropriate. Hypotension in children may be due to TBI rather than hypovolemia and should be considered in the appropriate clinic scenario.156

After initial evaluation based on the trauma ABCs, identification and management of specific injuries proceeds. Acute traumatic brain injury is the most common cause of death and disability in any pediatric age group. Although falls are the most common mechanism overall, severe brain injury most often is due to child abuse (in children <2 years) or motor vehicle collisions (in those >2 years). Head CT should be performed to determine intracranial pathology, followed by skull radiography to diagnose skull fractures. As in adults, CPP is monitored, and appropriate resuscitation is critical to prevent the secondary insults of hypoxemia and hypovolemia. Although some data indicate that the pediatric brain recovers from traumatic injury better than the adult brain, this advantage may be eliminated if hypotension is allowed to occur.

As is true in adults, the vast majority of thoracic trauma is also blunt. However, because a child’s skeleton is not completely calcified, it is more pliable. Significant internal organ damage may occur without overlying bony fractures. For example, adult patients with significant chest trauma have a 70% incidence of rib fractures, whereas only 40% of children with significant chest trauma do. Pneumothorax is treated similarly in the pediatric population; patients who are asymptomatic with a pneumothorax of <15% are admitted for observation, whereas those who have a pneumothorax of >15% or who require positive pressure ventilation undergo tube decompression. Presence of a hemothorax in this age group may be particularly problematic because the child’s chest may contain his or her entire blood volume. If the chest tube output is initially 20% of the patient’s blood volume (80 mL/kg) or is persistently >1 to 2 mL/kg per hour, thoracotomy should be considered. Aortic injuries are rare in children, and tracheobronchial injuries are more amenable to nonoperative management. Penetrating thoracic trauma, although uncommon, has 35% operative intervention rate, which is considerably higher than that of the adult population.157 Thoracic injuries are second only to brain injuries as the main cause of death according to the National Pediatric Trauma Registry; however, the overall mortality rate of 15% correlates with the levels in many adult studies.

The evaluation for abdominal trauma in the pediatric patient is similar to that in the adult. FAST is valid in the pediatric age group to detect intra-abdominal fluid. The mechanism of injury often correlates with specific injury patterns. A child sustaining a blow to the epigastrium (e.g., hitting the handlebars during a bike accident) should be evaluated for a duodenal hematoma and/or a pancreatic transection. After a motor vehicle collision in which the patient was wearing a passenger restraint, injuries comprising the “lap belt complex” or “seat belt syndrome” (i.e., abdominal wall contusion, small bowel perforation, flexion-distraction injury of the lumbar spine, diaphragm rupture, and occasionally abdominal aortic dissection) may exist. Nonoperative management of solid organ injuries, first used in children, is the current standard of care in the hemodynamically stable patient. If the patient shows clinical deterioration or hemodynamic lability, has a hollow viscus injury, or requires >40 mL/kg of packed RBCs, continued nonoperative management is not an option. Success rates of nonoperative management approach 95%,158 with an associated 10% to 23% transfusion rate. Findings of a hepatic or splenic blush on CT imaging does not uniformly require intervention; patient physiology should dictate embolization or operative intervention.159

PART I BASIC CONSIDERATIONS

156. Gardner AR, Diz DI, Tooze JA, Miller CD, Petty J. Injury patterns associated with hypotension in pediatric trauma patients:

Surgical care of the burned patient has evolved into a specialized field incorporating the interdisciplinary skills of burn surgeons, nurses, burn therapists, and other healthcare specialists. However, recent mass casualty events have been a reminder that healthcare systems may be rapidly pressed to care for large numbers of burn patients. Naturally, general surgeons may be at the forefront in these events, so it is crucial that they are comfortable with the care of burned patients and well equipped to provide the standard of care.

**BACKGROUND**

Burn injury historically carried a poor prognosis. With advances in fluid resuscitation and the advent of early excision of the burn wound, survival has become an expectation even for patients with severe burns. Continued improvements in critical care and progress in skin bioengineering herald a future in which functional and psychologic outcomes are equally important as survival alone. With this shift in priority, the American Burn Association (ABA) has emphasized referral to specialized burn centers after early stabilization. Specific criteria should guide transfer of patients with more complex injuries or other medical needs to a burn center (Table 8-1). The ABA has published standards of care and created a verification process to ensure that burn centers meet those standards. Because of increased prehospital safety measures, burn patients are transferred longer distances for definitive care at regional burn centers; data from one burn center with a particularly wide catchment area confirmed that even transport times averaging several hours did not affect the long-term outcomes of burn patients.

**INITIAL EVALUATION**

Initial evaluation of the burned patient should follow the same initial priorities of all trauma patients and involves four crucial assessments: airway management, evaluation of other injuries, estimation of burn size, and diagnosis of CO and cyanide poisoning. With direct thermal injury to the upper airway or smoke inhalation, rapid and severe airway edema is potentially lethal. Anticipating the need for intubation and establishing an early airway are critical. Signs of impending respiratory compromise include a hoarse voice, wheezing, or stridor; subjective dyspnea is a particularly concerning symptom and should trigger prompt elective endotracheal intubation. Perioral burns and singed nasal hairs alone do not indicate an upper airway injury, but are signs that the oral cavity and pharynx should be further evaluated for mucosal injury. Orotracheal intubation is the preferred method for securing the airway. Nasotracheal intubation may be useful for patients with associated facial trauma when experienced providers are present, but it should be avoided if oral intubation is safe and easy.

Burned patients are trauma patients and evaluated with a primary survey in accordance with Advanced Trauma Life Support guidelines. Concurrently with the primary survey, large-bore peripheral intravenous (IV) catheters should be placed and fluid resuscitation should be initiated; for a burn larger than 40% total body surface area (TBSA), two large-bore IVs are ideal. IV placement through burned skin is safe and effective but requires attention to securing the catheters. Central venous access and intraosseous (IO) access should be considered when peripheral access cannot be easily obtained. Rarely, IV resuscitation is indicated in patients with burns smaller than 15% who can usually hydrate orally. Pediatric patients with burns larger than 15% may require IO access in emergent situations if venous access cannot be attained. An early and comprehensive secondary survey must be performed on all burn patients, but especially those with a history of associated mechanical trauma such as a motor vehicle collision. Also, patients from structural fires in which the manner of egress is not known should be carefully evaluated for injuries from a possible jump or fall. Urgent radiology studies, such as a chest X-ray, should be performed in the emergency department, but nonurgent skeletal evaluation (i.e., extremity X-rays) can be
done in the intensive care unit (ICU) to avoid hypothermia and delayed resuscitation. Hypothermia is a common prehospital complication that contributes to resuscitation failure. Patients should be wrapped with clean blankets in transport. Cooling should be avoided in patients with moderate or large (>20% TBSA) burns. Patients with acute burn injuries should never receive prophylactic antibiotics. This intervention has been clearly demonstrated to promote development of fungal infections and resistant organisms and was abandoned in the mid-1980s. A tetanus booster should be administered in the emergency department depending on patient immunization status.

The importance of pain management for these patients has been widely recognized over the past 25 years. While pain management is a priority for burn patients, it is important to acknowledge the opioid crisis and the recent push toward decreasing opiate use in general. In order to limit opiate-related morbidity, we recommend responsible opiate use in conjunction with multimodal pain control and development of a weaning plan starting at opioid commencement. Clear expectations around pain medication use should be set with patients. Anxiety is another component of the psychological response of burn patients, seen with both wound care and general postinjury hospital course. Benzodiazepines are a staple in the treatment of acute anxiety; however, they can contribute significantly to hospital delirium. We recommend conservative benzodiazepine use to mitigate the effects of anxiety while minimizing delirogenic effects of benzodiazepines.

**Key Points**

1. Follow American Burn Association criteria for referral of a patient to a regional burn center.
2. Never administer prophylactic antibiotics other than tetanus vaccination.
3. Early excision and grafting of full-thickness and deep partial-thickness burns improve outcomes.
4. Intravenous fluid resuscitation for patients with burns >20% of total body surface area (children with burns >15% of total body surface area) should be titrated to mean arterial pressure (MAP) >60 mmHg and appropriate urine output.

Most burn resuscitation formulas estimate fluid requirements based on burn size measured as a percentage of TBSA (%TBSA). The “rule of nines” is a crude but quick and effective method of estimating burn size (Fig. 8-1). In adults, the anterior and posterior trunk each account for 18%, each lower extremity is 18%, each upper extremity is 9%, and the head is 9%. In children under 3 years old, the head accounts for a larger relative surface area and should be taken into account when estimating burn size. For smaller or odd-shaped burns, the “rule of the palm” where the palmar surface of the hand, including the digits, is 1% TBSA is useful. Diagrams such as the Lund and Browder chart give a more accurate accounting of the true burn size in children and adults. The importance of an accurate burn size assessment cannot be overemphasized. Superficial or first-degree burns should not be included when calculating burn size, and thorough cleaning of soot and debris is mandatory to avoid confusing soiled skin with burns. Examination of referral data suggests that physicians inexperienced with burns tend to overestimate the size of small burns and underestimate the size of large burns, with potentially detrimental effects on pretransfer resuscitation.

**BURN CLASSIFICATION**

Burns are commonly classified as thermal, electrical, or chemical burns, with thermal burns consisting of flame, contact, or scald burns. Flame burns are the most common cause for hospital admission of burns, and have the highest mortality. This is primarily related to their association with structural fires and the accompanying inhalation injury and/or CO poisoning.

Electrical burns make up 3% of U.S. hospital admissions but have special concerns, including cardiac arrhythmia and compartment syndrome with concurrent rhabdomyolysis. A baseline ECG is recommended in all patients with an electrical injury, and a normal ECG in a low-voltage injury (<1000 V) may preclude hospital admission. Because compartment syndrome and rhabdomyolysis are common in high-voltage electrical injuries, vigilance must be maintained for neurologic or vascular compromise, and fasciotomies should be performed even in cases of moderate clinical suspicion. Long-term neurologic symptoms and cataract development are not uncommon with high-voltage electrical injuries, and neurologic and ophthalmologic consultation should be obtained to define baseline patient function.

Chemical burns also comprise 3% of admitted burn patients and result in potentially severe burns. Typically, acid chemical burns result in coagulation necrosis and alkali chemical burns cause liquefactive necrosis (with an exception of hydrofluoric acid, which also causes liquefactive necrosis).

TBSA = total body surface area.
The most important components of initial therapy are careful removal of the toxic substance from the patient and irrigation of the affected area with water for a minimum of 30 minutes. In cases of exposure to dry chemicals, such as concrete or powdered forms of lye, the substance should be swept from the patient to avoid a thermal reaction with water. The offending agents in chemical burns can be systemically absorbed and may cause specific metabolic derangements. Formic acid has been known to cause hemolysis and hemoglobinuria, and hydrofluoric acid causes hypocalcemia. Hydrofluoric acid is a particularly common offender due to its widespread industrial uses.

Calcium-based therapies are the mainstay of treating hydrofluoric acid burns, with topical application of calcium gluconate onto wounds and IV administration of calcium gluconate for systemic hypocalcemia symptoms. Intra-arterial calcium gluconate infusion provides effective treatment of progressive tissue injury and intense pain. Patients undergoing intra-arterial therapy need continuous cardiac monitoring. Persistent refractory hypocalcemia with electrocardiographic abnormalities may signal the need for emergent excision of the burned areas.

**BURN DEPTH**

Based on the original burn depth classification by Dupuytren in 1832, burn wounds are commonly classified as superficial (first-degree), partial-thickness (second-degree), full-thickness (third-degree), and fourth-degree burns, which affect underlying soft tissue. Fifth-degree burns (through muscle to bone) and sixth degree burns (charring bone) were also described although are less common. Partial-thickness burns are classified as either superficial or deep partial-thickness burns by depth of involved dermis. Clinically, first-degree burns are painful but do not blister, second-degree burns have dermal involvement and are extremely painful with weeping and blisters, and third-degree burns are leathery, painless, and nonblanching. Jackson described three zones of tissue injury following burn injury. The zone of coagulation is the most severely burned portion and is typically in the center of the wound. As the name implies, the affected tissue is coagulated and sometimes frankly necrotic, much like a full thickness burn, and will need excision and grafting. Peripheral to that is a zone of stasis, with variable degrees of vasoconstriction and resultant ischemia, much like a second-degree burn. Appropriate resuscitation and wound care may prevent conversion to a deeper wound, but infection or suboptimal perfusion may result in an increase in burn depth. This is clinically relevant because many superficial partial-thickness burns will heal with nonoperative management, and the majority of deep partial-thickness burns benefit from excision and skin grafting. The outermost area of a burn is called the zone of hyperemia, which will heal with minimal or no scarring and is most like a superficial partial thickness burn or first-degree burn.

Unfortunately, even experienced burn surgeons have limited ability to accurately predict the healing potential of partial-thickness burns soon after injury; one reason is that burn wounds evolve over the 48 to 72 hours after injury. Numerous burn depth assessment tools have been developed with the idea that...
earlier burn depth definition will expedite appropriate surgical decision-making. One of the most effective ways to determine burn depth is full-thickness biopsy, but this has several limitations; not only is the procedure painful and potentially scarring, but accurate interpretation of the histopathology requires a specialized pathologist and may have slow turnaround times. Laser Doppler can measure skin perfusion to predict burn depth with sensitivities and specificity of up to 83% and 97%, respectively. Noncontact ultrasound has been postulated as a painless modality to predict nonhealing wounds and has the advantage of easily performed serial measurements. Unfortunately, none of these newer therapies have proven adequately superior to justify their cost and as yet have not substituted serial examination by experienced burn surgeons.

**PROGNOSIS**

The Baux score (mortality risk equals age plus %TBSA) was used for many years to predict mortality in burns. Analysis of multiple risk factors for burn mortality has validated age and burn size as the strongest predictors of mortality. Advance-ments in burn care have lowered overall mortality to the point that the original Baux score may no longer be accurate. However, the Revised Baux Score, which accounts for age, burn size, and inhalation injury, has been found to be independently associated with mortality. As such, age, burn size, and inhalation injury continue to be the most robust indicators for burn mortality. Age even as a single variable strongly predicts mortality in burns, and in-hospital mortality in elderly burn patients is a function of age regardless of other comorbidities. In nonelderly patients, comorbidities such as preinjury human immunodeficiency virus (HIV), metastatic cancer, and kidney or liver disease may influence mortality and length of stay. A large database study of 68,661 burn patients found that the variables with the highest predictive value for mortality were age, %TBSA, inhalation injury, coexistent trauma, and pneumonia. A more recent study analyzing 506,628 burn inpatients between 1998 and 2008 demonstrated an association between burn size, age, inhalation injury, and mortality. Other factors associated with mortality included African American race, female gender, and treatment in urban private hospitals (as opposed to urban academic hospitals).

Mortality is not the only outcome of interest in the burn population. Burn injury can significantly impact the subsequent quality of life for survivors, including but not limited to appearance, mobility, functional status, and ability to work. One study found that burn injury reduces short term quality of life by 30% and long-term quality of life by approximately 11%. Predictors of poorer physical and mental health 12 months removed from burn injury include older age, female gender, and greater %TBSA burn size. One factor impacting quality of life is itching—a late and bothersome consequence of burn injury that affects both adult and pediatric population. Other factors discussed later in this chapter include hypertrophic scarring, contracture, and heterotopic ossification. Finally, return to work or school has been a useful tool to evaluate recovery and prognosis. A recent meta-analysis found that approximately 28% of burn survivors never return to work. A recent study using an interventional bundle involving the patient, the employee, worker’s compensation, and burn clinic staff demonstrated a return to work rate of 93%. The return to school for pediatric patients is actually very prompt, averaging about 10 days after discharge. However, further study is needed to determine whether attendance and performance suffer despite early reentry to school.

It is important to recognize these potential quality-of-life issues in burn patients and take necessary steps to diminish the impact that burn injury has on quality of life both in the hospital and following discharge.

**RESUSCITATION**

A myriad of formulas exist for calculating fluid needs during burn resuscitation, suggesting that no one formula benefits all patients. The most commonly used formula, the Parkland or Baxter formula, consists of 3 to 4 mL/kg per % burn of Lactated Ringer’s, of which half is given during the first 8 hours after burn and the remaining half is given over the subsequent 16 hours. The most recent American Burn Association consensus formula recommends 2 mL/kg per % burn of Lactated Ringers given the tendency toward excessive fluid administration with the traditional formulas. The concept behind continuous fluid requirements is simple. The burn (and/or inhalation injury) drives an inflammatory response that leads to capillary leak; as plasma leaks into the extravascular space, crystalloid administration maintains the intravascular volume. Therefore, if a patient receives a large fluid bolus in a prehospital setting or emergency department, the fluid has likely leaked into the interstitium, and the patient still requires ongoing burn resuscitation according to the estimates. Continuation of fluid volumes should depend on the time since injury, urine output, and mean arterial pressure (MAP). As the capillary leak closes, the patient will require less volume to maintain these two resuscitation endpoints. Children under 20 kg have the additional requirement that they do not have sufficient glycogen stores to maintain an adequate glucose level in response to the inflammatory response. Specific pediatric formulas have been described, but the simplest approach is to deliver a weight-based maintenance IV fluid with glucose supplementation in addition to the calculated resuscitation with lactated Ringer’s.

It is important to remember that any formula for burn resuscitation is merely a guideline, and fluid must be titrated based on appropriate response to therapy. A number of parameters are widely used to gauge burn resuscitation, but the most common remain the simple outcomes of blood pressure and urine output. As in any critically ill patient, a target MAP of 60 mmHg ensures optimal end-organ perfusion. Goals for urine output should be 30 mL/h in adults and 1 to 1.5 mL/kg per h in pediatric patients. Because blood pressure and urine output may not correlate perfectly with true tissue perfusion, the search continues for other adjunctive parameters that may more accurately reflect adequate resuscitation. Some centers have found serum lactate to be a better predictor of mortality in severe burns, and others have found that base deficit predicts eventual organ dysfunction and mortality. Because burned patients with normal blood pressure and serum lactate levels may have compromised gastric mucosal perfusion, continuous measurement of mucosal pH with its logistical difficulties has garnered limited popularity. Invasive monitoring with pulmonary artery catheters typically results in significant excessive fluid administration without improved cardiac output or preload measurements; use of invasive monitoring seems to have variable effects on long-term outcomes.

Actual administrated fluid volumes typically exceed volumes predicted by standard formulas. One survey of burn
centers showed that 58% of patients end up getting more fluids than would be predicted by Baxter’s formula. Comparison of modern-day patients with historical controls shows that over-resuscitation may be a relatively recent trend. One theory is that increased opioid analgesic use results in peripheral vasodilation and hypotension and the need for greater volumes of bolused resuscitative fluids. A classic study by Navar et al showed that burned patients with inhalation injury required an average of 5.76 mL/kg per % burn, vs. 3.98 mL/kg per % burn for patients without inhalation injury, and this has been corroborated by subsequent studies. Prolonged mechanical ventilation may also play a role in increased fluid needs. A multicenter study found that age, weight, %TBSA, and intubation on admission were significant predictors of more fluid delivery during the resuscitation period. Those patients receiving higher fluid volumes were at increased risk of complications and death. Common complications include abdominal compartment syndrome, extremity compartment syndrome, intraocular compartment syndrome, and pleural effusions. Monitoring bladder pressures can provide valuable information about development of intra-abdominal hypertension.

The use of colloid as part of the burn resuscitation has generated much interest over the years. In late resuscitation when the capillary leak has closed, colloid administration may decrease overall fluid volumes and potentially may decrease associated complications such as intra-abdominal hypertension. A recent meta-analysis accounting for statistical heterogeneity among studies included demonstrated a trend toward mortality benefit for patients receiving albumin. However, albumin use has never been shown to definitively improve mortality in burn patients and has controversial effects on mortality in critically ill patients. Still, many burn centers including ours continue to use albumin as an adjunct during burn resuscitation. Attempts to minimize fluid volumes in burn resuscitation have included study of hypertonic solutions. A recent meta-analysis evaluating hyperosmotic vs. isosmotic fluid resuscitation demonstrates decreased total fluid load (vol/%TBSA per weight) over the first 24 hours with use of hyperosmotic fluid with no difference in total fluid, urine output, creatinine, or mortality. A described downside of hypertonic fluid administration is hyperchloremic acidosis.

Other adjuncts are being increasingly used during initial burn resuscitation. High-dose ascorbic acid (vitamin C) may decrease fluid volume requirements and ameliorate respiratory embarrassment during resuscitation, although no mortality benefit has been noted thus far in two trials. Plasmapheresis has also been associated with decreased fluid requirements and increased urine output in patients who require higher resuscitative volumes than predicted to maintain adequate urine output and MAP. It is postulated that plasmapheresis may filter out inflammatory mediators, thus decreasing ongoing vasodilation and capillary leak.

One adjunct that has found increasing utility in surgical ICUs has been the application of bedside ultrasound. Ultrasound offers the potential to make rapid, noninvasive assessments during acute changes in clinical condition. For burn patients, bedside ultrasonography may be indicated for evaluation of volume status, gross assessment of cardiac function, and diagnosis of pneumothorax. Determining patient cardiac function and volume status may guide fluid resuscitation. Cardiac function can be evaluated with three common heart views: the parasternal long axis, parasternal short axis, and apical four-chamber views. Whereas no study has used ultrasound to guide fluid resuscitation in burn patients, volume status can be estimated by examination of cardiac function and evaluation of the inferior vena cava (IVC) diameter with changes in respiration, as has been done in patients with hemorrhage and shock. Ultrasound also allows timely diagnosis of pneumothorax. A high-frequency probe with an adequate window between ribs permits identification of lung parenchyma against the chest well. A pneumothorax appears as a transition on ultrasound between lung parenchyma, which has a heterogeneous appearance, and air, which has a hypoechoic appearance. Further studies are warranted to identify indications for the use of ultrasound in burned patients.

Machine learning and bedside computer decision support are other adjuncts gaining traction in caring for burn patients. These modalities can enhance patient care and aid in diagnosis, treatment, and research. The use of bedside computer decision support has been particularly appealing for resuscitation of burn patients in the first 48 hours and has been shown to improve fluid management during initial resuscitation.

The role of blood transfusion in critically injured patients has undergone a reevaluation in recent years. Blood transfusions are considered to be immunomodulatory and potentially immunosuppressive, which is one explanation to the links between blood transfusions and increased infection and shorter time to recurrence after oncologic surgery. A large multicenter study of blood transfusions in burn patients found that increased numbers of transfusions were associated with increased infections and higher mortality in burn patients, even when correcting for burn severity. A follow-up study implementing a restrictive transfusion policy in burned children showed that a hemoglobin threshold of 7 g/dL had no more adverse outcomes vs. a traditional transfusion trigger of 10 g/dL. In addition, costs incurred to the institution were significantly less. A recent randomized control trial in patients with >20% TBSA compared outcomes of a restrictive to a liberal red blood cell transfusion strategy (hemoglobin 7–8 vs. 10–11, respectively). There were no differences in blood stream infection, organ dysfunction, ventilator days, time to wound healing, or 30-day mortality between both groups. These data, in concert with other reported complications such as transfusion-related lung injury, have led to recommendations that blood transfusions be used only when there is an apparent physiologic need. Attempts to minimize blood transfusion in nonburned critically ill patients have led to use of erythropoietin by some centers. However, burn patients often have elevated erythropoietin levels, and a randomized study in burn patients showed that recombinant human erythropoietin did not effectively prevent anemia or decrease the number of transfusions given. Promising animal studies demonstrating erythropoietin-mediated prevention of secondary burn progression have yet to be validated in humans.

INHALATION INJURY AND VENTILATOR MANAGEMENT

Inhalation injuries are commonly seen in tandem with burn injuries and are known to increase mortality in burned patients. Smoke inhalation is present in as many as 35% of hospitalized burn patients and may triple the hospital stay compared to isolated burn injuries. Mortality for inhalation injury has been reported to be as high as 25%, with this increasing to 50% in patients with ≥20% TBSA burns. The pneumonia rate in
patients with inhalation injury has been reported to be three times higher than those without inhalation injury, and it has been associated with increased length of stay, increased ventilator days, and need for tracheostomy.91,92 The combination of burns, inhalation injury, and pneumonia increases mortality by up to 60% over burns alone.93 Subsequent development of the adult respiratory distress syndrome (ARDS) is common in these patients and may be caused in part by recruitment of alveolar leukocytes with an enhanced endotoxin-activated cytokine response.94 When ARDS complicates burns and inhalation injury, mortality approaches 66%; in one study, patients with burns ≥60% TBSA in combination with inhalation injury and ARDS had 100% mortality.95

Smoke inhalation causes injury in two ways: by direct heat injury to the upper airways and inhalation of combustion products into the lower airways. Direct injury to the upper airway causes airway swelling that typically leads to maximal edema in the first 24 to 48 hours after injury and often requires a short course of endotracheal intubation for airway protection. Combustion products found in smoke, most commonly from synthetics in structural fires, cause lower airway injury. These irritants cause direct mucosal injury, which in turn leads to mucosal sloughing, edema, reactive bronchoconstriction, and finally obstruction of the lower airways. Injury to both the epithelium and pulmonary alveolar macrophages causes release of prostanoids, chemokines, and other inflammatory mediators; neutrophil migration; increased tracheobronchial blood flow; and, finally, increased capillary permeability. All of these components of acute lung injury increase the risk of pneumonia and ARDS following an inhalation injury.

The physiologic effects of smoke inhalation are numerous. Inhalation injury decreases lung compliance⁹⁸ and increases airway resistance work of breathing.⁹⁷ Inhalation injury in the presence of burns also increases overall metabolic demands.⁹⁹ The most common physiologic derangement seen with inhalation injury is increased fluid requirement during resuscitation. Since severe inhalation injury may result in mucosal sloughing with obstruction of smaller airways, bronchoscopy findings including carbon deposits, erythema, edema, bronchorrhea, and a hemorrhagic appearance may be useful for staging inhalation injury. The Abbreviated Injury Score—a scale from 0 to 4, with 0 representing no injury and 4 representing massive injury—is commonly used for grading inhalation injury. Higher grades of bronchoscopic inhalation injury have been associated with increased incidence of ARDS, increased ventilator days, higher rate of multiple organ dysfunction syndrome, and higher mortality.⁹⁸ Bronchoscopic evaluation can also help isolate organisms early in the course of a potential pneumonia. Bronchoalveolar lavage (BAL) within 24 hours after an inhalation injury demonstrates a high rate of positive quantitative cultures,¹⁰⁰ suggesting that pneumonia develops soon after the acute lung injury. Bacterial contamination from urgent intubation may contribute to early development of pneumonia in patients with inhalation injury.¹⁰⁶ Early evaluation with bronchoscopy can identify causative organisms and guide appropriate antibiotic therapy.

Because bronchoscopy is an invasive test, attempts have been made to utilize other diagnostic modalities, such as thoracic computed tomography (CT) scans¹⁰¹ and xenon ventilation-perfusion scanning.¹⁰²,¹⁰³ However, these are generally not utilized unless otherwise indicated, and the best tools available for diagnosing inhalation injury remain clinical presentation and bronchoscopic evaluation. Decreased PaO₂/FiO₂ ratio (<350) on admission may not only predict inhalation injury but also indicate increased fluid needs more accurately than bronchoscopic grading of the severity of inhalation.¹⁰⁴

Treatment of inhalation injury consists primarily of supportive care. Aggressive pulmonary toilet and routine use of nebulized bronchodilators such as albuterol are recommended. Nebulized N-acetylcysteine is an antioxidant free radical scavenger designed to decrease the toxicity of high oxygen concentrations. Aerosolized heparin aims to prevent formation of fibrin plugs and decrease the formation of airway casts and has been associated with increased number of ventilator-free days.¹⁰⁵ A recent meta-analysis demonstrated improved mortality with the use of inhaled anticoagulation regimens.¹⁰⁶ Aerosolized tissue plasminogen activator¹⁰⁷ and recombinant human antithrombin¹⁰⁸ have shown promise in sheep models but have not yet seen widespread clinical use. Administration of intrabronchial surfactant has been used as a salvage therapy in patients with severe burns and inhalation injury.¹⁰⁹ Inhaled nitric oxide may also be useful as a last effort in burn patients with severe lung injury who are failing other means of ventilator support.¹¹⁰ The use of steroids has traditionally been avoided due to the worse outcomes in burn patients¹¹¹, however, some data demonstrate selectively improved outcomes with septic shock requiring vasopressor circulatory.¹¹²

An important contributor to early mortality in burn patients and often seen in patients with inhalation injury is carbon monoxide (CO) poisoning. This clear, odorless gas has an affinity for hemoglobin is approximately 200 to 250 times more than that of oxygen. Carboxyhemoglobin decreases the levels of normal oxygenated hemoglobin and can quickly lead to anoxia and death.¹¹³ CO also causes uncoupling of oxidative phosphorylation in mitochondria, free radical generation, and increased systemic inflammatory response via platelet activation—all of which may increase cardiac and neurologic morbidity and mortality in CO toxicity.¹¹⁴ Unexpected neurologic or cardiac symptoms should raise the level of suspicion, and an arterial carboxyhemoglobin level must be obtained because pulse oximetry can be falsely elevated. Administration of 100% normobaric oxygen is the gold standard for treating CO poisoning and reduces the half-life of CO from 250 minutes in room air to 40 to 60 minutes.¹¹⁵ Some authors have proposed hyperbaric oxygen as an adjunctive therapy for CO poisoning.¹¹⁶ However, a recent meta-analysis offers mixed results regarding the success and long-term outcomes of hyperbaric oxygen, and its associated logistical difficulties and complications have limited its usefulness for patients with moderate or large burns.¹¹⁷ Patients who sustain a cardiac arrest as a result of their CO poisoning have an extremely poor prognosis regardless of the success of initial resuscitation attempts.¹¹⁸

Hydrogen cyanide toxicity may also be a component of an overwhelming smoke inhalation injury. Cyanide inhibits cytochrome oxidase, which is required for oxidative phosphorylation.¹¹⁹ Afflicted patients may have a persistent, severe lactic acidosis, neurologic symptoms, pulmonary edema, or cardiac sequelae (ST elevation on electrocardiogram).¹²⁰,¹²¹ Classic signs of cyanide poisoning—including bitter almond breath and cherry-red skin changes—are rare and should not be used as the sole diagnostic criteria. Treatment consists of sodium thiosulfate, hydroxocobalamin, and 100% oxygen. Sodium thiosulfate works as a substrate for the metabolism cyanide into a nontoxic derivative, but it works slowly and is not effective for acute therapy.¹²¹ Hydroxocobalamina vitamin B₁₂ precursor—quickly
complexes with cyanide, is excreted by the kidney, and is recommended for immediate therapy.\(^{122}\) In the majority of patients, lactic acidosis will resolve with ventilation, and sodium thiosulfate treatment becomes unnecessary.\(^{123}\) Given the unknown side-effects of hydroxocobalamin administration, it should be reserved only for patients with a strong suspicion of cyanide poisoning.

New ventilator strategies have contributed to the improved mortality with ARDS. Although ARDS still contributes to mortality in burn patients, treatments have improved so that mortality is primarily from multisystem organ failure rather than isolated respiratory causes.\(^{124}\) The ARDS Network Study finding that low tidal volume (6 cc/kg) or “lung-protective ventilation” had a 22% lower mortality than patients with traditional tidal volumes (12 cc/kg)\(^{124}\) has dramatically changed the management of patients with acute lung injury. A similar approach had previously been shown to improve outcomes in pediatric burn patients.\(^{125}\) In patients with refractory hypoxemia despite lung-protective ventilation, prone positioning may improve oxygenation and mortality.\(^{126,127}\) No specific studies have examined prone positioning in burned patients, and in fact exclusion criteria from a large prone positioning trial included patients with ≥20% TBSA.\(^{127}\) Select reports demonstrate the feasibility of prone positioning in burn patients,\(^{128}\) although they present logistical challenges and caution must be used in patients with frontal and facial burns who are already at risk for loss of the grafts, invasive catheters, and the endotracheal tube. High-frequency percussive ventilation (HFPV) has shown early promise in patients with inhalation injury.\(^{129}\) One study showed notable decreases in both morbidity and mortality with HFPV, especially in patients with burns <40% TBSA and inhalation injury.\(^{130}\) A randomized controlled trial between low-tidal volume ventilation and HFPV in burn patients requiring mechanical ventilation demonstrated no significant difference in primary clinical outcomes.\(^{131}\) A related technique is high-frequency oscillatory ventilation (HFOV), which has been used primarily as a salvage modality in patients refractory to more conventional measures.\(^{132}\) However, two recent studies and a recent meta-analysis have concluded that HFOV yields no mortality benefit and in fact may actually increase patient mortality in patients with ARDS.\(^{133,134}\) Extracorporeal membrane oxygenation (ECMO) is typically reserved for salvage situations, although utilization of ECMO for burn patients is increasing and outcomes have been shown to be similar to other ECMO patients.\(^{135}\)

TREATMENT OF THE BURN WOUND

Multitudes of topical therapies exist for the treatment of burn wounds, many of which contain antimicrobial properties. A recent Cochrane Database Review nicely summarizes the data surrounding antisepsis for burns; however, much of the data is inconclusive.\(^{137}\) Silver sulfadiazine is one of the most widely used in clinical practice. Silver sulfadiazine has a wide range of antimicrobial activity, primarily as prophylaxis against burn wound infections rather than treatment of existing infections. It has the added benefits of being inexpensive, being easily applied, and having soothing qualities. It is not significantly absorbed systemically and thus has minimal metabolic derangements. Silver sulfadiazine has a reputation for causing neutropenia, but this association is more likely due to neutrophil margination from the inflammatory response following burn injury. True allergic reactions to the sulfa component of silver sulfadiazine are rare, and at-risk patients can have a small test patch applied to identify a burning sensation or rash. Silver sulfadiazine destroys skin grafts and is contraindicated on burns or donor sites in proximity to newly grafted areas. Also, silver sulfadiazine may retard epithelial migration in healing partial-thickness wounds.

Mafenide acetate, either in cream or solution form, is an effective topical antimicrobial. It is effective even in the presence of eschar and can be used in both treating and preventing wound infections; the solution formulation is an excellent antimicrobial for fresh skin grafts. Use of mafenide acetate may be limited by pain with application to partial-thickness burns. As mafenide is a carbonic anhydrase inhibitor, a historically described side effect is metabolic acidosis. However, multiple studies have been performed using mafenide to treat burn wounds without any significant incidence of metabolic acidosis.\(^{138,139}\)

Silver nitrate has broad-spectrum antimicrobial activity as a topical solution. The solution used must be dilute (0.5%), and prolonged topical application leads to electrolyte extravasation with resulting hyponatremia. A rare complication is methemoglobinemia.\(^{140}\) Although inexpensive, silver nitrate solution causes black stains, and laundry costs may offset any fiscal benefit to the hospital. Although there is no definitive evidence regarding use in the burn population, Dakin’s solution (0.5% sodium hypochlorite solution) is an acceptable alternative as an inexpensive topical antimicrobial.

For smaller burns or larger burns that are nearly healed, topical ointments such as bacitracin, neomycin, and polymyxin B can be used. These are also useful for superficial partial-thickness facial burns as they can be applied and left open to air without dressing coverage. Meshed skin grafts in which the interstices are nearly closed are another indication for use of these agents, preferably with greasy gauze to help retain the ointment in the affected area. All three have been reported to cause nephrotoxicity and should be used sparingly in large burns. Recent media coverage of mexitilin-resistant Staphylococcus aureus (MRSA) has led to widespread use by community practitioners of mupirocin for new burns. Unless the patient has known risk factors for MRSA, mupirocin should only be used in culture-positive burn wound infections to prevent emergence of further resistance.

Silver-impregnated dressings are increasingly being used for donor sites, skin grafts, and partial-thickness burns because of their potential to avoid daily dressing changes. These may be more comfortable for the patient, reduce the number of dressing changes, and shorten hospital length of stay, but they limit serial wound examinations. Biologic membranes such as Biobrane (Smith & Nephew Global Products) provide a prolonged barrier under which wounds may heal. Because of the occlusive nature of these dressings, these are typically used only on fresh, superficial, partial-thickness burns that are clearly not contaminated.

NUTRITION

Nutritional support may be more important in patients with large burns than in any other patient population. Not only does adequate nutrition play a role in acute issues such as immune responsiveness, but the hypermetabolic response in burn injury may raise baseline metabolic rates by as much as 200%.\(^{141}\) This can lead to catabolism of muscle proteins and decreased lean body mass that may delay functional recovery.\(^{142}\) Early enteral
feeding for patients with burns >20% TBSA is safe and may reduce loss of lean body mass. Early enteral feeds have also been associated with shorter duration of ICU stay and decreased rates of wound infection. If the enteral feeds are started within the first few hours after admission, gastric ileus may be avoided. Adjuncts such as metoclopramide promote gastrointestinal motility; if other measures for gastric feeding are unsuccessful, advancing the tube into the small bowel with nasojejunal feeding can be attempted. In endotracheally intubated patients, trips to the operating room do not necessitate holding enteral feedings. Immune-modulating supplements such as glutamine may decrease infectious complications in burn patients, although the effect on mortality and wound closure remains unknown. One proposed mechanism for glutamine’s immune modulating properties is via prevention of T-cell suppression in mesenteric lymph nodes. There is currently a multicenter randomized control trial recruiting to determine the effect of glutamine on mortality, blood stream infections, and health-related quality of life (https://clinicaltrials.gov/ct2/show/NCT00985205). Micronutrient supplementation with antioxidant vitamins (vitamin E and ascorbic acid) and trace minerals (selenium, zinc, and copper) optimizes wound healing, enhances immune function, and fights oxidative stress.

Calculating the appropriate caloric needs of the burn patient can be challenging. A commonly used formula in non-burned patients is the Harris-Benedict equation, which calculates caloric needs using factors such as gender, age, height, and weight. This formula uses an activity factor for specific injuries, and for burns, the basal energy expenditure is multiplied by two. The Harris-Benedict equation may be inaccurate in burns of <40% TBSA, and in these patients, the Curreri formula may be more appropriate. This formula estimates caloric needs to be 25 kcal/kg per d plus 40 kcal/%TBSA per d. Indirect calorimetry can also be used to calculate resting energy expenditure, but in burn patients, a “metabolic cart” has not been documented to be more beneficial than the predictive equations. Titrating caloric needs closely is important because overfeeding patients will lead to storage of fat instead of muscle anabolism.

Modifying the hypermetabolic response is an area of intense study. ß-Blocker use in pediatric patients decreases heart rate and resting energy expenditure and abrogates protein catabolism, even in long-term use. There may be benefits to ß-blockade in adult patients, and many centers use ß-blockers routinely in the adult population with limited safety and efficacy data. Some data suggests that ß-blocker use in the adult burn population has a greater incidence of iatrogenic hypotension and bradycardia. As such, it is important to monitor hemodynamic status when starting ß-blockers in these populations.

The anabolic steroid oxandrolone has been extensively studied in burn patients as well and has demonstrated improvements in lean body mass and bone density in severely burned children. The weight gain and functional improvements seen with oxandrolone may persist even after stopping administration of the drug. A double-blind, randomized study of oxandrolone showed decreased length of stay, improved hepatic protein synthesis, and no adverse effects on endocrine function, although the authors noted a rise in transaminases with unclear clinical significance. Oxandrolone therapy has also been associated with overall decreased mortality in patients with large burns. 

Hyperglycemia has been associated with increased mortality after burn injury, and intensive insulin therapy in critically ill patients has shown benefit, presumably from avoidance of hyperglycemia. However, in burn patients, the insulin itself may have a metabolic benefit, with improvements in lean body mass and amelioration of the inflammatory response to burn injury. Oral hypoglycemic agents such as metformin also help to avoid hyperglycemia and may contribute to prevention of muscle catabolism.

### Complications in Burn Care

There are several complications commonly associated with treatment of burn patients. Though not always avoidable, maintaining vigilance for typical complications and using appropriate techniques for prevention may limit the frequency and severity of complications. Ventilator-associated pneumonia, as in critically ill patients, is a significant problem in burned patients. However, it is so common in patients with inhalation injury that a better nomenclature may be postinjury pneumonia. Unfortunately, commonly used scores in critical illness such as the Clinical Pulmonary Infection Score (CPIS) have not been shown to be reliable in burn patients. Quantitative bronchoscopic cultures in the setting of clinical suspicion of pneumonia should guide treatment of pneumonia. Simple measures such as elevating the head of the bed and maintaining excellent oral hygiene and pulmonary toilet are recommended to help decrease the risk of postinjury pneumonia. There is some question as to whether early tracheostomy decreases infectious morbidity in burn patients and whether it improves long-term outcomes. There do not seem to be any major differences in the rates of pneumonia with early tracheostomy, though there may be reduced development of subglottic stenosis compared with prolonged endotracheal intubation. Practical considerations such as protection of facial skin grafts may influence the decision for tracheostomy placement. One major consideration in deciding whether to perform a tracheostomy has been the presence of eschar at the insertion site, which complicates tracheostomy site care and increases the risk of airway infection. Bedside percutaneous dilatational tracheostomy is a facile method for performing tracheostomy and is reported to be as safe as open tracheostomy in the burn population.

Massive resuscitation of burned patients may lead to an abdominal compartment syndrome characterized by increased airway pressures with hypoventilation and decreased urine output and hemodynamic compromise. Decompressive laparotomy is the standard of care for refractory abdominal compartment syndrome but carries an especially poor prognosis in burn patients. Adjunctive measures such as minimizing fluid, performing torso escharotomies, decreasing tidal volumes, and chemical paralysis should be initiated before resorting to decompressive laparotomy. Patients undergoing massive resuscitation also develop elevated intraocular pressures and may require lateral canthotomy.

Deep vein thrombosis (DVT) and prophylaxis in the burn population has received increasing attention in the literature recently. Up to 25% of burn patients develop DVT, and fatal pulmonary emboli have been reported in burn patients. A recent prospective trial demonstrated an 8% incidence of DVT in patients with 30% to 60% TBSA burns not receiving low molecular weight heparin prophylaxis with no evidence of DVT in patients receiving prophylaxis. There were no complications.
from low molecular weight heparin prophylaxis. Thus, it appears that heparin prophylaxis is safe in burn patients and may help prevent thrombotic complications.

Unfortunately, the use of both prophylactic and therapeutic heparin may be associated with heparin-associated thrombocytopenia (HIT). One study of HIT in burn patients showed an incidence of 1.6% in heparinized burn patients. Thrombotic complications included DVT, pulmonary embolus, and even arterial thrombosis requiring limb amputation. Nonheparin anticoagulation for HIT commonly caused bleeding complications requiring transfusion. Although rare, a high index of suspicion for HIT should be maintained in thrombocytopenic burn patients, particularly if the platelet counts drop at hospital days 7 to 10.

Burn patients often require central venous access for fluid resuscitation and hemodynamic monitoring. Because of the anatomic relation of their burns to commonly used access sites, burn patients may be at higher risk for catheter-related bloodstream infections. The 2012 Centers for Disease Control and Prevention National Healthcare Safety Network report indicates that American burn centers have higher infectious complication rates than any other ICUs. Because burn patients may commonly exhibit leukocytosis with a documented bloodstream infection, practice has been to rewire lines over a guide wire and to culture the catheter tip. However, this may increase the risk of catheter-related infections in burned patients, and a new site should be used if at all possible.

**SURGERY**

Full-thickness burns with a rigid eschar can form a tourniquet effect as the edema progresses, leading to compromised venous outflow and eventually arterial inflow. The resulting compartment syndrome is most common in circumferential extremity burns, but abdominal and thoracic compartment syndromes also occur. Warning signs of impending compartment syndrome may include paresthesias, pain, decreased capillary refill, and progression to loss of distal pulses; in an intubated patient, the surgeon should anticipate the compartment syndrome and perform frequent neurovascular evaluations. Abdominal compartment syndrome should be suspected with decreased urine output, increased ventilator airway pressures, and hypotension. Hypoventilation, increased airway pressures, and hypotension may also characterize thoracic compartment syndrome. Escharotomies are rarely needed within the first 8 hours following injury and should not be performed unless indicated because of the terrible aesthetic sequelae. When indicated, they are usually performed at the bedside, preferably with electrocautery to minimize blood loss. Extremity incisions are made on the lateral and medial aspects of the limbs in an anatomic position and may extend onto the hand and hypothenar eminences of the hand. Digital escharotomies do not usually result in any meaningful salvage of functional tissue and are not recommended. Inadequate perfusion despite proper escharotomies may indicate the need for fasciotomy, but this procedure should not be routinely performed as part of the eschar release. Thoracic escharotomies should be placed along the anterior axillary lines with bilateral subcostal and subclavicular extensions. Extension of the anterior axillary incisions down the lateral abdomen typically will allow adequate release of abdominal eschar.

The strategy of early excision and grafting in burned patients revolutionized survival outcomes in burn care. Not only did it improve mortality, but early excision also decreased reconstruction surgery, hospital length of stay, and costs of care. Once the initial resuscitation is complete and the patient is hemodynamically stable, attention should be turned to excising the burn wound. Burn excision and wound coverage should ideally start within the first several days, and in larger burns, serial excisions can be performed as patient condition allows. Excision is performed with repeated tangential slices using a Watson or Goulian blade until viable, diffusely bleeding tissue remains. It is appropriate to leave healthy dermis, which will appear white with punctate areas of bleeding. Excision to fat or fascia may be necessary in deeper burns. The downside of tangential excision is a high blood loss, though this may be ameliorated using techniques such as instillation of an epinephrine tumescence solution underneath the burn. Pneumatic tourniquets are helpful in extremity burns, and compresses soaked in a dilute epinephrine solution are necessary adjuncts after excision. A fibrinogen and thrombin spray sealant (Tisseel Fibrin Sealant; Baxter, Deerfield, IL) also has beneficial effects on both hemostasis and graft adherence to the wound bed. The use of these techniques has markedly decreased the number of blood transfusions given during burn surgery. For patients with clearly deep burns and concern for excessive blood loss, fascial excision may be employed. In this technique, electrocautery is used to excise the burned tissue and the underlying subcutaneous tissue down to muscle fascia. This technique markedly decreases blood loss but results in a cosmetically inferior appearance due to the loss of subcutaneous tissue. For excision of burns in difficult anatomic areas, such as the face, eyelids, or hands, a pressurized water dissector may offer more precision but is time consuming, has a steep learning curve, and is expensive.

**WOUND COVERAGE**

Since full-thickness burns are impractical for most burn wounds, split-thickness sheet autografts harvested with a power dermatome make the most durable wound coverings and have a decent cosmetic appearance. In larger burns, meshed autografted skin provides a larger area of wound coverage. This also allows drainage of blood and serous fluid to prevent accumulation under the skin graft with subsequent graft loss. Areas of cosmetic importance such as the face, neck, and hands should be grafted with nonmeshed sheet grafts to ensure optimal appearance and function. Unfortunately, even extensive meshing of skin grafts in patients with limited donor sites may not provide adequate amounts of skin. One emerging technique for large burns with limited donor sites is the Meek micrografting technique, or “postage-stamp” technique, where expansion ratios of up to 9:1 are able to be achieved. This technique has a considerable learning curve and requires further investigation to determine whether it is the optimal technique for large surface area burns with limited donor sites. Options for temporary wound coverage include human cadaveric allograft, which is incorporated into the wound but is rejected by the immune system and must be eventually replaced. This allows temporary biologic wound coverage until donor sites heal enough so that they may be reharvested. Xenograft appears to function as well as allograft for temporary wound coverage and is considerably less expensive.

The search for a perfect permanent synthetic skin substitute remains elusive. Integra (Integra LifeSciences Corporation, Plainsboro, NJ) is a bilayer product with a porous
collagen-chondroitin 6-sulphate inner layer that is attached to an outer silastic sheet, which helps prevent fluid loss and infection as the inner layer becomes vascularized, creating an artificial neodermis. At approximately 2 weeks after placement, the silastic layer can be removed and a thin autograft can be placed over the neodermis. This results in faster healing of the more superficial donor sites and has been increasingly utilized for treatment of complex wounds and injuries. Alloderm (LifeCell Corporation, The Woodlands, TX) is a dermal substitute consisting of cryopreserved acellular human dermis. NovoSorb™ Biodegradable Temporizing Matrix (PolyNovo Limited, Melbourne, Australia) is a biodegradable polyurethane dermal substitute newly available and recently approved by the United States Food and Drug Administration (FDA). These dermal substitutes should also be used in combination with thin split-thickness skin grafts for final wound coverage.

Epidermal skin substitutes such as cultured epithelial autografts are an option in patients with massive burns and very limited donor sites. Their clinical use has been limited by a long turnaround time for culturing, as well as the fragility of the cultured skin, which creates great difficulty with intraoperative handling and graft take. There are promising developments in skin culturing techniques and engineered skin development, but no other products are FDA approved and commercially available.

Thighs make convenient anatomic donor sites; they are easily harvested and relatively hidden from an aesthetic standpoint. The thicker skin of the back is useful in older patients, who have thinner skin elsewhere and may have difficulty with healing of donor sites. The buttocks are an excellent donor site in infants and toddlers; silver sulfadiazine can be applied to the donor site with a diaper as coverage. The scalp is also an excellent donor site; the skin is thick and the many hair follicles allow rapid healing, with the added advantage of being completely hidden once hair regrows. Epinephrine tumesence is necessary for harvesting the scalp, for both hemostasis of this hypervascular area and also to create a smooth contoured surface for harvesting.

The list of commonly used donor site dressings is long and includes simple transparent films to hydrocolloids, petrolatum gauzes, and silver-impregnated dressings. Donor sites close to fresh grafts may be dressed with a porous nonadherent gauze, and both the donors and grafts are soaked with an antimicrobial solution. Principles behind choosing a dressing should balance ease of care, comfort, infection control, and cost. The choice of donor site dressing is largely institution dependent, and few data support the clear superiority of any single treatment plan.

**REHABILITATION**

Rehabilitation is an integral part of the clinical care plan for the burn patient and should be initiated on admission. Immediate and ongoing physical and occupational therapy is mandatory to prevent functional loss. Patients who are unable to actively participate should have passive range-of-motion exercises done at least twice a day. This includes patients with burns over joints, such as with hand burns. Patients should be taught exercises they can do themselves to maintain full range of motion. Patients with foot and extremity burns should be instructed to walk independently without crutches or other assistive devices to prevent extremity swelling, desensitize the burned areas, and prevent disuse atrophy; when patients are not ambulating, they must elevate the affected extremity to minimize swelling. If postoperative immobilization is used for graft protection, the graft should be evaluated early and at frequent intervals so that active exercise can be resumed at the earliest possible occasion. The transition to outpatient care should also include physical and occupational therapy, with introduction of exercises designed to accelerate return to activities of daily living as well as specific job-related tasks. Tight-fitting pressure garments provide vascular support in burns that are further along in the healing process. Whether they prevent hypertrophic scar formation has been long debated. However, they do provide vascular support that many patients find more comfortable.

**LATE COMPLICATIONS: HYPERTROPHIC SCAR, CONTRACTURES, AND HETEROOTOPIC OSSIFICATION**

Once patients have recovered from their acute burns, many face management of the hypertrophic burn scars. In patients with healed burns or donor sites, hypertrophic scar-related morbidity includes pruritus, erythema, pain, thickened tight skin, and even contractures. Within these scars, there is believed to be an increased inflammatory response, irregular neovascularization, aberrant cytokine and Toll-like receptor expression, abundant collagen production, and abnormal extracellular matrix structure. Treatment for these scars has included nonsurgical therapies such as compression garments, silicone gel sheeting, massage, physical therapy, and corticosteroid. Surgical excision and scar revision represent more invasive scar management approaches that are often necessary for functional and aesthetic recovery.

Laser-based therapies provide additional treatment options for symptomatic hypertrophic scars. Two of the most common ones are the pulsed dye laser (PDL) and the ablative carbon dioxide (CO2) laser. The PDL causes photothermolysis of hemoglobin, resulting in coagulative necrosis. It obliterates small capillaries close to the skin and has had success treating congenital, cutaneous vascular malformations. The CO2 laser has been used for treatment of acne and recently has been gaining acceptance for its use to treat hypertrophic burn scars. It works by ablating microscopic columns of tissue to flatten scars and is also believed to stimulate matrix metalloproteinases and other signaling pathways to induce collagen reorganization. Lasers are ultimately believed to help with scar remodeling and collagen reorganization. CO2 laser therapy has been shown to decrease symptoms associated with hypertrophic scarring, including scar appearance, pliability, contracture, neuropathic pain, and pruritus. A recent prospective study utilizing PDL and CO2 laser therapy demonstrated improved signs and symptoms of hypertrophic scars based on the Vancouver Scar Scale and the University of North Carolina 4P Scar Scale. Outpatient and office-based treatment sessions are tolerated well by most patients. There is wide practice variation on when to start therapy and the number of treatments, but the literature has general support for starting treatment at 6 to 12 months and offering three treatments. More research is needed to determine the full potential of laser therapy to provide burn survivors a less invasive treatment of hypertrophic scars with improved symptoms and quality of life.

Contractures are another long-term complication of burn injury that can result in significant morbidity. Contractures result from both wound contracture and scar contracture and prevents range of motion of a particular joint. Factors influencing contracture development include burn depth and activation...
of dermal fibroblasts, myofibroblasts, fibrocytes, and helper T cells.\textsuperscript{196} Despite aggressive physiotherapy, contractures have been reported to develop in as many as one-third of burn patients. A recent study of 1,865 patients demonstrated that the shoulder is the most affected joint, followed by the elbow, wrist, ankle, and knee.\textsuperscript{197} A similar study in the pediatric population yielded similar results. Gender, race, and %TBSA were associated with contracture development in the adult population. Age and length of stay in the ICU were associated with contracture development, severity of contracture, and total number of contractures in the pediatric population. Treatment of contractures includes both nonsurgical and surgical options, ranging from pressure garments and splints to laser therapy and contracture excision.

Heterotopic ossification (HO) is another long-term morbidity associated with burn injury. HO is the pathologic development of lamellar bone in peripheral tissue. Its incidence has been reported to be between 1% and 3% of burn patients.\textsuperscript{198} Symptoms include decreased range of motion, pain, and swelling overlying the affected joints. Often times, the pathologic bone formation can be visualized radiographically with plain X-rays. Risk factors include >30% TBSA, arm burns, arm grafts, ventilator days, and number of trips to the operating room.\textsuperscript{199} Treatment includes aggressive physiotherapy, NSAIDs, bisphosphonates, radiation therapy, and rarely surgical excision. A risk scoring system has been developed to predict which burn patients are at risk of developing HO based on admission criteria; however, further validation is warranted.\textsuperscript{200}

**PSYCHOLOGICAL RECOVERY**

Psychological rehabilitation is equally important in the burn patient. Depression, posttraumatic stress disorder (PTSD), concerns about image, and anxiety about returning to society constitute predictable barriers to progress in both the inpatient and outpatient setting. Psychological distress occurs in as many as 38% of burn patients and persists in severity long after discharge.\textsuperscript{201} Rates of depression vary between 4% and 54% following injury, although these numbers vary dramatically based on the methodology used to diagnose depression.\textsuperscript{202} Still, depressive symptoms have been documented in up to 43% of patients 2 years following injury and have been associated with the female gender. Factors such as gender, extraversion, capacity for forgiveness, the event as a disaster or nondisaster, alcohol use, and peritraumatic emotional response have been identified as contributing factors to PTSD.\textsuperscript{203} Despite the psychological impact of burn injury, many patients will be able to quickly return to work or school, and goals should be set accordingly. The involvement of clinical psychologists and psychiatrists is invaluable in providing guidance and coping techniques to lessen the significant psychological burden of burn injury.

**PREVENTION**

Despite many areas of progress in prevention over the past century, burns continue to be a common source of injury. The cornerstone for burn prevention programs has been “The Five Step Process,” a systematic method of assessing, implementing, and evaluating burn hazards and subsequent intervention impact, and The Five E’s—engineering/environment, enforcement, education, emergency response, and economic initiative.\textsuperscript{204} It has been shown that patients who live in environments optimal for sustaining burn injury have decreased knowledge of burn prevention strategies.\textsuperscript{205} Some successful initiatives have included school-based education and community-based interventions targeting simple home safety measures. A 6-year study of second-graders demonstrated both short- and long-term retention of information related to burn, fire, and life safety following multiple educational sessions. Smoke alarms are known to decrease mortality from structural fires, but not all homes are equipped with proper smoke alarms, particularly in low-income households. Mandatory smoke alarm installation via community initiatives can be successful but seems to be contingent on close, long-term follow-up to ensure proper maintenance and function.\textsuperscript{206,207} Regulation of hot water heater temperatures has had some success and may be even more effective in conjunction with community-based programs emphasizing education and in-home inspections.\textsuperscript{208,209} A recent systematic review of prevention in low- and middle-income countries identified multiple successful prevention programs.\textsuperscript{210} Burn professionals have also demonstrated incomplete knowledge on best practices for fire safety and burn prevention.\textsuperscript{211} As such, appropriate education of burn professionals participating in prevention programs is necessary.

**BURN DISASTERS**

Although rare, burn disasters can be devastating to those involved due to the sudden nature of the event, the difficulty of managing personnel and resources,\textsuperscript{212} a deficit of staff experience in burn management, and relatively small resource availability for a potentially large number of patients.\textsuperscript{213} The American Burn Association has estimated that up to 30% of patients in mass casualty incidents suffer from burn injury.\textsuperscript{214} A recent review of the literature between 1990 and 2016 identified 752 burn disasters world-wide, defined as an incident with ≥50 burn injuries and/or ≥30 burn-related deaths. The majority occurred in Asia and the Middle East and are thought to be secondary to rapid industrialization, inadequate fire-prevention strategies, and poor building codes. There was a significant increase in terrorist-related incidences from 2000 to 2015. Finally, the authors demonstrated that international adoption of the U.S. Health and Human Services guidelines on bed availability for burns and trauma dramatically underestimated the number of beds needed for burn disasters.\textsuperscript{215}

Preparedness is paramount for reacting quickly, efficiently, and effectively to a burn disaster. General surgeons not trained in burn care may feel uncomfortable longitudinally caring for severely burned patients following a burn disaster. However, due to resource limitations, they should be prepared to care for burn patients for the first 72 hours of resuscitation or until the patients can be transferred to a center that specializes in burn care. This will involve initial evaluation, resuscitation, and potential interventions including central line placement, intubation, and escharotomies. Coordination for burn disasters should take place at three levels: institutional/intrafacility, interfacility/intrastate, and interstate/regional. It is important to have multiple stakeholders involved in the development of a disaster plan, from the burn surgeons to the emergency department personnel to the emergency medical personnel who are first responders.\textsuperscript{216} Resource utilization can be guided by The American Burn Association Age/TBSA survival grid, which stratifies patients into benefit-to-resource categories (outpatient, high, low, and expectant) based on age and %TBSA.\textsuperscript{3} This allows providers to allocate resources during burn disasters based on the severity of injury.
and expected survival. Another important consideration is the involvement of nonburn hospitals in the planning for burn disasters as burn centers do not possess enough resources to be sole providers in these events. Multiple strategies have been adopted by local burn centers, including the development of a consortium of hospitals surrounding one burn center in New Jersey to allow transfer of patients when resource capacity is in jeopardy.

Interest in mass burn casualty disaster planning invariably includes a discussion of radiation burns. Radioactive material results in both acute injury from immediate exposure and more prolonged injury from delayed exposure to radioactive fallout or contamination. When a 10-kiloton nuclear bomb is detonated, people at a distance 0.7 miles from ground zero absorb 4.5 Gy. At 60 days, the median lethal radiation dose (LD50) is 3.5 Sv; with aggressive medical care, this dose might be doubled to nearly 7 Sv. To put this in context, radiation exposure from a diagnostic CT of the chest or abdomen is 5 mSv, and the average annual background absorbed radiation dose is 3.6 mSv. Radiation is known to impact several organ systems and result in several syndromes based on increasing exposure doses. These syndromes include hematologic (1–8 Sv exposure), gastrointestinal (8–30 Sv exposure), and cardiovascular/neurologic syndromes (>30 Sv exposure), with the latter two being nonsurvivable.

After initial evaluation and decontamination by removing clothing, a useful way to estimate exposure is by determining the time to emesis. Patients who do not experience emesis within 4 hours of exposure are unlikely to have severe clinical effects. Emesis within 2 hours suggests a dose of at least 3 Sv, and emesis within 1 hour suggests at least 4 Sv. The hematologic system follows a similar dose-dependent temporal pattern for predicting radiation exposure, mortality, and treatment. These have been determined based on the Armed Forces Radiobiology Research Institute’s Biodosimetry Assessment Tool, which can be downloaded from www.afri.usuhs.mil.

The combination of radiation exposure and burn wounds has the potential to increase mortality compared with traditional burns. Early closure of wounds before radiation depletes circulating lymphocytes may be needed for wound healing (which occurs within 48 hours). Also, in radiation injuries combined with burn or trauma, laboratory lymphocyte counts may be unreliable. A significant difference between burn/traumatic injuries and radiation injuries is that burn/traumatic injuries can result in higher mortality when not treated within hours.

Decontamination and triage are vital to maximize the number of survivors. Initial decontamination requires removal of clothing and washing wounds with water. Irrigation fluid should be collected to prevent radiation spread into the water supply. Work by many professional organizations, including the ABA, has focused on nationwide triage for disasters and will be vital to save as many lives as possible. Yet, it is likely that expectant or comfort care could be offered to more patients than typically seen in civilian hospitals, due to resource availability after the disaster.

Finally, agents used in warfare—including white phosphorus and sulfur mustard—can cause significant morbidity and mortality. White phosphorus oxidizes when exposed to the atmosphere, creating the highly corrosive phosphorus pentoxide. Absorption of even small amounts of white phosphorus can result in hypocalcemia and hyperphosphatemia and their subsequent cardiac side effects. Treatment consists of removal of all clothing, irrigation with cool liquid (as phosphorus pentoxide liquidizes above 44°C), application of saline soaked gauze to prevent drying out and reignition, and potential surgical excision. Sulfur mustard, more commonly known as mustard gas, is another chemical warfare agent that can cause lesions similar to burn lesions. The gas infiltrates the skin surface, causing degranulation of mast cells, leukocyte invasion, and subsequent blistering of the skin. Treatment includes scrubbing to relieve the remaining skin of sulfur mustard, irrigation, and traditional burn therapy depending on the depth of the lesion.

**FUTURE AREAS OF STUDY**

It has long been anecdotally noted that two patients of similar ages and burn size may have very divergent responses to their burn injuries. Attention is being increasingly turned to identifying genetic differences among burn patients and how they affect response to injury. Specific allele variants have been linked with increased mortality in burned patients. It may be that genetic differences may predispose burn patients to severe sepsis, perhaps by downregulating the immune response. The Inflammation and the Host Response to Injury trial was a prospective, multicenter, federally funded study that aimed to define specific genetic pathways that differ in the response to both burns and traumatic injury. Blood and tissue samples from a strictly defined patient population were analyzed using gene arrays to determine whether differential expression in certain genetic pathways affects clinical outcomes. Although data from this study are still being analyzed, some interesting findings suggest that sepsis, trauma, and burn patients share common gene expression patterns, starting early after injury. These genes can upregulate proinflammatory pathways as well as disrupt antigen presentation pathways. A better understanding of these common genomic responses may allow for the targeted treatment of immunologic and signal pathways to help improve patient survival from burn injuries.

Another area of increasing interest includes integration of technology to burn size estimation and resuscitation. These include the use of smart device applications to assist with estimation of burn size and resuscitation recommendations. Further investigation is needed to determine the applicability of these models to burn estimation and resuscitation. However, as these models can include hourly updates and recommendations, they nudge clinicians to frequently reconsider fluid parameters during the critical stages of resuscitation.

With the dramatic progress in improving survival following a major burn injury during the twentieth century, understanding and addressing functional and psychological outcomes is critical to the well-being of burn survivors. Since 1993, the National Institute of Disability and Rehabilitation Research has funded four burn model systems to identify long-term sequelae of burn injuries and to develop ways to improve outcomes for survivors. Ongoing outcome studies are crucial for dismantling barriers that our patients face in returning to their communities and to the workplace or to school.

HISTORY OF WOUND HEALING

The earliest accounts of wound healing date back to about 2000 B.C., when the Sumerians employed two modes of treatment: a spiritual method consisting of incantations, and a physical method of applying poultice-like materials to the wound. The Egyptians were the first to differentiate between infected and diseased wounds compared to noninfected wounds. The Edwin Smith Surgical Papyrus, a copy of a much older document, describes at least 48 different types of wounds. A later document (Ebers Papyrus, 1550 B.C.) relates the use of concoctions containing honey (antibacterial properties), lint (absorbent properties), and grease (barrier) for treating wounds. These same properties are still considered essential in contemporary daily wound management.

The Greeks, equipped with the knowledge bequeathed by the Egyptians, went even further and classified wounds as acute or chronic in nature. Galen of Pergamum (120–201 A.D.), appointed as the doctor to the Roman gladiators, had an enormous number of wounds to deal with following gladiatorial combats. He emphasized the importance of maintaining a moist environment to ensure adequate healing. It took almost 19 centuries for this important concept to be proven scientifically, when it was shown that the epithelialization rate increases by 50% in a moist wound environment when compared to a dry wound environment.1

The next major stride in the history of wound healing was the discovery of antiseptics and their importance in reducing wound infections. Ignaz Philipp Semmelweis, a Hungarian obstetrician (1818–1865), noted that the incidence of puerperal fever was much lower if medical students, following cadaver-dissection class and prior to attending childbirth, washed their hands with soap and hypochlorite. Louis Pasteur (1822–1895) was instrumental in dispelling the theory of spontaneous generation of germs and proving that germs existed in and were always introduced from the environment. Joseph Lister probably made one of the most significant contributions to wound healing. On a visit to Glasgow, Scotland, Lister noted that some areas of the city’s sewer system were less murky than the rest. He discovered that the water from pipes that were dumping waste containing carbolic acid (phenol) was clear. In 1865, Lister began soaking his surgical instruments in phenol and spraying the operating rooms, reducing the postoperative mortality rates from 50% to 15%. After attending an impressive lecture by Lister in 1876, Robert Wood Johnson left the meeting and began 10 years of research that would ultimately result in the production of an antiseptic dressing in the form of cotton gauze impregnated with iodoform. Since then, several other materials have been used to impregnate cotton gauze to achieve antisepsis.

The 1960s and 1970s led to the development of polymeric dressings. These polymeric dressings can be custom made to specific parameters, such as permeability to gases (occlusive vs. semi-occlusive), varying degrees of absorbency, and different physical forms. Due to the ability to customize, the available range of materials that aid in wound care has grown exponentially to include an ever-expanding variety. Currently, the practice of wound healing encompasses manipulation and/or use of, among others, inflammatory cytokines, growth factors, and bioengineered tissue. It is the combination of all these modalities that enables optimal wound healing. The role of organism in the perpetuation of nonhealing of chronic wounds
Wound healing is a complex cellular and biochemical cascade that leads to restitution of integrity and function. Although wounds are classified under one entity, it is believed that they behave differently based on the host and organism involved. The future of wound healing is in “precision medicine” in which treatment strategies will be based on the host, the underlying mechanism, and the organisms in the wound bed and tissue.

PHASES OF WOUND HEALING
Wound healing is a complex process of overlapping phases that is initiated by an injury or wound. Normal wound healing is divided into phases defined by characteristic cellular populations and biochemical activities: (a) hemostasis and inflammation, (b) proliferation, and (c) maturation and remodeling. An approximate timeline of these events is depicted in Fig. 9-1. This sequence of events in most circumstances spans the time from injury to resolution of acute wounds. All wounds need to progress through this series of cellular and biochemical events that characterize the phases of healing in order to successfully reestablish tissue integrity. However, multiple factors can interfere with this sequence and can lead to lengthy healing (chronic wounds) or nonhealing.

Hemostasis and Inflammation
Hemostasis precedes and initiates inflammation with the ensuing release of chemotactic factors from the wound site (Fig. 9-2A). Wounding by definition disrupts tissue integrity, leading to division of blood vessels and direct exposure of extracellular matrix to platelets. Exposure of subendothelial collagen to platelets results in platelet aggregation, degranulation, and activation of the coagulation cascade. Platelet α granules release a number of wound-active substances, such as platelet-derived growth factor (PDGF), transforming growth factor-β (TGF-β), platelet-activating factor (PAF), fibronectin, and serotonin. In addition to achieving hemostasis, the fibrin clot serves as scaffolding for the migration into the wound of inflammatory cells such as polymorphonuclear leukocytes (PMNs, neutrophils) and monocytes.

Cellular infiltration after injury follows a characteristic, predetermined sequence (see Fig. 9-1). PMNs are the first infiltrating cells to enter the wound site, peaking at 24 to 48 hours. Increased vascular permeability, local prostaglandin release, and the presence of chemotactic substances such as complement factors, interleukin-1 (IL-1), tumor necrosis factor-α (TNF-α), TGF-β, platelet factor 4, or bacterial products all stimulate neutrophil migration.

The postulated primary role of neutrophils is phagocytosis of bacteria and tissue debris. PMNs are also a major source of cytokines early during inflammation, especially TNF-α which may have a significant influence on subsequent angiogenesis and collagen synthesis (see Fig. 9-2B). PMNs also release proteases such as collagenases, which participate in matrix and ground substance degradation in the early phase of wound healing. Other than their role in limiting infections, these cells do not appear to play a role in collagen deposition or acquisition of mechanical wound strength. On the contrary, neutrophil factors have been implicated in delaying the epithelial closure of wounds.

The second population of inflammatory cells that invades the wound consists of macrophages, which are recognized as being essential to successful healing. Derived from circulating monocytes, macrophages achieve significant numbers in the wound by 48 to 96 hours post injury and remain present until wound healing is complete.

Macrophages, like neutrophils, participate in wound debridement via phagocytosis and contribute to microbial stasis via oxygen radical and nitric oxide synthesis (see Fig. 9-2B,C). The macrophage’s central function is activation and recruitment of other cells via mediators such as cytokines and growth factors, as well as directly by cell-cell interaction and intercellular adhesion molecules (ICAM). By releasing such mediators as TGF-β, vascular endothelial growth factor (VEGF), insulin-like growth factor (IGF), epithelial growth factor (EGF), and lactate, macrophages regulate cell proliferation, matrix synthesis, and angiogenesis. Macrophages also play a significant role in regulating angiogenesis and matrix deposition and remodeling (Table 9-1).

T lymphocytes comprise another population of inflammatory/immune cells that routinely invades the wound. Less
numerous than macrophages, T-lymphocyte numbers peak at about 1 week post injury and truly bridge the transition from the inflammatory to the proliferative phase of healing. Though known to be essential to wound healing, the role of lymphocytes in wound healing is not fully defined. A significant body of data supports the hypothesis that T lymphocytes play an active role in the modulation of the wound environment. Depletion of most wound T lymphocytes decreases wound strength and collagen content, while selective depletion of the CD8+ suppressor subset of T lymphocytes enhances wound healing. However, depletion of the CD4+ helper subset has no effect. Lymphocytes also exert a downregulating effect on fibroblast collagen synthesis by cell-associated interferon IFN-γ, TNF-α, and IL-1. This effect is lost if the cells are physically separated, suggesting that extracellular matrix synthesis is regulated not only via soluble factors but also by direct cell-cell contact between lymphocytes and fibroblasts.

**Proliferation**

The proliferative phase is the second phase of wound healing and roughly spans days 4 through 12 (see Fig. 9-2C). It is during this phase that tissue continuity is reestablished. Fibroblasts and endothelial cells are the last cell populations to infiltrate the healing wound, and the strongest chemotactic factor for fibroblasts is PDGF. Upon entering the wound environment, recruited fibroblasts first need to proliferate, and then become activated, to carry out their primary function of matrix synthesis remodeling. This activation is mediated mainly by the cytokines and growth factors released from wound macrophages.

Fibroblasts isolated from wounds synthesize more collagen than nonwound fibroblasts, they proliferate less, and they actively carry out matrix contraction. Although it is clear that the cytokine-rich wound environment plays a significant role in this phenotypic alteration and activation, the exact mediators are only partially characterized. Additionally, lactate, which accumulates in significant amounts in the wound environment over time (~10 mmol), is a potent regulator of collagen synthesis through a mechanism involving adenosine diphosphate (ADP)-ribosylation.

Endothelial cells also proliferate extensively during this phase of healing. These cells participate in the formation of new capillaries (angiogenesis), a process essential to successful wound healing. Endothelial cells migrate from intact venules close to the wound. Their migration, replication, and new capillary tubule formation is under the influence of such cytokines and growth factors as TNF-α, TGF-β, and VEGF. Although
many cells produce VEGF, macrophages represent a major source in the healing wound, and VEGF receptors are located specifically on endothelial cells. 18,19

**Matrix Synthesis**

**Biochemistry of Collagen.** Collagen, the most abundant protein in the body, plays a critical role in the successful completion of adult wound healing. Its deposition, maturation, and subsequent remodeling are essential to the functional integrity of the wound.

Although there are at least 18 types of collagen described, the main ones of interest to wound repair are types I and III. Type I collagen is the major component of extracellular matrix in skin. Type III, which is also normally present in skin, becomes more prominent and important during the repair process.

Biochemically, each chain of collagen is composed of a glycine residue in every third position. The second position in the triplet is made up of proline or lysine during the translation process. The polypeptide chain that is translated from mRNA contains approximately 1000 amino acid residues and is called protocollagen. Release of protocollagen into the endoplasmic reticulum results in the hydroxylation of proline and lysine by specific hydroxylases (Fig. 9-3). Prolyl hydroxylase requires oxygen and iron as cofactors, α-ketoglutarate as co-substrate, and ascorbic acid (vitamin C) as an electron donor. In the endoplasmic reticulum, the protocollagen chain is also glycosylated by the linking of galactose and glucose at specific hydroxyl-sine residues. These steps of hydroxylation and glycosylation alter the hydrogen bonding forces within the chain, imposing steric changes that force the protocollagen chain to assume an α-helical configuration. Three α-helical chains entwine to form a right-handed superhelical structure called procollagen. At both ends, this structure contains nonhelical peptide domains called registration peptides. Although initially joined by weak, ionic bonds, the procollagen molecule becomes much stronger by the covalent cross-linking of lysine residues.

Extracellularly, the nonhelical registration peptides are cleaved by a procollagen peptidase, and the procollagen strands undergo further polymerization and cross-linking. The resulting collagen monomer is further polymerized and cross-linked by the formation of intra- and intermolecular covalent bonds.

Collagen synthesis, as well as posttranslational modifications, are highly dependent on systemic factors such as an adequate oxygen supply; the presence of sufficient nutrients (amino acids and carbohydrates) and cofactors (vitamins and trace metals); and the local wound environment (vascular supply and lack of infection). Addressing these factors and reversing nutritional deficiencies can optimize collagen synthesis and deposition.

**Proteoglycan Synthesis.** Glycosaminoglycans comprise a large portion of the “ground substance” that makes up granulation tissue. Rarely found free, they couple with proteins to form proteoglycans. The polysaccharide chain is made up of repeating disaccharide units composed of glucuronic or iduronic acid and a hexosamine, which is usually sulfated. The disaccharide
The composition of proteoglycans varies from about 10 units in the case of heparin sulfate to as much as 2000 units in the case of hyaluronic acid.

The major glycosaminoglycans present in wounds are dermatan and chondroitin sulfate. Fibroblasts synthesize these compounds, increasing their concentration greatly during the first 3 weeks of healing. The interaction between collagen and proteoglycans is being actively studied. It is thought that the assembly of collagen subunits into fibrils and fibers is dependent upon the lattice provided by the sulfated proteoglycans.

Furthermore, it appears that the extent of sulfation is critical in determining the configuration of the collagen fibrils. As scar collagen is deposited, the proteoglycans are incorporated into the collagen scaffolding. However, with scar maturation and collagen remodeling, the content of proteoglycans gradually diminishes.

**Maturation and Remodeling**

The maturation and remodeling of the scar begins during the fibroplastic phase and is characterized by a reorganization of previously synthesized collagen. Collagen is broken down by matrix metalloproteinases (MMPs), and the net wound collagen content is the result of a balance between collagenolysis and collagen synthesis. There is a net shift toward collagen synthesis and eventually the reestablishment of extracellular matrix composed of a relatively acellular collagen-rich scar.

Wound strength and mechanical integrity in the fresh wound are determined by both the quantity and quality of the newly deposited collagen. The deposition of matrix at the wound site follows a characteristic pattern: fibronectin and collagen type III constitute the early matrix scaffolding; glycosaminoglycans and proteoglycans represent the next significant matrix components; and collagen type I is the final matrix. By several weeks post injury, the amount of collagen in the wound reaches a plateau, but the tensile strength continues to increase for several more months. Fibril formation and fibril cross-linking result in decreased collagen solubility, increased strength, and increased resistance to enzymatic degradation of the collagen matrix. Fibrillin, a glycoprotein secreted by fibroblasts, is essential for the formation of elastic fibers found in connective tissue. Scar remodeling continues for many (6 to 12) months post injury, gradually resulting in a mature, avascular, and acellular scar. The mechanical strength of the scar never achieves that of the uninjured tissue.

There is a constant turnover of collagen in the extracellular matrix, both in the healing wound as well as during normal tissue homeostasis. Collagenolysis is the result of collagenase activity, a class of MMPs that require activation. Both collagen synthesis and lysis are strictly controlled by cytokines and growth factors. Some factors affect both aspects of collagen remodeling. For example, TGF-β increases new collagen transcription and also decreases collagen breakdown by stimulating synthesis of tissue inhibitors of metalloproteinase. This balance of collagen deposition and degradation is the ultimate determinant of wound strength and integrity.

**Epithelialization**

Epithelialization is the final step in establishing tissue integrity. This process is characterized primarily by proliferation and migration of epithelial cells adjacent to the wound (Fig. 9-4). The process begins within 1 day of injury and is seen as thickening of the epidermis at the wound edge. Marginal basal cells at the edge of the wound lose their firm attachment to the underlying dermis, enlarge, and begin to migrate across the surface of the provisional matrix. Fixed basal cells in a zone near the cut edge undergo a series of rapid mitotic divisions, and these cells appear to migrate by moving over one another in a leapfrog fashion until the defect is covered. Once the defect is bridged, the migrating epithelial cells lose their flattened appearance, become more columnar in shape, and increase their mitotic activity. Layering of the epithelium is reestablished, and the surface layer eventually keratinizes.

Figure 9-3. The steps of collagen synthesis. mRNA = messenger RNA.
Reepithelialization is complete in less than 48 hours in the case of approximated incised wounds but may take substantially longer in the case of larger wounds, where there is a significant epidermal/dermal defect. If only the epithelium and superficial dermis are damaged, such as occurs in split-thickness skin graft donor sites or in superficial second-degree burns, then repair consists primarily of reepithelialization with minimal or no fibroplasia and granulation tissue formation. The stimuli for reepithelialization remain incompletely defined; however, it appears that the process is mediated by a combination of a loss of contact inhibition; exposure to constituents of the extracellular matrix, particularly fibronectin; and cytokines produced by immune mononuclear cells. In particular EGF, TGF-β, basic fibroblast growth factor (bFGF), PDGF, and IGF-1 have been shown to promote epithelialization.

**Role of Growth Factors in Normal Healing**

Growth factors and cytokines are polypeptides produced in normal and wounded tissue that stimulate cellular migration, proliferation, and function. They often are named for the cells from which they were first derived (e.g., platelet-derived growth factor, PDGF) or for their initially identified function (e.g., fibroblast growth factor, FGF). These names are often misleading because growth factors have been demonstrated to have multiple functions. Most growth factors are extremely potent and produce significant effects in nanomolar concentrations.

They may act in an autocrine manner (where the growth factor acts on the cell producing it), a paracrine manner (by release into the extracellular environment, where it acts on the immediately neighboring cells), or in an endocrine manner (where the effect of the substance is distant to the site of release, and the substance is carried to the effector site through the blood stream). In addition to the concentration of the growth factor, the timing of release is as important to determine their effectiveness. As these growth factors exert their effects by cell-surface receptor binding, the appropriate receptor on the responding cells must be present at the time of release in order for the biologic effect to occur. Table 9-2 summarizes the principal growth factors found in healing wounds and their known effects on cells participating in the healing process. Growth factors have divergent actions on different cells; they can be chemotaxative to one cell type while stimulating replication of a different cell type. Little is known about the ratio of growth factor concentrations, which may be as important as the absolute concentration of individual growth factors.

Growth factors act on cells via surface receptor binding. Various receptor types have been described, such as ion channels, G-protein linked, or enzyme linked. The response elicited in the cell is usually one of phosphorylation or dephosphorylation of second-messenger molecules through the action of phosphatases or kinases, resulting in activation or deactivation of proteins in the cytosol or nucleus of the target cell. Phosphorylation of nuclear proteins is followed by the initiation of transcription of target genes. The signal is stopped by internalization of the receptor-ligand complex.

**Wound Contraction**

All wounds undergo some degree of contraction. For wounds that do not have surgically approximated edges, the area of the wound will be decreased by this action (healing by secondary intention). The myofibroblast has been postulated as the major cell responsible for contraction, and it differs from the normal fibroblast in that it possesses a cytoskeletal structure. Typically this cell contains α-smooth muscle actin in thick bundles called stress fibers, giving myofibroblasts contractile capability. The α-smooth muscle actin is undetectable until day 6, and then it is increasingly expressed for the next 15 days of wound healing. After 4 weeks, this expression fades, and the cells are believed to undergo apoptosis. A puzzling point is that the identification of myofibroblasts in the wound does not correspond directly to the initiation of wound contraction, which starts almost immediately after injury. It is believed that fibroblasts might play a role in contraction. In vitro, fibroblasts placed in a collagen lattice actively move in the lattice and contract it without expressing stress fibers. It is postulated that the movement of cells with concomitant reorganization of the cytoskeleton is responsible for contraction.

**HERITABLE DISEASES OF CONNECTIVE TISSUE**

Heritable diseases of connective tissue consist of a group of generalized, genetically determined, primary disorders of one of the elements of connective tissue: collagen, elastin, or mucopolysaccharide. Five major types, Ehlers-Danlos syndrome, Marfan’s syndrome, osteogenesis imperfecta, epidermolysis bullosa, and acrodermatitis enteropathica, will be discussed, as each provides unique challenges to the surgeon.

**Ehlers-Danlos Syndrome**

Ehlers-Danlos syndrome (EDS) is a group of 10 disorders that present as a defect in collagen formation. Over half of the

affected patients manifest genetic defects encoding \( \alpha \)-chains of collagen type V, causing it to be either quantitatively or structurally defective. These changes lead to “classic” EDS with phenotypic findings that include thin, friable skin with prominent veins, easy bruising, poor wound healing, atrophic scar formation, recurrent hernias, and hyperextensible joints. Gastrointestinal problems include bleeding, hiatal hernia, intestinal diverticulae, and rectal prolapse. Small blood vessels are fragile, making suturing difficult during surgery. Large vessels may develop aneurysms, varicosities, or arteriovenous fistulas or may spontaneously rupture.\textsuperscript{31-33} Table 9-3 presents a description of EDS subtypes, including a recently recognized autosomal recessive form characterized by tenasin-X deficiency. The defect is a quantitative loss of protein, resulting in phenotypic changes similar to those observed in other types of EDS.

EDS must be considered in every child with recurrent hernias and coagulopathy, especially when accompanied by platelet abnormalities and low coagulation factor levels. Inguinal hernias in these children resemble those seen in adults. Great care should be taken to avoid tearing the skin and fascia. The transversalis fascia is thin, and the internal ring is greatly dilated. Like adults, hernia repair in these patients with the use of mesh or felt may result in a lower incidence of recurrence.\textsuperscript{34}

Closing wounds in patients with EDS might represent a major challenge to the surgeon. Dermal wounds should be closed in two layers, approximated with the sutures under tension, and the stitches should be left in place twice as long as usual. In addition, external fixation with adhesive tape can help reinforce the scar and prevent stretching.\textsuperscript{35}

---

**Marfan’s Syndrome.** Patients with Marfan’s syndrome have tall stature, arachnodactyly, lax ligaments, myopia, scoliosis, pectus excavatum, and aneurysm of the ascending aorta. Patients who suffer from this syndrome also are prone to hernias. Skin may be hyperextensible but shows no delay in wound healing.\textsuperscript{36,37}

The genetic defect associated with Marfan’s syndrome is a mutation in the \( FBN1 \) gene, which encodes for fibrillin. Previously, it was thought that structural alteration of the microfibrillar system was responsible for the phenotypic changes seen with the disease. However, recent research indicates an intricate role that \( FBN1 \) gene products play in TGF-β signaling. These extracellular matrix molecules normally bind and regulate TGF-β signaling; abnormal \( FBN1 \) gene function may cause an increase in TGF-β signaling, particularly in the aortic wall.\textsuperscript{38}

**Osteogenesis Imperfecta**

Patients with osteogenesis imperfecta (OI) have brittle bones, osteopenia, low muscle mass, hernias, and ligament and joint laxity. OI is a result of a mutation in type I collagen. Mutations in prolidase, an enzyme responsible for cleaving c-terminal proline and hydroxyproline, may have a role in the disease. There are four major OI subtypes with mild to lethal manifestations. Patients experience dermal thinning and increased bruisability. Scarring is normal, and the skin is not hyperextensible. Surgery can be successful but difficult in these patients, as the bones fracture easily under minimal stress.\textsuperscript{31,34} Table 9-4 lists the various features associated with the clinical subtypes of OI.
Epidermolysis Bullosa

Epidermolysis bullosa (EB) is classified into four major subtypes: EB simplex, junctional EB, dystrophic EB, and Kindler’s syndrome. The first three are determined by location in various skin layers; the last can present as multiple blisters throughout different layers of skin. There are identified genetic defects for each subtype, but the overall phenotype is remarkably similar. The disease manifestations include impairment in tissue adhesion within the epidermis, basement membrane, or dermis, resulting in tissue separation and blistering with minimal trauma. Characteristic features of EB are blistering and ulceration. The recessively inherited dystrophic type is characterized by defects in the COL7A1 gene, encoding type 7 collagen, important for connecting the epidermis to the dermis, and therefore phenotypically resulting in blistering. Management of nonhealing wounds in patients with EB is a challenge, as their nutritional status is compromised because of oral erosions and esophageal obstruction. Surgical interventions include esophageal dilatation and gastrostomy tube placement. Dermal incisions must be meticulously placed to avoid further trauma to skin. The skin requires nonadhesive pads covered by a “bulky” dressing to avoid blistering.

Acrodermatitis Enteropathica

Acrodermatitis enteropathica (AE) is an autosomal recessive disease of children that causes an inability to absorb sufficient zinc from breast milk or food. The AE mutation affects zinc transport in the intestine by preventing zinc from binding to the transporter, with impaired granulation tissue formation, as zinc is a necessary cofactor for DNA polymerase and reverse transcriptase, as well as different responses to cytokines and growth factors among these different fibroblast populations. Ultimate anastomotic strength is not always related to the absolute amount of collagen, and the structure and arrangement of the collagen matrix may be more important.

HEALING IN SPECIFIC TISSUES

Gastrointestinal Tract

Repair and healing of the gastrointestinal tract is essential for the normal functions of the GI tract such as absorptive, barrier, and motor functions. Full-thickness GI injury healing remains an unresolved clinical issue. Healing of full-thickness GI wounds begins with a surgical or mechanical reapposition of the bowel ends, which is most often the initial step in the repair process. Sutures or staples are principally used, although various other means such as buttons, plastic tubes, and various wrappings have been attempted with variable success. Failure of healing results in dehiscence, leaks, and fistulas, which carry significant morbidity and mortality. Conversely, excessive healing can be just as troublesome, resulting in stricture formation and stenosis of the lumen.

The gross anatomic features of the GI tract are remarkably constant throughout most of its length. Within the lumen, the epithelium is supported by the lamina propria and underlying muscularis mucosa. The submucosa lies radially and circumferentially outside of these layers, is comprised of abundant collagenous and elastic fibers, and supports neural and vascular structures. Further toward the peritoneal surface of the bowel are the inner and outer muscle layers and ultimately a peritoneal extension, the serosa. The submucosa is the layer that imparts the greatest tensile strength and greatest suture-holding capacity, a characteristic that should be kept in mind during surgical repair of the GI tract. Additionally, serosal healing is essential for quickly achieving a watertight seal from the luminal side of the bowel. The importance of the serosa is underscored by the significantly higher rates of anastomotic failure observed clinically in segments of bowel that are extraperitoneal and lack serosa (i.e., the esophagus and rectum).

Injuries to all parts of the GI tract undergo the same sequence of healing as cutaneous wounds. However, there are some significant differences (Table 9-5). Mesothelial (serosal) and mucosal healing can occur without scarring. The early integrity of the anastomosis is dependent on formation of a fibrin seal on the serosal side, which achieves water tightness, and on the suture-holding capacity of the intestinal wall, particularly the submucosal layer. There is a significant decrease in marginal strength during the first week due to an early and marked collagenolysis. The lysis of collagen is carried out by collagenase derived from neutrophils, macrophages, and intraluminal bacteria. Recently, it has been shown that strains of Pseudomonas aeruginosa undergo phenotypic shifts characterized by higher collagenase secretion in an injured/anastomosed bowel environment. Collagenase activity occurs early in the healing process, and during the first 3 to 5 days, collagen breakdown far exceeds collagen synthesis. The integrity of the anastomosis represents equilibrium between collagen lysis, which occurs early, and collagen synthesis, which takes a few days to initiate (Fig. 9-5). Collagenase is expressed following injury in all segments of the GI tract, but it is much more marked in the colon compared to the small bowel. Collagen synthesis in the GI tract is carried out by both fibroblasts and smooth muscle cells. Colon fibroblasts produce greater amounts of collagen than skin fibroblasts, reflecting different phenotypic features, as well as different responses to cytokines and growth factors among these different fibroblast populations.
Technical Considerations. Traditional teaching holds that in order for an anastomosis to heal without complications it must be tension free, have an adequate blood supply, receive adequate nutrition, and be free of sepsis. Although sound principles for all wound healing, there are several considerations unique to GI anastomotic healing. From a technical viewpoint, the ideal method of suturing two ends of bowel together has not yet been identified. Although debate exists concerning methods of creating an anastomosis, clinically there has been no convincing evidence that any given technique has any advantage over another (i.e., hand-sutured vs. stapled, continuous vs. interrupted sutures, absorbable vs. nonabsorbable sutures, or single- vs. two-layer closure). A recent meta-analysis revealed that stapled ileocolic anastomoses have fewer leak rates than hand-constructed ones, but this might not apply to colo-colic or small bowel anastomoses.46

Fluid third spacing, tissue edema, and increased intraabdominal pressure secondary to overzealous fluid administration can result in blood flow compromise in small vessels at the edge of anastomosis and thus interfere with GI healing.47,48

Bone
Following any type of injury to bone, several changes take place at the site of injury to restore structural and functional integrity. Most of the phases of healing resemble those observed in dermal healing, but some notable individual characteristics apply to

Figure 9-5. Diagrammatic representation of the concept of GI wound healing as a fine balance between collagen synthesis and collagenolysis. The “weak” period when collagenolysis exceeds collagen synthesis can be prolonged or exacerbated by any factors that upset the equilibrium. (Reproduced with permission from Dunphy JE: Fundamentals of Wound Management in Surgery. New York, NY: Chirurgecom, Inc.; 1976.)
bone injuries. The initial stage of hematoma formation consists of an accumulation of blood at the fracture site, which also contains devitalized soft tissue, dead bone, and necrotic marrow. The next stage accomplishes the liquefaction and degradation of nonviable products at the fracture site. The normal bone adjacent to the injury site can then undergo revascularization, with new blood vessels growing into the fracture site. This is similar to the formation of granulation in soft tissue. The symptoms associated with this stage are characteristic of inflammation, with clinical evidence of swelling and erythema.

Three to 4 days following injury, soft tissue forms a bridge between the fractured bone segments in the next stage (soft callus stage). The soft tissue is deposited where neovascularization has taken place and serves as an internal splint, preventing damage to the newly laid blood vessels and achieving a fibrocartilaginous union. The soft callus is formed externally along the bone shaft and internally within the marrow cavity. Clinically, this phase of healing is characterized by the cessation of pain and inflammatory signs.

The next phase consists of mineralization of the soft callus and conversion to bone (hard callus stage). This may take up to 2 to 3 months and leads to complete bony union. The bone is now considered strong enough to allow weight bearing and will appear healed on radiographs. Then remodeling phase follows, in which the excessive callus is reabsorbed and the marrow cavity is recanalized. Remodeling allows for the correct transmission of forces and restores the contours of the bone.

As in dermal healing, the process of osseous union is mediated by soluble growth factors and cytokines. The most extensively studied group is the bone morphogenetic proteins (BMPs), which belong to the TGF-β superfamily. By stimulating the differentiation of mesenchymal cells into chondroblasts and osteoblasts, BMPs directly affect bone and cartilage repair. Other growth factors such as PDGF, TGF-β, TNF-α, and bFGF also participate in bony repair by mediating the inflammatory and proliferative phases of healing.

**Cartilage**

Cartilage consists of cells (chondrocytes) surrounded by an extracellular matrix made up of several proteoglycans, collagen fibers, and water. Unlike bone, cartilage is very avascular and depends on diffusion for transmittal of nutrients across the matrix. Additionally, the hypovascular perichondrium contributes substantially to the nutrition of the cartilage. Therefore, injuries to cartilage may be associated with permanent defects due to tenuous blood supply.

The healing response of cartilage depends on the depth of injury. In a superficial injury, there is disruption of the proteoglycan matrix and injury to the chondrocytes. There is no inflammatory response, but an increase in synthesis of proteoglycan and collagen dependent entirely on the chondrocyte. The healing power of cartilage is often inadequate, and overall regeneration is incomplete. Therefore, superficial cartilage injuries are slow to heal and often result in persistent structural defects.

In contrast to superficial injuries, deep injuries involve the underlying bone and soft tissue. This leads to the exposure of vascular channels of the surrounding damaged tissue that may help in the formation of granulation tissue. Hemorrhage allows for the initiation of the inflammatory response and the subsequent mediator activation of cellular function for repair. As the granulation tissue is laid down, fibroblasts migrate toward the wound and synthesize fibrous tissue that undergoes chondrification. Gradually, hyaline cartilage is formed, which restores the structural and functional integrity of the injured site.

**Tendon**

Tendons and ligaments are specialized structures that link muscle and bone, and bone and bone, respectively. They consist of parallel bundles of collagen interspersed with spindle cells. Tendons and ligaments can be subjected to a variety of injuries, such as laceration, rupture, and contusion. Due to the mobility of the underlying bone or muscles, the damaged ends usually separate. Tendon and ligament healing progresses in a similar fashion as in other areas of the body (i.e., through hematoma formation, organization, laying down of reparative tissue, and scar formation). Matrix is characterized by accumulation of types I and III collagen along with increased water, DNA, and glycosaminoglycan content. As the collagen fibers are organized, transmission of forces across the damaged portion can occur. Restoration of the mechanical integrity may never be equal to that of the undamaged tendon.

Tendon vasculature has a clear effect on healing. Hypovascular tendons tend to heal with less motion and more scar formation than tendons with better blood supply. The specialized cells, tenocytes, are metabolically very active and retain a large regenerative potential, even in the absence of vascularity. Cells on the tendon surface are identical to those within the sheath and play a role in tendon healing as well.

**Nerve**

Nerve injuries are very common, with an estimated 200,000 repairs performed every year in the United States. Peripheral nerves are a complex arrangement of axons, nonneuronal cells, and extracellular elements. There are three types of nerve injuries: neurapraxia (focal demyelination), axonotmesis (interruption of axonal continuity but preservation of Schwann cell basal lamina), and neurotmesis (complete transection). Following all types of injury, the nerve ends progress through a predictable pattern of changes involving three crucial steps: (a) survival of axonal cell bodies; (b) regeneration of axons that grow across the transected nerve to reach the distal stump; and (c) migration and connection of the regenerating nerve ends to the appropriate nerve ends or organ targets.

Phagocytes remove the degenerating axons and myelin sheath from the distal stump (Wallerian degeneration). Regenerating axonal sprouts extend from the proximal stump and probe the distal stump and the surrounding tissues. Schwann cells envelope and help in remyelinating the regenerating axons. Functional units are formed when the regenerating axons connect with the appropriate end targets. Several factors play a role in nerve healing, such as growth factors, cell adhesion molecules, and nonneuronal cells and receptors. Growth factors include nerve growth factor, brain-derived neurotrophic factor, basic and acidic fibroblastic growth factors, and neuroleukin. Cell adhesion molecules involved in nerve healing include nerve adhesion molecule, neuron-glia adhesion molecule, myelin adhesion glycoprotein, and N-cadherin. This complex interplay of growth factors and adhesion molecules helps in nerve regeneration.

**Fetal Wound Healing**

The main characteristic that distinguishes the healing of fetal wounds from that of adult wounds is the lack of scar formation. Understanding how fetal wounds achieve integrity without...
Evidence of scarring holds promise for the possible manipulation of unwanted fibrosis or excessive scar formation in adults. Although early fetal healing is characterized by the absence of scarring and resembles tissue regeneration, there is a phase of transition during gestational life when a more adult-like healing pattern emerges. This so-called “transition wound” occurs at the beginning of the third trimester, and during this period, there is scarless healing; however, there is a loss of the ability to regenerate skin appendages. Eventually a classic, adult-patterned healing with scar formation occurs exclusively, although overall healing continues to be faster than in adults.

There are a number of characteristics that may influence the differences between fetal and adult wounds. These include wound environment, inflammatory responses, differential growth factor profiles, and wound matrix.

**Wound Environment.** The fetus is bathed in a sterile, temperature-stable fluid environment, although this alone does not explain the observed differences. Experiments have demonstrated that scarless healing may occur outside of the amniotic fluid environment, and conversely, scars can form in utero.

**Inflammation.** The extent and robustness of the inflammatory response correlates directly with the amount of scar formation in all healing wounds. Reduced fetal inflammation due to the immaturity of the fetal immune system may partially explain the lack of scarring observed. Not only is the fetus neutropenic, but fetal wounds also contain lower numbers of PMNs and macrophages.

**Growth Factors.** Fetal wounds are notable for the absence of TGF-β, which may have a significant role in scarring. Blocking TGF-β1 or TGF-β2 using neutralizing antibodies considerably reduces scar formation in adult wounds. Exogenous application of TGF-β3 downregulates TGF-β1 and TGF-β2 levels at the wound site with a resultant reduction in scarring. Thus, the balance between the concentration and/or activity of TGF-β isoforms may be important for regulating scar production.

**Wound Matrix.** The fetal wound is characterized by excessive and extended hyaluronic acid production, a high-molecular-weight glycosaminoglycan that is produced primarily by fibroblasts. Although adult wounds also produce hyaluronic acid, its synthesis is sustained only in the fetal wound. Components of amniotic fluid, most specifically fetal urine, have a unique ability to stimulate hyaluronic acid production. Fetal fibroblasts produce more collagen than adult fibroblasts, and the increased level of hyaluronic acid may aid in the orderly organization of collagen. As a result of these findings, hyaluronic acid is used topically to enhance healing and to inhibit postoperative adhesion formation. The collagen pattern of fetal wounds is reticular in nature and resembles surrounding tissue, while adult patterns express large bundles of parallel collagen fibrils oriented perpendicular to the surface.

**CLASSIFICATION OF WOUNDS**

Wounds are classified as either acute or chronic. By definition, an acute wound becomes chronic if healing is not achieved after 4 weeks of treatment. Acute wounds heal in a predictable manner and time frame as previously mentioned. The process occurs with few, if any, complications, and the end result is a well-healed wound. Surgical wounds can heal in several ways. An incised wound that is clean and closed by sutures is said to heal by primary intention. Often, because of bacterial contamination or tissue loss, a wound will be left open to heal by granulation tissue formation and contraction; this constitutes healing by secondary intention. Delayed primary closure, or healing by tertiary intention, represents a combination of the first two, consisting of the placement of sutures, allowing the wound to stay open for a few days, and the subsequent closure of the sutures (Fig. 9-6).

The healing spectrum of acute wounds is broad (Fig. 9-7). In examining the acquisition of mechanical integrity and strength during healing, the normal process is characterized by a constant and continual increase that reaches a plateau at some point after injury. In regular wounds, the maximal wound strength is reached after about 6 weeks of healing. A fully healed wound achieves only 75% to 80% of a normal tissue. Wounds with delayed healing are characterized by decreased wound-breaking strength in comparison to wounds that heal at a normal rate; however, they eventually achieve the same integrity and strength as wounds that heal normally. Conditions such as nutritional deficiencies, infections, or severe trauma cause delayed healing, which reverts to normal with correction of the underlying pathophysiology. Impaired healing is characterized by a failure to achieve mechanical strength equivalent to normally healed wounds. Patients with compromised immune systems such as those with diabetes, chronic steroid usage, or tissues damaged by radiotherapy are prone to this type of impaired healing. The surgeon must be aware of these situations and exercise great care in the placement of incision and suture selection, postoperative care, and adjunctive therapy to maximize the chances of healing without supervening complications.

In general, wounds heal by a combination of mechanisms, including connective tissue deposition, contraction, and...
epithelialization, depending on wound type. Surgically closed wounds need mostly epithelialization for healing, while open wounds require a combination of tissue contraction, connective tissue deposition, and epithelialization to a lesser extent. Chronic ulcers heal by secondary intention similar to open wounds.

Normal healing is affected by both systemic and local factors (Table 9-6). The clinician must be familiar with these factors and should attempt to counteract their deleterious effects. Complications occurring in wounds with higher risk can lead to failure of healing or the development of chronic, nonhealing wounds.

### Factors Affecting Wound Healing

#### Advanced Age

Most surgeons believe that aging produces intrinsic physiologic changes that result in delayed or impaired wound healing. Clinical experience with elderly patients tends to support this belief. Studies of hospitalized surgical patients show a direct correlation between older age and poor wound healing outcomes such as dehiscence and incisional hernia. However, these statistics fail to take into account underlying illnesses or diseases as a possible source of impaired wound healing in the elderly. The increased incidence of cardiovascular disease, metabolic diseases (diabetes mellitus, malnutrition, and vitamin deficiencies), and cancer, and the widespread use of drugs that impair wound healing may all contribute to the higher incidence of wound problems in the elderly. However, more recent clinical experience suggests that major operative interventions can be accomplished safely in the elderly.

The results of animal studies regarding the effects of aging on wound healing have yielded contradictory results. In healthy human volunteers, there was a significant delay of 1.9 days in the epithelialization of superficial skin defects in those older than 70 years of age when compared to younger volunteers. In the same volunteers, using a micro-model of fibroplasia, no difference in DNA or hydroxyproline wound accumulation could be demonstrated between the young and elderly groups; however, the young volunteers had a significantly higher amount of total α-amino nitrogen in their wounds, a reflection of total protein content of the wound. Thus, although wound collagen synthesis does not seem to be impaired with advanced age, noncollagenous protein accumulation at wounded sites is decreased with aging, which may impair the mechanical properties of scarring in elderly patients. Generally, in a relatively healthy person age will cause a delay in healing rather than nonhealing.

### Hypoxia, Anemia, and Hypoperfusion

Low oxygen tension has a profoundly deleterious effect on all aspects of wound healing. Fibroplasia, although stimulated initially by the hypoxic wound environment, is significantly impaired by local hypoxia. Optimal collagen synthesis requires oxygen as a cofactor, particularly for the hydroxylation steps. Increasing subcutaneous oxygen tension levels by increasing the fraction of inspired oxygen ($\text{FiO}_2$) of inspired air for brief periods during and immediately following surgery results in enhanced collagen deposition and in decreased rates of wound infection after elective surgery.

Major factors affecting local oxygen delivery include hypoperfusion either for systemic reasons (low volume or cardiac failure) or due to local causes (arterial insufficiency, local vasoconstriction, or excessive tension on tissues). The level of vasoconstriction of the subcutaneous capillary bed is exquisitely responsive to fluid status, temperature, and hyperactive sympathetic tone as is often induced by postoperative pain. Correction of these factors can have a remarkable influence on wound outcome, particularly on decreasing wound infection rates. Mild to moderate normovolemic anemia does not appear to adversely affect wound oxygen tension and collagen synthesis. However, profound anemia with 15% less hematocrit can interfere with wound healing.

### Steroids and Chemotherapeutic Drugs

Large doses or chronic usage of glucocorticoids reduce collagen synthesis and wound strength. The major effect of steroids is to inhibit the inflammatory phase of wound healing (angiogenesis, neutrophil and macrophage migration, and fibroblast proliferation) and the release of lysosomal enzymes. The stronger the anti-inflammatory effect of the steroid compound used, the greater the inhibitory effect on wound healing. Steroids used after the first 3 to 4 days after injury do not affect wound healing as severely as when they are used in the immediate postoperative phase.

period. Therefore, if possible, their use should be delayed, or alternatively, forms with lesser anti-inflammatory effects should be administered.

In addition to their effect on collagen synthesis, steroids also inhibit epithelialization and contraction and contribute to increased rates of wound infection, regardless of the time of administration. Steroid-delayed healing of cutaneous wounds can be stimulated to epithelialize by topical application of vitamin A. Collagen synthesis of steroid-treated wounds also can be stimulated by vitamin A.

All chemotherapeutic antimitabolite drugs adversely affect wound healing by inhibiting early cell proliferation, wound DNA and protein synthesis, attenuation of the inflammatory phase, decrease fibrin deposition, and delay wound contraction, all of which are critical to successful healing. The effect is worse if these agents are given preoperatively; so a delay in the use of such drugs for about 2 weeks after injury appears to lessen wound healing impairment. Extravasation of most chemotherapeutic agents is associated with tissue necrosis, marked ulceration, and protracted healing at the affected site.

**Metabolic Disorders.** Diabetes mellitus is the best known of the metabolic disorders contributing to increased rates of wound infection and failure. Uncontrolled diabetes results in reduced inflammation, angiogenesis, and collagen synthesis. Additionally, the large- and small-vessel disease that is the hallmark of advanced diabetes contributes to hypoperfusion and local hypoxemia. Defects in granulocyte function, capillary ingrowth, and fibroblast proliferation all have been described in diabetes. Obesity, insulin resistance, hyperglycemia, and diabetic renal failure contribute significantly and independently to the impaired wound healing observed in diabetics. In wound studies on experimental diabetic animals, insulin restores collagen synthesis and granulation tissue formation to normal levels if given during the early phases of healing. In clean, noninfected, and well-perfused experimental wounds in human diabetic volunteers, type I diabetes mellitus was noted to decrease wound collagen accumulation in the wound, independent of the degree of glycemic control. Type 2 diabetic patients showed no effect on collagen accumulation when compared to healthy, age-matched controls. Furthermore, the diabetic wound appears to be lacking in sufficient growth factor levels, which signal normal healing. It remains unclear whether decreased collagen synthesis or an increased breakdown due to an abnormally high proteolytic wound environment is responsible.

Careful preoperative correction of blood sugar levels improves the outcome of wounds in diabetic patients. Increasing the inspired oxygen tension, judicious use of antibiotics, and correction of other coexisting metabolic abnormalities all can result in improved wound healing. Additionally, revascularization to local areas with chronic ulcers will aid in the healing process.

Uremia also has been associated with disordered wound healing and impairs defenses for infection. Experimentally, uremic animals demonstrate decreased wound collagen synthesis and breaking strength, causing delayed healing of intestinal anastomosis and abdominal wounds. The contribution of uremia alone to this impairment, rather than that of associated malnutrition, is difficult to assess. The clinical use of dialysis to correct the metabolic abnormalities and nutritional restoration should impact greatly on the wound outcome of such patients. In some uremic patients, wounds might be associated with abnormal deposition of calcium and phosphate in the tissue leading to uremic gangrene syndrome (calciphylaxis). In such patients, the wounds are extremely painful and difficult to heal.

Obesity is the largest growing public health problem in the United States and the world. Over 60% of Americans are overweight or obese. Uncomplicated obesity (i.e., in the absence of comorbid conditions such as cardiovascular disease, diabetes, or respiratory insufficiency) has by itself significant deleterious effects on wound healing. Visceral adiposity is active metabolically and immunologically and, through generation of proinflammatory cytokines and adipokines, leads to the development of the metabolic syndrome. Many of these molecules have effects on cells participating in the healing response. In nondiabetic obese rodents, wounds are mechanically weaker, and there is less dermal and reparative scar collagen. Preadipocytes infiltrate the dermis, and although they can evolve into fibroblasts, their regulatory mechanisms appear different from those of dermal or wound fibroblasts. Many studies indicate that obese patients have higher rates of perioperative complications, with estimates as high as 30% for wound dehiscence, 17% for surgical site infections, 30% for incisional hernias, 19% for seromas, 13% for hematomas, and 10% for fat necrosis. Increased subcutaneous fat was associated with a tenfold increased risk of surgery-related complications including anastomotic leaks, abdominal collection, and wound infections. In many studies, obesity is a constant and major risk factor for hernia formation and recurrence after repair. The mechanism by which obesity impairs wound healing awaits complete delineation.

**Nutrition.** The importance of nutrition in the recovery from traumatic or surgical injury has been recognized by clinicians since the time of Hippocrates. Poor nutritional intake or lack of individual nutrients significantly alters many aspects of wound healing. The clinician must pay close attention to the nutritional status of patients with wounds, since wound failure or wound infections may be no more than a reflection of poor nutrition. Although the full interaction of nutrition and wound healing is still not fully understood, efforts are being made to develop wound-specific nutritional interventions and institute the pharmacologic use of individual nutrients as modulators of wound outcomes.

Experimental rodents fed either a 0% or 4% protein diet have impaired collagen deposition with a secondary decrease in skin and fascial wound-breaking strength and increased wound infection rates. Induction of energy-deficient states by providing only 50% of the normal caloric requirement leads to decreased granulation tissue formation and matrix protein deposition in rats. Acute fasting in rats markedly impairs collagen synthesis while decreasing procollagen mRNA.

Clinically, it is extremely rare to encounter pure energy or protein malnutrition, and the vast majority of patients exhibit combined protein-energy malnutrition. Such patients have diminished hydroxyproline accumulation (an index of collagen deposition) into subcutaneously implanted polystyrene tubes when compared to normally nourished patients (Fig. 9-8). Furthermore, malnutrition correlates clinically with enhanced rates of wound complications and increased wound failure following diverse surgical procedures. This reflects impaired healing response as well as reduced cell-mediated immunity, phagocytosis, and intracellular killing of bacteria by macrophages and neutrophils during protein-calorie malnutrition.

Two additional nutrition-related factors warrant discussion. First, the degree of nutritional impairment need not be
long-standing in humans, as opposed to the experimental situation. Thus, patients with brief preoperative illnesses or reduced nutrient intake in the period immediately preceding the injury or operative intervention will demonstrate impaired fibroplasia.\(^7\)\(^7\)\(^8\) Second, brief and not necessarily intensive nutritional intervention, either via the parenteral or enteral route, can reverse or prevent the decreased collagen deposition noted with malnutrition or with postoperative starvation.\(^7\)\(^9\)

The possible role of single amino acids in enhanced wound healing has been studied for the last several decades. Arginine appears most active in terms of enhancing wound fibroplasia. Arginine deficiency results in decreased wound-breaking strength and wound-collagen accumulation in chow-fed rats. Rats that are given 1% arginine HCl supplementation, and therefore are not arginine-deficient, have enhanced wound-breaking strength and collagen synthesis when compared to chow-fed controls.\(^8\)\(^0\) Studies have been carried out in healthy human volunteers to examine the effect of arginine supplementation on collagen accumulation. Young, healthy, human volunteers (age 25–35 years) were found to have significantly increased wound-collagen deposition following oral supplementation with either 30 g of arginine aspartate (17 g of free arginine) or 30 g of arginine Hall (24.8 g of free arginine) daily for 14 days.\(^8\)\(^1\) In a study of healthy older humans (age 67–82 years), daily supplements of 30 g of arginine aspartate for 14 days resulted in significantly enhanced collagen and total protein deposition at the wound site when compared to controls given placebos. There was no enhanced DNA synthesis present in the wounds of the arginine-supplemented subjects, suggesting that the effect of arginine is not mediated by an inflammatory mode of action.\(^8\)\(^2\) In this and later studies, arginine supplementation, whether administered orally or parenterally, had no effect on the rate of epithelialization of a superficial skin defect. This further suggests that the main effect of arginine on wound healing is to enhance wound collagen deposition. Recently, a dietary supplemental regimen of arginine, β-hydroxy-β-methylbutyrate, and glutamine was found to significantly and specifically enhance collagen deposition in elderly, healthy human volunteers when compared to an isocaloric, isonitrogenous supplement (Fig. 9-9).\(^3\)\(^3\) As increases in breaking strength during the first weeks of healing are directly related to new collagen synthesis, arginine supplementation may result in an improvement in wound strength as a consequence of enhanced collagen deposition.

The vitamins most closely involved with wound healing are vitamin C and vitamin A. Scurvy or vitamin C deficiency leads to a defect in wound healing, particularly via a failure in collagen synthesis and cross-linking. Biochemically, vitamin C is required for the conversion of proline and lysine to hydroxyproline and hydroxylysine, respectively. Vitamin C deficiency has also been associated with an increased incidence of wound infection, and if wound infection does occur, it tends to be more severe. These effects are believed to be due to an associated impairment in neutrophil function, decreased complement activity, and decreased walling-off of bacteria secondary to insufficient collagen deposition. The recommended dietary allowance is 60 mg daily. This provides a considerable safety margin for most healthy nonsmokers. In severely injured or extensively burned patients, this requirement may increase to as high as 2 g daily. There is no evidence that excess vitamin C is toxic; however, there is no evidence that supratherapeutic doses of vitamin C are of any benefit.\(^8\)\(^4\)

Vitamin A deficiency impairs wound healing, while supplemental vitamin A benefits wound healing in nondeficient humans and animals. Vitamin A increases the inflammatory
response in wound healing, probably by increasing the lability of lysosomal membranes. There is an increased influx of macrophages, with an increase in their activation and increased collagen synthesis. Vitamin A directly increases collagen production and epidermal growth factor receptors when it is added in vitro to cultured fibroblasts. As mentioned before, supplemental vitamin A can reverse the inhibitory effects of corticosteroids on wound healing. Vitamin A also can restore wound healing that has been impaired by diabetes, tumor formation, cyclophosphamide, and radiation. Serious injury or stress leads to increased vitamin A requirements. In the severely injured patient, supplemental doses of vitamin A have been recommended. Doses ranging from 25,000 to 100,000 IU per day have been advocated.

The connections between specific minerals and trace elements and deficits in wound healing are complex. Frequently, deficiencies are multiple and include macronutrient deficiencies. As with some of the vitamins described earlier, the specific trace element may function as a cofactor or part of an enzyme that is essential for homeostasis and wound healing. Clinically, preventing deficiencies is often easier to accomplish than diagnosing them.

Zinc is the most well-known element in wound healing and has been used empirically in dermatologic conditions for centuries. It is essential for wound healing in animals and humans. There are over 150 known enzymes for which zinc is either an integral part or an essential cofactor, and many of these enzymes are critical to wound healing. With zinc deficiency, there is decreased fibroblast proliferation, decreased collagen synthesis, impaired overall wound strength, and delayed epithelialization. These defects are reversed by zinc supplementation. To date, no study has shown improved wound healing with zinc supplementation in patients who are not zinc deficient.

Infections. Wound infections continue to represent a major medical problem, both in terms of how they affect the outcome of surgical procedures (surgical site infections), and for their impact on the length of hospital stay and medical costs. Many otherwise successful surgical operations fail because of the development of wound infections. The occurrence of infections is of major concern when implants are used, and their occurrence may lead to the removal of the prosthetic material, thus subjecting the patient to further operations and severe risk of morbidity and mortality. Infections can weaken an abdominal closure or hernia repair and result in wound dehiscence or recurrence of the hernia. Cosmetically, infections can lead to disfiguring, unsightly, or delayed closures.

Exhaustive studies have been undertaken that examine the appropriate prophylactic treatment of operative wounds. Bacterial contaminants normally present on skin are prevented from entry into deep tissues by intact epithelium. Surgery breaches the intact epithelium, allowing bacteria access to these tissues and the bloodstream. Antibiotic prophylaxis is most effective when adequate concentrations of antibiotic are present in the tissues at the time of incision, and assurance of adequate preoperative antibiotic dosing and timing has become a significant hospital performance measure. The addition of antibiotics after operative contamination has occurred clearly is ineffective in preventing postoperative wound infections.

Studies that compare operations performed with and without antibiotic prophylaxis demonstrate that classes II, III, and IV procedures (see below) treated with appropriate prophylactic antibiotics have only one third the wound infection rate of previously reported untreated series. More recently, repeat dosing of antibiotics has been shown to be essential in decreasing postoperative wound infections in operations with durations exceeding the biochemical half-life (t1/2) of the antibiotic or in which there is large-volume blood loss and fluid replacement. In lengthy cases, those in which prosthetic implants are used, or when unexpected contamination is encountered, additional doses of antibiotic may be administered for 24 hours postoperatively.

Selection of antibiotics for use in prophylaxis should be tailored to the type of surgery to be performed, operative contaminants that might be encountered during the procedure, and the profile of resistant organisms present at the institution where the surgery is performed. The continuing widespread appearance of methicillin-resistant Staphylococcus aureus (MRSA), and vancomycin-resistant enterococci (VRE) has significantly restricted the selection of these agents for routine use. Surgery-specific treatment guidelines are provided in Table 9-7.

Patients with prosthetic heart valves or any implanted vascular or orthopedic prostheses should receive antibiotic prophylaxis prior to any procedure in which significant contaminants are encountered. Dental procedures require prophylaxis with broad-spectrum penicillins or amoxicillin, while urologic instrumentation should be pretreated with a second-generation cephalosporin. Patients with prostheses who undergo gastrointestinal surgery should receive anaerobic coverage combined with a cephalosporin. Nasal screening and decolonization for S. aureus carriers are recommended for selected procedures (i.e., cardiac, orthopedic, neurosurgical procedures with implants).

The incidence of wound infection is about 5% to 10% nationwide and has not changed during the last few decades. Quantitatively, it has been shown that if the wound is contaminated with >10^5 microorganisms per gram of tissue, the risk of wound infection is markedly increased, but this threshold may be much lower in the presence of foreign materials. The source of pathogens for the infection is usually the endogenous flora of the patient's skin, mucous membranes, or from hollow organs. The most common organisms responsible for wound infections in order of frequency are Staphylococcus species, coagulase-negative Streptococcus, enterococci, and Escherichia coli. The incidence of wound infection bears a direct relationship to the degree of contamination that occurs during the operation from the disease process itself (clean—class I, clean contaminated—class II, contaminated—class III, and dirty—class IV). Many factors contribute to the development of postoperative wound infections. Most surgical wound infections become apparent within 7 to 10 days postoperatively, although a small number manifest years after the original operative intervention. With the hospital stay becoming shorter and shorter, many infections are detected in the outpatient setting, leading to underreporting of the true incidence of wound infections absent intensive surveillance. There has been much debate about the actual definition of wound infection. The narrowest definition would include wounds that drain purulent material with bacteria identified on culture. The broader definition would include all wounds draining pus, whether or not the bacteriologic studies are positive; wounds that are opened by the surgeon; and wounds that the surgeon considers infected.

Anatomically, wound infections can be classified as superficial incisional, deep incisional, and organ/space wound infections, involving fascia, muscle, or the abdominal cavity.

(Continued)
About three-fourths of all wound infections are superficial, involving skin and subcutaneous tissue only. Clinical diagnosis is easy when a postoperative wound looks edematous and erythematous and is tender. Often the presentation is more subtle, and the development of postoperative fever, usually low-grade; the development of a mild and unexplained leukocytosis; or the presence of undue incisional pain should direct attention to the wound. Inspection of the wound is most useful in detecting subcutaneous and skin layers to the full extent of the infected pocket. Samples should be taken for aerobic and anaerobic cultures, with very few patients requiring antibiotic therapy. Patients who are immunosuppressed (diabetics and those on steroids or chemotherapeutic agents), who have evidence of tissue penetration or systemic toxicity, or who have had prosthetic devices inserted (vascular grafts, heart valves, artificial joints, or mesh) should be treated with systemic antibiotics.92

Deep wound infections arise immediately adjacent to the fascia, either above or below it, and often have an intra-abdominal component. Most intra-abdominal infections do not, however, communicate with the wound. Deep infections present with fever and leukocytosis. The incision may drain pus spontaneously, or the intra-abdominal extension may be recognized following the drainage of what was thought to be a superficial wound infection, but pus draining between the fascial sutures will be noted. Sometimes wound dehiscence will occur.

The most dangerous of the deep infections is necrotizing fasciitis. It results in high mortality, particularly in the elderly. This is an invasive process that involves the fascia and leads to secondary skin necrosis. Pathophysiologically, it is a septic thrombosis of the vessels between the skin and the deep layers.
The skin demonstrates hemorrhagic bullae and subsequent frank necrosis, with surrounding areas of inflammation and edema. The fascial necrosis is usually wider than the skin involvement or than the surgeon estimates on clinical grounds. The patient is toxic and has high fever, tachycardia, and marked hypovolemia, which if uncorrected, progresses to cardiovascular collapse. Bacteriologically, this is a mixed infection, and samples should be obtained for Gram stain smears and cultures to aid in diagnosis and treatment. As soon as bacteriologic studies have been obtained, high-dose penicillin treatment needs to be started (20–40 million U/d intravenously) due to concern over the presence of Clostridia perfringens and other related species; broad-spectrum antibiotics should be added and the regimen modified based on culture results. Cardiovascular resuscitation with electrolyte solutions, blood, and/or plasma is carried out as expeditiously as possible prior to induction of anesthesia. The aim of surgical treatment is thorough removal of all necrosed skin and fascia. If viable skin overlies necrotic fascia, multiple longitudinal skin incisions can be made to allow for excision of the devitalized fascia. Although removal of all necrotic tissue is the goal of the first surgical intervention, the distinction between necrotic and simply edematous tissue often is difficult. Careful inspection every 12 to 24 hours will reveal any new necrotic areas, and these need further debridement and excision. When all necrotic tissue has been removed and the infection has been controlled, the wounds may be covered with homografts or xenografts until definitive reconstruction and autografting can take place.

The mere presence of bacteria in an open wound, either acute or chronic, does not constitute an infection, because large numbers of bacteria can be present in the normal situation. In addition, the bacteria identified by cultures may not be representative of the bacteria causing the actual wound infection. There seems to be confusion as to what exactly constitutes wound infection. For purposes of clarity, we have to differentiate between contamination, colonization, and infection. Contamination is the presence of bacteria without multiplication, colonization is multiplication without host response, and infection is the presence of host response in reaction to deposition and multiplication of bacteria. The presence of a host response helps to differentiate between infection and colonization as seen in chronic wounds. The host response that helps in diagnosing wound infection comprises celluitis, abnormal discharge, delayed healing, change in pain, abnormal granulation tissue, bridging, and abnormal color and odor.

As discussed previously, neutrophils play a major role in preventing wound infections. Chronic granulomatous disease (CGD) comprises a genetically heterogeneous group of diseases in which the reduced nicotinamide adenine dinucleotide phosphate (NADPH)-dependent oxidase enzyme is deficient. This defect impairs the intracellular killing of microorganisms, leaving the patient liable to infection by bacteria and fungi. Afflicted patients have recurrent infections and form granulomas, which can lead to obstruction of the gastric antrum and genitourinary tracts and poor wound healing. Surgeons become involved when the patient develops infectious or obstructive complications.

The nitro blue tetrazolium (NBT) reduction test is used to diagnose CGD. Normal neutrophils can reduce this compound, while neutrophils from affected patients do not, facilitating the diagnosis via a colorimetric test. Clinically, patients develop recurrent infections such as pneumonia, lymphadenitis, hepatic abscess, and osteomyelitis. Organisms most commonly responsible are S. aureus, Aspergillus, Klebsiella, Serratia, or Candida. When CGD patients require surgery, a preoperative pulmonary function test should be considered since they are predisposed to obstructive and restrictive lung disease. Wound complications, mainly infection, are common. Sutures should be removed as late as possible since the wounds heal slowly. Abscess drains should be left in place for a prolonged period until the infection is completely resolved.

Hyperglycemia has been shown to be a significant risk factor of postoperative infections. Tight blood glucose control, beginning preoperatively and continued into the operating room and beyond, has been associated with significant reduction in infectious complications, in particular following cardiac surgery. Too tight of a glycemic control (80–100 mg/dL) appears to be associated with more complications and is as effective, if not less than, moderate control (120–180 mg/dL).

Another host factor that has been implicated in the development of superficial surgical site infection relates to the state of the subcutaneous capillary bed. Thomas K. Hunt had shown through several decades of work that this capillary bed is exquisitely sensitive to hypovolemia, hypothermia, and stress, leading to rapid vasoconstriction with secondary impaired oxygen delivery and increased rates of infection. Maintenance of euovolemia, core temperature above 36°C to 36.5°C, and pain control have all been shown singly and additively to reduce rates of wound infections. Another suggestion has been to increase inspired FiO₂ to 0.8 for the duration of the operation and in the immediate postoperative period, as a means of increasing subcutaneous tissue oxygen delivery. Although successful in most studies, there have also been negative results from such a single approach; this suggests that addressing volume, temperature, pain control, and oxygen delivery in concert may be the more fruitful approach to reduce surgical wound infections.

**Chronic Wounds**

Chronic wounds are defined as wounds that have failed to proceed through the orderly process that produces satisfactory anatomic and functional integrity or that have proceeded through the repair process without producing an adequate anatomic and functional result. The majority of wounds that have not healed in 3 months are considered chronic, although a duration as low as 4 weeks has been used to indicate chronicity. Skin ulcers, which usually occur in traumatized or vascular compromised soft tissue, are also considered chronic in nature, and proportionately are the major component of chronic wounds. In addition to the factors discussed earlier that can delay wound healing, other causative mechanisms may also play a role in the etiology of chronic wounds. Repeated trauma, poor perfusion or oxygenation, and/or excessive inflammation contribute to the causation and the perpetuation of the chronicity of wounds.

Unresponsiveness to normal regulatory signals also has been implicated as a predictive factor of chronic wounds. This may come about as a failure of normal growth factor synthesis, and thus an increased breakdown of growth factors within a wound environment that is markedly proteolytic because of overexpression of protease activity or a failure of the normal antiprotease inhibitor mechanisms. Fibroblasts from chronic wounds also have been found to have decreased proliferative potential, perhaps because of senescence or decreased expression of growth factor receptors. Chronic wounds occur due to various etiologic factors, and several of the most common are discussed later.
Malignant transformation of chronic ulcers can occur in any long-standing wound (Marjolin’s ulcer). Any wound that does not heal for a prolonged period of time is prone to malignant transformation. Malignant wounds are differentiated clinically from nonmalignant wounds by the presence of overturned wound edges (Fig. 9-10). In patients with suspected malignant transformations, biopsy of the wound edges must be performed to rule out malignancy. Cancers arising de novo in chronic wounds include both squamous and basal cell carcinomas.

Ischemic Arterial Ulcers. These wounds occur due to a lack of blood supply and are typically extremely painful in patients with pure ischemic ulcers. They usually are associated with other symptoms of peripheral vascular disease, such as history of intermittent claudication, rest pain, and color or trophic changes. These wounds commonly are present at the most distal portions of the extremities such as the interdigital clefts, although more proximal locations are also encountered. On examination, there may be diminished or absent pulses with decreased ankle-brachial index and poor formation of granulation tissue. Other signs of peripheral ischemia, such as dryness of skin, hair loss, scaling, and pallor can be present. The wound itself usually is shallow with smooth margins, and a pale base and surrounding skin may be present. The management of these wounds is two-pronged and includes revascularization and wound care. Nonhealing of these wounds is the norm unless successful revascularization is performed. In patients with ischemia and bed confinement, prevention of ulcer development is extremely important. Removal of restrictive stockings (in patients with critical ischemia), frequent repositioning, and surveillance are vital to preventing these ulcers.

Venous Stasis Ulcers. Although there is unanimous agreement that venous ulcers are due to venous stasis and increased venous pressure, there is less consensus as to what are the exact pathophysiologic pathways that lead to ulceration and impaired healing. On the microvascular level, there is alteration and distention of the dermal capillaries with leakage of fibrinogen into the tissues; polymerization of fibrinogen into fibrin cuffs leads to perivascular cuffing that can impede oxygen exchange, thus contributing to ulceration. These same fibrin cuffs and the leakage of macromolecules such as fibrinogen and α₂-macroglobulin trap growth factors and impede wound healing. Another hypothesis suggests that neutrophils adhere to the capillary endothelium and cause plugging with diminished dermal blood flow. Venous hypertension and capillary damage lead to extravasation of hemoglobin. The products of this breakdown are irritating and cause pruritus and skin damage. The resulting brownish pigmentation of skin combined with the loss of subcutaneous fat produces characteristic changes called lipodermatosclerosis. Regardless of the pathophysiologic mechanisms, the clinically characteristic picture is that of an ulcer that fails to reepithelialize despite the presence of adequate granulation tissue in a patient with skin color changes in the area of ulceration and signs of venous hypertension.

Venous stasis occurs due to increased venous hypertension caused by either venous insufficiency or venous outflow obstruction. Venous insufficiency can be due to any combination of deep, superficial, and perforator vein valvular reflux. The higher the ambulatory venous hypertension, the higher the chance of ulceration. Chronic venous ulcers are commonly painless. Stasis ulcers tend to occur at the sites of incompetent
perforators, the most common being above the medial malleolus, over Cockett’s perforator. Upon examination, the typical location combined with a history of venous incompetence and other skin changes is diagnostic. The wound usually is shallow with irregular margins and pigmented surrounding skin.

The cornerstone of treatment of venous ulcers is compression therapy, although the best method to achieve it remains controversial. Compression can be accomplished via rigid or flexible means. The most commonly used method is the rigid, zinc oxide–impregnated, nonelastic bandage. Others have proposed a four-layered bandage approach as a more optimal method of obtaining graduated compression. Wound care in these patients focuses on maintaining a moist wound environment, which can be achieved with hydrocolloids. Other, more modern approaches include use of vasoactive substances and growth factor application, as well as the use of skin substitutes. Recently, sprayed allogeneic keratinocytes and fibroblasts plus four-layer bandages have been shown to hasten healing when compared to compression alone. Addressing the causes of venous hypertension aids in the healing of venous ulcers. Unfortunately, recurrences are frequent despite preventative measures, largely because of patients’ lack of compliance.

Diabetic Wounds. Ten percent to 25% of diabetic patients run the risk of developing ulcers. There are approximately 50,000 to 60,000 amputations performed in diabetic patients each year in the United States. The major contributors to the formation of diabetic ulcers include neuropathy, foot deformity, and ischemia. It is estimated that 60% to 70% of diabetic ulcers are due to neuropathy. 15% to 20% are due to ischemia, and another 15% to 20% are due to a combination of both. The neuropathy is both sensory and motor and is secondary to persistently elevated glucose levels. The loss of sensory function allows unrecognized injury to occur from ill-fitting shoes, foreign bodies, or other trauma. The motor neuropathy or Charcot’s foot leads to collapse or dislocation of the interphalangeal or metatarsophalangeal joints, causing pressure on areas with little protection. There is also severe micro- and macrovascular circulatory impairment.

Once ulceration occurs, the chances of healing are poor and the chances of recurrent ulceration are high. The treatment of diabetic wounds involves local and systemic measures. Achievement of adequate blood sugar levels is very important. Most diabetic wounds are infected, and eradication of the infectious source is paramount to the success of healing. Treatment should address the possible presence of osteomyelitis and should employ antibiotics that achieve adequate levels both in soft tissue and bone. Wide debridement of all necrotic or infected tissue is another cornerstone of treatment. Off-loading of the ulcerated area by using specialized orthotic shoes or casts allows for ambulation while protecting the fragile wound environment. Topical application of PDGF and granulocyte-macrophage colony-stimulating factor has met with limited but significant success in achieving closure. The application of engineered skin allograft substitutes, although expensive, also has shown some significant success. Prevention and specifically foot care play an important role in the management of diabetics.

Decubitus or Pressure Ulcers. The incidence of pressure ulcers ranges from 2.7% to 9% in the acute care setting, in comparison to 2.4% to 23% in long-term care facilities. A pressure ulcer is a localized area of tissue necrosis that develops when soft tissue is compressed between a bony prominence and an external surface. Excessive pressure causes capillary collapse and impedes the delivery of nutrients to body tissues. Pressure ulcer formation is accelerated in the presence of friction, shear forces, and moisture. Other contributory factors in the pathogenesis of pressure ulcers include immobility, altered activity levels, altered mental status, chronic conditions, and altered nutritional status. The four stages of pressure ulcer formation are as follows: stage I, no blanching erythema of intact skin; stage II, partial-thickness skin loss involving epidermis or dermis or both; stage III, full-thickness skin loss, but not through the fascia; and stage IV, full-thickness skin loss with extensive involvement of muscle and bone.

The treatment of established pressure ulcers is most successful when carried out in a multidisciplinary manner by involving wound care teams consisting of physicians, nurses, dietitians, physical therapists, and nutritionists. Care of the ulcer itself comprises debridement of all necrotic tissue, maintenance of a favorable moist wound environment that will facilitate healing, relief of pressure, and addressing host issues such as nutritional, metabolic, and circulatory status. Debridement is most efficiently carried out surgically, but enzymatic proteolytic preparations and hydrotherapy also are used. The wound bed should be kept moist by employing dressings that absorb secretions but do not desiccate the wound. Operative repair, usually involving flap rotation, has been found to be useful in obtaining closure. Unfortunately, recurrence rates are extremely high, owing to the population at risk and the inability to fully address the causative mechanisms.

EXCESS HEALING

Clinically, excess healing can be as significant as delayed or nonhealing. It is likely that more operative interventions are required for correction of the morbidity associated with excessive healing than are required for wound failure. The clinical manifestations of exuberant healing are protean and differ in the skin (mutilating or debilitating scars, burn contractions), tendons (frozen repairs), the GI tract (strictures or stenoses), solid organs (cirrhosis, pulmonary fibrosis), or the peritoneal cavity (adhesive disease). Hypertrophic scars (HTSs) and keloids represent an overabundance of fibroplasia in the dermal healing process. HTSs rise above the skin level but stay within the confines of the original wound and often regress over time. Keloids rise above the skin level as well, but they extend beyond the border of the original wound and rarely regress spontaneously. Both HTSs and keloids occur after trauma to the skin and may be tender, pruritic, and cause a burning sensation. Keloids are 15 times more common in darker-pigmented ethnicities, with individuals of African, Spanish, and Asian ethnicities being especially susceptible. Men and women are equally affected. Genetically, the predilection to keloid formation appears to be autosomal dominant with incomplete penetration and variable expression.

HTSs usually develop within 4 weeks after trauma. The risk of HTS increases if epithelialization takes longer than 21 days, independent of site, age, and race. Rarely elevated more than 4 mm above the skin level, HTSs stay within the boundaries of the wound. They usually occur across areas of tension and flexor surfaces, which tend to be at right angles to joints or skin creases. The lesions are initially erythematous and raised and over time may evolve into pale, flatter scars.
Keloids can result from surgery, burns, skin inflammation, acne, chickenpox, zoster, folliculitis, lacerations, abrasions, tattoos, vaccinations, injections, insect bites, or ear piercing, or may arise spontaneously. Keloids tend to occur 3 months to years after the initial insult, and even minor injuries can result in large lesions. They vary in size from a few millimeters to large, pedunculated lesions with a soft to rubbery or hard consistency. While they project above surrounding skin, they rarely extend into underlying subcutaneous tissues. Certain body sites have a higher incidence of keloid formation, including the skin of the earlobe as well as the deltoid, presternal, and upper back regions. They rarely occur on eyelids, genitalia, palms, soles, or across joints. Keloids rarely involute spontaneously, and surgical intervention can lead to recurrence, often with a worse result (Table 9-8).

Histologically, both HTSs and keloids demonstrate increased thickness of the epidermis with an absence of rete ridges. There is an abundance of collagen and glycoprotein deposition. Normal skin has distinct collagen bundles, mostly parallel to the epithelial surface, with random connections between bundles by fine fibrillar strands of collagen. In HTS, the collagen bundles are flatter and more random, and the fibers are in a wavy pattern. In keloids, the collagen bundles are virtually nonexistent, and the fibers are connected haphazardly in loose sheets with a random orientation to the epithelium. The collagen fibers are larger and thicker, and myofibroblasts are generally absent. Keloidal fibroblasts have normal proliferation parameters but synthesize collagen at a rate 20 times greater than that observed in normal dermal fibroblasts, and 3 times higher than fibroblasts derived from HTS. Abnormal amounts of extracellular matrix such as fibronectin, elastin, and proteoglycans also are produced. The synthesis of fibronectin, which promotes clot generation, granulation tissue formation, and reepithelialization, decreases during the normal healing process; however, production continues at high levels for months to years in HTSs and keloids. This perturbed synthetic activity is mediated by altered growth factor expression. TGF-β expression is higher in HTS, and both HTS- and keloid-derived fibroblasts respond to lower concentrations of TGF-β than do normal dermal fibroblasts. HTSs also express increased levels of insulin-like growth factor-1, which reduces collagenase mRNA activity and increases mRNA for types I and II procollagen. Keloid fibroblasts have enhanced expression of TGF-β1 and TGF-β2, VEGF, and plasminogen activator inhibitor-1 and an increased number of PDGF receptors; they also have upregulated antiapoptotic gene expression, which can be differentially expressed within different areas of the same scar.

The underlying mechanisms that cause HTSs and keloids are not known. The immune system appears to be involved in the formation of both HTSs and keloids, although the exact relationship is unknown. Much is inferred from the presence of various immune cells in HTSs and keloids. For example, in both HTSs and keloids, keratinocytes express human leukocyte antigen (HLA)-2 and ICAM-1 receptors, which are absent.

</table>
in normal scar keratinocytes. Keloids also have increased deposition of immunoglobulins IgG, IgA, and IgM, and their formation correlates with serum levels of IgE. Antinuclear antibodies against fibroblasts, epithelial cells, and endothelial cells are found in keloids, but not HTSs. HTSs have higher T lymphocyte and Langerhans cell contents. There is also a larger number of mast cells present in both HTSs and keloids compared to normal scars. Another recently described cell population is the fibrocyte, a leukocyte subpopulation derived from peripheral mononuclear cells. Present in large numbers at the site of excess scarring, fibrocytes can stimulate fibroblast numbers and collagen synthesis. They also generate large numbers of cytokines, growth factors, and extracellular matrix proteins, which are characteristically upregulated in keloid tissue. Other mechanisms that may cause abnormal scarring include mechanical tension (although keloids often occur in areas of minimal tension) and prolonged irritation and/or inflammation that may lead to the generation of abnormal concentrations of profibrotic cytokines.

Treatment goals for keloid and HTS include restoration of function to the area, relief of symptoms, and prevention of recurrence. Many patients seek intervention due to cosmetic concerns. Because the underlying mechanisms causing keloids and HTSs remain unknown, many different modalities of treatment have been used without consistent success.  

Excision alone of keloids is subject to a high recurrence rate, ranging from 45% to 100%. Inclusion of the dermal advancing edge that characterizes keloids, use of incisions in skin tension lines, and tension-free closure all have been proposed to decrease recurrence rates. There are fewer recurrences when surgical excision is combined with other modalities such as intralesional corticosteroid injection, topical application of silicone sheets, or the use of radiation or pressure. Surgery is recommended for debulking large lesions or as second-line therapy when other modalities have failed. Silicone application is relatively painless and should be maintained for 24 hours a day for about 3 months to prevent rebound hypertrophy. It may be secured with tape or worn beneath a pressure garment. The mechanism of action is not understood, but increased hydration of the skin, which decreases capillary activity, inflammation, hyperemia, and collagen deposition, may be involved. Silicone is more effective than other occlusive dressings and is an especially good treatment for children and others who cannot tolerate the pain involved in other modalities.

Intralesional corticosteroid injections decrease fibroblast proliferation, collagen and glycosaminoglycan synthesis, the inflammatory process, and TGF-β levels. When used alone, however, there is a variable rate of response and recurrence; therefore, steroids are recommended as first-line treatment for keloids and second-line treatment for HTSs if topical therapies have failed. Intralesional injections are more effective on younger scars. They may soften, flatten, and give symptomatic relief to keloids, but they cannot make the lesions disappear, and they cannot narrow wide HTSs. Success is enhanced when used in combination with surgical excision. Serial injections every 2 to 3 weeks are required. Complications include skin atrophy, hypopigmentation, telangiectasias, necrosis, and ulceration.

Although radiation destroys fibroblasts, it has variable, unreliable results and produces poor results, with 10% to 100% recurrence when used alone. It is more effective when combined with surgical excision. The timing, duration, and dosage for radiation therapy are still controversial, but doses ranging from 1500 to 2000 rads appear effective. Given the risks of hyperpigmentation, pruritus, erythema, paresthesias, pain, and possible secondary malignancies, radiation should be reserved for adults with scars resistant to other modalities.

Pressure aids collagen maturation, flattens scars, and improves thinning and pliability. It reduces the number of cells in a given area, possibly by creating ischemia, which decreases tissue metabolism and increases collagenase activity. External compression is used to treat HTSs, especially after burns. Therapy must begin early, and a pressure between 24 and 30 mmHg must be achieved in order to exceed capillary pressure, yet preserve peripheral blood circulation. Garments should be worn for 23 to 24 hours a day for up to 1 or more years to avoid rebound hypertrophy. Scars older than 6 to 12 months respond poorly.

Topical retinoids also have been used as treatment for both HTSs and keloids, with reported responses of 50% to 100%. Intralesional injections of IFN-γ, a cytokine released by T lymphocytes, reduce collagen types I, II, and III by decreasing mRNA and possibly by reducing levels of TGF-β. As monotherapy, IFN-γ has failed because of high recurrence rates due to resistance to repeated injections. More recently, imiquimod, an immunomodulator that induces IFN-γ and other cytokines at the site of application, has been recommended following excision. Intralesional injections of chemotherapeutic agents such as 5-fluorouracil have been used both alone and in combination with steroids. The use of bleomycin or mitomycin C has been reported to achieve some success in older scars resistant to steroids.

Peritoneal Scarring. Peritoneal adhesions are fibrous bands of tissues formed between organs that are normally separated and/or between organs and the internal body wall. Most intra-abdominal adhesions are a result of peritoneal injury, either by a prior surgical procedure or due to intra-abdominal infection. Postmortem examinations demonstrate adhesions in 67% of patients with prior surgical procedures and in 28% with a history of intra-abdominal infection. Intra-abdominal adhesions are the most common cause (65%–75%) of small bowel obstruction, especially in the ileum. Operations in the lower abdomen have a higher chance of producing small bowel obstruction. Following rectal surgery, left colectomy, or total colectomy, there is an 11% chance of developing small bowel obstruction within 1 year, and this rate increases to 30% by 10 years. Adhesions also are a leading cause of secondary infertility in women and can cause substantial abdominal and pelvic pain. Adhesions account for 2% of all surgical admissions and 3% of all laparotomies in general surgery.

Adhesions form when the peritoneal surface is damaged due to surgery, thermal or ischemic injury, inflammation, or foreign body reaction. The injury disrupts the protective mesothelial cell layer lining the peritoneal cavity and the underlying connective tissue. The injury elicits an inflammatory response consisting of hyperemia, fluid exudation, release, and activation of white blood cells and platelets in the peritoneal cavity, activation of inflammatory cytokines, and the onset of the coagulation and complement cascades. Fibrin deposition occurs between the damaged but opposed serosal surfaces. These filmy adhesions often are transient and degraded by proteases of the fibrinolytic system, with restoration of the normal peritoneal surface. If insufficient fibrinolytic activity is present, permanent fibrous adhesions will form by collagen deposition within 1 week of the injury (Fig. 9-12).
There are two major strategies for adhesion prevention or reduction. Surgical trauma is minimized within the peritoneum by careful tissue handling, avoiding desiccation and ischemia, and spare use of cautery, laser, and retractors. Fewer adhesions form with laparoscopic surgical techniques due to reduced tissue trauma. The second major advance in adhesion prevention has been the introduction of barrier membranes and gels, which separate and create barriers between damaged mesothelial surfaces, allowing for adhesion-free healing. Currently, only three products are Food and Drug Administration (FDA) approved for reducing adhesion formation: Interceed (oxidized regenerated cellulose, indicated only in pelvic surgery), Seprafilm (a film composed of hyaluronic acid and carboxymethylcel lulose) that is usually applied below the incision, and Adept (4% icodextrin, a corn starch derivative in electrolyte solution, also for use mainly in pelvic surgery). However, use of these substances directly over bowel anastomoses is contraindicated due to an elevated risk of leak. There have been innumerable studies investigating different molecules in hopes of preventing adhesion formation, but most of the success is limited to animal models, and clinically significant results in humans have yet to be achieved.

TREATMENT OF WOUNDS

Local Care (Fig. 9-13)

Management of acute wounds begins with obtaining a careful history of the events surrounding the injury. The history is followed by a meticulous examination of the wound. Examination should assess the depth and configuration of the wound, the extent of nonviable tissue, and the presence of foreign bodies and other contaminants. The wound/ulcer should be described based on location, dimensions, presence of infection, drainage and type of drainage, base characteristics, presence or absence of necrosis, presence of pain, and description of edges. Possible etiology should be mentioned, and the presence of systemic factors and circulation should be evaluated.

After completion of the history, examination, and administration of tetanus prophylaxis, the wound should be meticulously anesthesitized. Lidocaine (0.5%–1%) or bupivacaine (0.25%–0.5%) combined with a 1:100,000 to 1:200,000 dilution of epinephrine provides satisfactory anesthesia and hemostasis.
Epinephrine should not be used in wounds of the fingers, toes, ears, nose, or penis, due to the risk of tissue necrosis secondary to terminal arteriole vasospasm in these structures.

Irrigation to visualize all areas of the wound and remove foreign material is best accomplished with normal saline (without additives). High-pressure wound irrigation is more effective in achieving complete debridement of foreign material and nonviable tissues. Iodine, povidone-iodine, hydrogen peroxide, and organically based antibacterial preparations have all been shown to impair wound healing due to injury to wound neutrophils and macrophages, and thus should not be used. All hematomas present within wounds should be carefully evacuated and any remaining bleeding sources controlled with ligature or cautery. If the injury has resulted in the formation of a marginally viable flap of skin or tissue, this should be resected or revascularized prior to further wound repair and closure.

After the wound has been anesthetized, explored, irrigated, and debrided, the area surrounding the wound should be cleaned, inspected, and the surrounding hair clipped. The area surrounding the wound should be prepared with povidone iodine, chlorhexidine, or similar bacteriostatic solutions and draped with sterile towels. Having ensured hemostasis and adequate debridement of nonviable tissues and removal of any remaining foreign bodies, irregular, macerated, or beveled wound edges should be debrided in order to provide a fresh edge for reapproximation. Although plastic surgical techniques such as W- or Z-plasty are seldom recommended for acute wounds, great care must be taken to realign wound edges properly. This is particularly important for wounds that cross the vermilion border, eyebrow, or hairline. Initial sutures that realign the edges of these different tissue types will speed and greatly enhance the aesthetic outcome of the wound repair.

In general, the smallest suture required to hold the various layers of the wound in approximation should be selected in order to minimize suture-related inflammation. Nonabsorbable or slowly absorbing monofilament sutures are most suitable for approximating deep fascial layers, particularly in the abdominal wall. Subcutaneous tissues should be closed with braided absorbable sutures, with care to avoid placement of sutures in fat. Multiple layer closure of the abdominal wall is preferable. However, additional layers with sutures might increase the risk of wound infection.

In areas of significant tissue loss, rotation of adjacent musculocutaneous flaps or free flaps may be required to provide sufficient tissue mass for closure. In cases of significant superficial tissue loss, split-thickness skin grafting (placed in a delayed manner to assure an adequate tissue bed) may be required and will speed formation of an intact epithelial barrier to fluid loss and infection. In acute, contaminated wounds with skin loss, use of porcine skin xenografts or skin cadaveric allografts might be needed to avoid infection.

After closing deep tissues and replacing significant tissue deficits, skin edges should be reapproximated for cosmesis and to aid in rapid wound healing. Skin edges may be quickly reapproximated with stainless steel staples or nonabsorbable monofilament sutures. Care must be taken to remove these from the wound prior to epithelialization of the skin tracts where sutures or staples penetrate the dermal layer. Failure to remove the sutures or staples prior to 7 to 10 days after repair will result in a cosmetically inferior wound. Where wound cosmesis is important, the aforementioned problems may be avoided by placement of buried dermal sutures using absorbable braided sutures. This method of wound closure allows for a precise reapproximation of wound edges and may be enhanced by application of wound closure tapes to the surface of the wound. Intradermal absorbable sutures do not require removal.

The development of octyl-cyanoacrylate tissue glue has shown good results for the management of simple, linear wounds with viable skin edges. These new glues are less prone to brittleness and have superior burst-strength characteristics. Studies have shown them to be suitable for use in contaminated situations without significant risk of infection. When used in the previously mentioned types of wounds, these glues appear to provide superb cosmetic results and result in significantly less trauma than sutured repair, particularly when used in pediatric patients.

**Antibiotics**

Antibiotics should be used only when there is an obvious wound infection. Most wounds are contaminated or colonized with bacteria. The presence of a host response constitutes an infection and justifies the use of antibiotics. Signs of infection to look for include erythema, cellulitis, swelling, and purulent discharge. Indiscriminate use of antibiotics should be avoided to prevent emergence of multidrug-resistant bacteria.

Antibiotic treatment of acute wounds must be based on organisms suspected to be found within the infected wound and the patient’s overall immune status. When a single specific organism is suspected, treatment may be commenced using a single antibiotic. Conversely, when multiple organisms are suspected, as with enteric contamination or when a patient’s immune function is impaired by diabetes, chronic disease, or medication, treatment should commence with a broad-spectrum antibiotic or several agents in combination. Antibiotics also can be delivered topically as part of irrigations or dressings, although their efficacy is questionable.

**Dressings**

The main purpose of wound dressings is to provide the ideal environment for wound healing. The dressing should facilitate the major changes taking place during healing to produce an optimally healed wound. Although the ideal dressing still is not a clinical reality, technological advances are promising (Table 9-9).

Dressings should take into account the type of wound and the comorbid conditions and associated factors such as edema and circulation. In patients with edema, dressing should compress the edematous area to aid in healing. In patients with significant circulation compromise, a compressing dressing should be avoided. The dressing should maintain

an adequate moist environment but should help absorption excessive drainage. Occlusion of a wound with dressing material helps healing by controlling the level of hydration and oxygen tension within the wound. It also allows transfer of gases and water vapor from the wound surface to the atmosphere. Occlusion affects both the dermis and epidermis, and it has been shown that exposed wounds are more inflamed and develop more necrosis than covered wounds. Occlusion also helps in dermal collagen synthesis and epithelial cell migration and limits tissue desiccation. Since it may enhance bacterial growth, occlusion is contraindicated in infected and/or highly exudative wounds.

Dressings can be classified as primary or secondary. A primary dressing is placed directly on the wound and may provide absorption of fluids and prevent desiccation, infection, and adhesion of a secondary dressing. A secondary dressing is one that is placed on the primary dressing for further protection, absorption, compression, and occlusion. Although the ideal dressing does not exist, many types of dressings help achieve certain goals, so knowledge of the wound and the dressing function is essential to make it possible to choose the appropriate dressing.

Absorbent Dressings. This type of dressing helps control exudate without soaking through the dressing, which can increase infection potential.

Nonadherent Dressings. Nonadherent dressings are impregnated with paraffin, petroleum jelly, or water-soluble jelly for use as nonadherent coverage. A secondary dressing must be placed on top to seal the edges and prevent desiccation and infection.

Occlusive and Semiocclusive Dressings. Occlusive and semiocclusive dressings provide a good environment for clean, minimally exudative wounds. These film dressings are waterproof and impervious to microbes but permeable to water vapor and oxygen.

Hydrophilic and Hydrophobic Dressings. These dressings are components of a composite dressing. Hydrophilic dressing aids in absorption, whereas a hydrophobic dressing is waterproof and prevents absorption.

Hydrocolloid and Hydrogel Dressings. Hydrocolloid and hydrogel dressings attempt to combine the benefits of occlusion and absorbency. Hydrocolloids and hydrogels form complex structures with water, and fluid absorption occurs with particle swelling, which aids in atraumatic removal of the dressing. Absorption of exudates by the hydrocolloid dressing leaves a yellowish-brown gelatinous mass after dressing removal that can be washed off. Hydrogel is a cross-linked polymer that has high water content. Hydrogels allow a high rate of evaporation without compromising wound hydration, which makes them useful in burn wound treatment.

Alginites. Alginites are derived from brown algae and contain long chains of polysaccharides containing mannuronic and glucuronic acid. The ratios of these sugars vary with the species of algae used, as well as the season of harvest. Processed as the calcium forms, alginites turn into soluble sodium alginate through ion exchange in the presence of wound exudates. The polymers gel, swell, and absorb a great deal of fluid. Alginites are being used when there is skin loss, in open surgical wounds with medium exudation, and on full-thickness chronic wounds. Alginate widely used as primary dressing and can be reinforced with other forms of dressing such as compression dressing.

Absorbable Materials. Absorbable materials are mainly used within wounds as hemostats and include collagen, gelatin, oxidized cellulose, and oxidized regenerated cellulose.

Medicated Dressings. Medicated dressings have long been used as a drug-delivery system. Agents delivered in the dressings include benzylic peroxide, zinc oxide, neomycin, and bacitracin-zinc. These agents have been shown to increase epithelialization by 28%.

The type of dressing to be used depends on the amount of wound drainage. A nondraining wound can be covered with semiocclusive dressing. Drainage of less than 1 to 2 mL/d may require a semiocclusive or absorbent nonadherent dressing. Moderately draining wounds (3–5 mL/d) can be dressed with a nonadherent primary layer plus an absorbent secondary layer plus an occlusive dressing to protect normal tissue. Heavily draining wounds (>5 mL/d) require a similar dressing as moderately draining wounds, but with the addition of a highly absorbent secondary layer.

Mechanical Devices. Mechanical therapy augments and improves on certain functions of dressings, in particular the absorption of exudates and control of odor. The negative pressure dressing systems assist in wound closure by applying localized negative pressure to the surface and margins of the wound. The negative-pressure therapy is applied to a special foam dressing cut to the dimensions of the wound and positioned in the wound cavity or over a flap or graft. The continuous negative pressure is very effective in removing exudates from the wound. This form of therapy has been found to be effective for chronic open wounds (diabetic ulcers and stages III and IV pressure ulcers), acute and traumatic wounds,125 flaps and grafts, and subacutent wounds (i.e., dehisced incisions), although more randomized trials need to be carried out to confirm efficacy. Different types of sponges are available to use on wounds with negative pressure systems.

Skin Replacements

All wounds require coverage in order to prevent evaporative losses and infection and to provide an environment that promotes healing. Both acute and chronic wounds may demand use of skin replacement, and several options are available.

Conventional Skin Grafts. Skin grafts have long been used to treat both acute and chronic wounds. Split-(partial)-thickness grafts consist of the epidermis plus part of the dermis, whereas full-thickness grafts retain the entire epidermis and dermis. Autologous grafts (autografts) are transplants from one site on the body to another; allogeneic grafts (allografts, homografts) are transplants from a living nonidentical donor or cadaver to the host; and xenogeneic grafts (heterografts) are taken from another species (e.g., porcine). Split-thickness grafts require less blood supply to restore skin function. The dermal component of full-thickness grafts lends mechanical strength and resists wound contraction better, resulting in improved cosmesis. Allogeneic and xenogeneic grafts require the availability of tissue, are subject to rejection, and may contain pathogens.

The use of skin grafts or bioengineered skin substitutes and other innovative treatments (e.g., topically applied growth factors, systemic agents, and gene therapy) cannot be effective unless the wound bed is adequately prepared. This may include debridement to remove necrotic or fibrinous tissue, control of edema, revascularization of the wound bed, reduction in the bacterial burden, with minimal exudate. Temporary
Cellular and Tissue-Based Products in Chronic Wound and Ulcer Management

Wound management and ulcer healing are among the most challenging problems in medical practices. The lack of large clinical trials, the heterogeneity of wound causes, and mechanisms of chronicity add to the complexity of wound management. In most cases, management is based on the experience of the providers and the availability of the treatment modalities within the health facilities. In spite of advances in wound care, the basic principles of wound management remain to be essential to healing. Additional measures and products might accelerate the rate of healing but will not replace basic wound care. The basic principles include achieving optimal blood flow, control of infection, removal of debris, proper dressing, offloading the injured area, and compression therapy in certain cases. Once these basic principles have been achieved, advanced treatment modalities such as cellular and tissue-based products (CTP) can be considered for enhanced healing. CTPs presumably act by altering the biology of wounds and ulcers or by preparing the wound/ulcer bed for healing and other potential procedures. CTPs are divided into two categories: dermoinductive and democonductive. As the name indicates, dermoinductive products help provide cells and factors that will activate healing within the wound by inducing tissue growth or inducing granulation within the wound. Such products include Apligraf (Organogenesis, Canton, MA), Theraskin (Soluble systems, LLC, Newport News, VA), and Dermagraft (Organogenesis Canton, MA). None of these products have achieved healing in all wounds, but generally they have improved the percentage of healing, or achieved healing over a shorter period of time. In a pivotal Apligraf study, for example, it was found that patients who received Apligraf achieved 56% healing over 65 days compared to 38% healing over 90 days in those who received saline dressing. On the other hand, the dermoconductive products provide scaffolding to a wound ending in a neodermis by allowing migration of surrounding tissues across the wound, and this helps healing. An example of such products is Integra, which is composed of type I bovine collagen, shark chondroitin 6-sulfate, and a silicone layer and helps to prepare the wound bed for subsequent skin grafting. In our experience, we use Integra for wound bed preparation in superficial wounds but also, in some cases, in deeper wounds. In addition, we also use it to cover exposed bone, especially smaller areas and tendons; however, it might require more than one application in some cases to achieve optimal wound bed preparation. In a systematic review of the literature, the authors reviewed 15 randomized trials, one prospective comparative study, and five systematic reviews. The authors concluded that living cell-based skin substitutes have a convincing supportive body of evidence in wound healing with some promise for acellular skin substitutes. In their review, the authors indicated that the evidence they based their review on was of low quality. Stem cell–based therapy is gaining more traction in the management of difficult wounds. Although it was initially used as an attempt to achieve scarless healing, stem cell therapy has gained more popularity in recent years as a means for enhanced healing and skin regeneration, in addition to reduction of scar formation. Similar to other fields, stem cells in wound healing produce growth factors and chemokines that can differentiate into different cells and tissues. Stem cells in wound healing are mostly derived from human amniotic membrane of placental tissue. Examples of such products include Epithex (MiMedx Group Inc, Marietta CA) and Grafix (Osirix Therapeutics Inc, Columbia, MD), among others. It is believed that the growth factors in the amniotic membranes are preserved through different processes, thus assisting with wound healing. Multiple growth factors derived from the amniotic membrane are thought to contribute to wound healing, including vascular endothelia growth factor, platelet-derived growth factor, epidermal growth factor, transforming growth factor, and others. A significant drawback of such products is that they are extremely expensive. Furthermore, it is recommended that these products should be used weekly to achieve optimal healing, which adds to the cost of using such products.

Originally, these products were devised to provide coverage of extensive wounds because of the limited availability of autografts, which remains the ideal tissue coverage. However, CTPs have now gained acceptance as natural dressings. Manufactured by tissue engineering, they combine novel materials with living cells to provide functional skin substitutes, providing a bridge between dressings and skin grafts.

Skin substitutes have the theoretical advantages of being readily available and not requiring painful harvests like in skin grafts, and they may be applied freely or with surgical suturing. In addition, they promote healing, either by stimulating host cytokine generation or by providing cells that may also produce growth factors locally. Their disadvantages include limited survival, high cost, and the need for multiple applications (Table 9-10). Allografting, albeit with a very thin graft, may at times be required to accomplish complete coverage.

A variety of skin substitutes are available, each with its own set of advantages and disadvantages; however, the ideal skin substitute has yet to be developed (Table 9-11). The development of the newer composite substitutes, which provide both the dermal and epidermal components essential for permanent skin replacement, may represent an advance toward that goal.

Cultured epithelial autografts (CEAs) represent expanded autologous or homologous keratinocytes. CEAs are expanded from a biopsy of the patient’s own skin, will not be rejected, and can stimulate reepithelialization as well as the growth of underlying connective tissue. Keratinocytes harvested from a biopsy roughly the size of a postage stamp are cultured with fibroblasts and growth factors and grown into sheets that can cover large areas and give the appearance of normal skin. Until the epithelial sheets are sufficiently expanded, the wound must be covered with an occlusive dressing or a temporary allograft or xenograft. The dermis regenerates very slowly, if at all, for full-thickness wounds because the sheets are very fragile, are difficult to work with, are susceptible to infection, and do not resist contracture well, leading to poor cosmetic results.

CEAs are available from cadavers, unrelated adult donors, or neonatal foreskins. Fresh or cryopreserved cultured allogeneic keratinocytes can be left in place long enough to be superseded by multiplying endogenous skin cells because, unlike allografts containing epidermal Langerhans cells, they do not express major histocompatibility antigens. Cryopreserved CEAs are readily available “off the shelf,” and provide growth factors that may aid healing. However, like autologous keratinocyte sheets, the grafts lack the strength provided by a dermal component and pose a risk of disease transmission.

Viable fibroblasts can be grown on bioabsorbable or nonbioabsorbable meshes to yield living dermal tissue that can act as a scaffold for epidermal growth. Fibroblasts stimulated by growth factors can produce type I collagen and glycosaminoglycans (e.g., chondroitin sulfates), which adhere to the wound surface to permit epithelial cell migration, as well as adhesive ligands (e.g., the matrix protein fibronectin), which promote cell adhesion. This approach has the virtue of being less time-consuming and expensive than culturing keratinocyte sheets. There are a number of commercially available, bioengineered dermal replacements approved for use in burn wound treatment as well as other indications.

Bioengineered skin substitutes have evolved from keratinocyte monolayers to dermal equivalents to split-thickness products with a pseudo-epidermis, and most recently, to products containing both epidermal and dermal components that resemble the three-dimensional structure and function of normal skin (see Table 9-11). Indicated for use with standard compression therapy in the treatment of venous insufficiency ulcers and for the treatment of neuropathic diabetic foot ulcers, these bilayered skin equivalents also are being used in a variety of wound care settings.

Growth Factor Therapy. As discussed previously, it is believed that nonhealing wounds result from insufficient or inadequate growth factors in the wound environment. A simplistic solution would be to flood the wound with single or multiple growth factors in order to “jump-start” healing and reepithelialization. Although there is a large body of work demonstrating the effects of growth factors in animals, translation of these data into clinical practice has met with limited success. Growth factors for clinical use may be either recombinant or homologous/autoologous. Autologous growth factors are harvested from the patient’s own platelets, yielding an unpredictable combination and concentration of factors, which are then applied to the wound. This approach allows treatment with patient-specific factors at an apparently physiologic ratio of growth factor concentrations. Disappointingly, a recent meta-analysis failed to demonstrate any value for autologous platelet-rich plasma in the treatment of chronic wounds. Recombinant molecular biologic means permit the purification of high concentrations of individual growth factors. Current FDA-approved formulations, as well as those used experimentally, deliver concentrations approximately 10^3 times higher than those observed physiologically.

At present, only platelet-derived growth factor BB (PDGF-BB) is currently approved by the FDA for treatment of diabetic foot ulcers. Application of recombinant human PDGF-BB in a gel suspension to these wounds increases the incidence of total healing and decreases healing time. Several other growth factors have been tested clinically and show some promise, but currently none are approved for use. A great deal more needs to be discovered about the concentration, temporal release, and receptor cell population before growth factor therapy is to make a consistent impact on wound healing.

Gene or Cell Therapy. Given the disappointing results from the application of purified growth factors onto wounds, the possible therapeutic potential of gene therapy has been recognized and studied. Direct access to the open wound bed, which characterizes almost all chronic wounds, has facilitated this therapy. Gene delivery to wounds includes traditional approaches such as viral vectors and plasmid delivery or, more recently, electroporation and microseeding.

Although a variety of genes expressing interleukin-8, PDGF, IGF-1, keratinocyte growth factor, and laminin-5 have been successfully delivered to wounds in both animal and human models, the effects have been modest and specific to unique wound situations. Delivering extra genes into the wound bed presents the challenge of expression of the necessary signals to turn the genes on and off at appropriate times so that dysregulated, hypertrophic, and abnormal healing does not occur. Elaborate systems have been created for topical use as on/off switches for genes. The more important question is which genes to express, in what temporal sequence, and in what regions of the wound bed, as it is unlikely that a single gene coding for one protein can significantly affect overall healing. There is growing consensus that delivery of genes is not going to represent the universal solution. Although gene therapy replaces missing or
defective genes, most acute wounds already have and express the necessary genes for successful healing and the wound environment produces signals adequate to the activation of these genes. What, if any, are the deficiencies in gene expression or activity in failed wounds is unknown.

Another approach is to deliver multiple genes coding for proteins that can act synergistically and even in a timed sequence, as would occur during normal healing. This would involve the use of activated cells that participate in the healing sequence that could be delivered in an activated state to the wound environment. Use of mesenchymal stem cells as a delivery vector for many genes simultaneously is the latest such approach. The feasibility of applying bone marrow-derived, umbilical cord-derived, adipose-derived, and epidermal stem cells that can differentiate into various cells that participate in the wound healing response also has been documented. These cells, as part of their differentiation and activation in the wound, have been shown to produce a variety of growth factors including VEGF, PDGF, bFGF, and MMP-9. The challenges remain how to maintain the viability and activity of the transplanted cells, how to document that the observed effects are due to the delivered cells, and what are the mechanisms necessary for regulating or ending their activity.

Oxygen Therapy in Wound Healing

Oxygen is required for almost all steps of wound healing and is also an important factor in the body’s defense against bacterial infection. In addition to its role in healing, oxygen plays an essential role in the production of reactive oxygen species such as superoxide that are angiogenesis stimulators and are bacteriostatic. Chronic wounds have a decreased oxygen supply, and for a long time lack of oxygen was recognized as a potential cause of delayed healing. To counteract this delay, supplemental oxygen therapy was used to improve healing, and both local oxygen therapy and systemic therapy were used for that purpose. Local therapy included oxygen dressings and topical oxygen therapy, while systemic therapy included supplemental inspired oxygen therapy and pressurized oxygen treatment.

Of the different methods of oxygen therapy, pressurized oxygen, also termed hyperbaric oxygen therapy (HBOT) is the most used modality and the most investigated. In HBOT, oxygen is delivered under pressure, more than atmospheric pressure, leading to a higher concentration of oxygen in tissues. The Undersea and Hyperbaric Medical Society (UHMS) defined HBOT as an intervention that involves breathing near 100% oxygen intermittently under high pressure achieved by a pressurized chamber to more than sea level pressure (sea level pressure = 1 atmosphere absolute [ATA]). The therapeutic pressure should be at least 1.4 ATA. Chambers can be single occupancy or multiple occupancy. Although there are numerous indications and potential indications for HBOT, there are 14 accepted indications by Undersea and Hyperbaric Medical Society, and the FDA. Indications related to wounds and ulcers include clostridial myonecrosis, crush injury, radiation-induced soft tissue and bone necrosis, necrotizing soft tissue infections, diabetic ulcers Wagner III or higher, refractory osteomyelitis, and thermal burns. Two systematic reviews were published on the effect of HBOT on wound healing. The first one was published in 2003 on all studies done up to 2001. Generally, the review showed beneficial effects of HBOT on different disease processes. HBOT was found to improve graft survival, complete healing of grafts, and lessen infection in patients with a graft. Patients with osteoradionecrosis showed improved bone changes. The effect on tissue radionecrosis was described as positive, but not all studies showed statistical significance. HBOT was found to have improved amputation rates in patients with gas gangrene with better healing. In addition, HBOT was found to reduce mortality rates from necrotizing fasciitis, and significantly decreased wound size in nonhealing diabetic wounds. In the second systematic review, a total of 29 studies published between 2001 and 2016 were included. A total of 14 studies were related to chronic wounds: 12 studies in acute wounds, 1 study on both acute and chronic wounds, and 2 experimental studies. Out of those 29 studies, 18 (62%) showed at least one positive outcome. One of the drawbacks of such studies in general is the lack of heterogeneity and the lack of accurate randomization. Perhaps, HBOT in diabetic foot ulcers attracted more attention than other forms of skin ulcers. In patients with diabetic foot ulcers, studies showed that HBOT led to significantly more healing wounds at 1 year, greater reduction in the wound bed, greater healing with less proximal amputation, and more complete wound healing at 1 month after HBOT.

Biofilm and Chronic Wound Healing

Traditionally, nonhealing of chronic wounds has been associated with numerous risk factors, including longer duration of ulcers, advanced age, increased body mass index, venous reflux, arterial and venous disease, nutritional deficiencies, diabetes mellitus, and smoking. Chronic bacterial infection is another factor that has been associated with nonhealing wounds.

Chronic wounds, in general, behave differently in relation to bacterial growth when compared to acute wounds. Chronic wounds develop bacterial growth that is resistant to invasion by antibiotics and is protected by the host immune defenses. Biofilm is the term used for the bacterial growth on a chronic wound that is encapsulated by a protective layer made up of the host and bacterial proteins. Bijnsholt et al have suggested a simplified definition of the biofilm as “an aggregate of bacteria tolerant to treatment and the host defense.” It has been found that more than 60% of chronic wounds have a biofilm. Biofilms lead to a chronic inflammatory process that will interfere with healing. Biofilms are formed in the wound environment, which provides a micro-environment that is ideal for bacterial growth. Once a biofilm colony forms, it will continuously shed bacteria to uncolonized areas, causing more biofilm colonies to form.

The presence of biofilms protects bacteria from the host defenses. Bacteria will then begin to exhibit phenotypic and genotypic plurality: the former allows bacteria to adapt to different growth conditions such as nutrient availability, pH, and oxidizing potential within the biofilm, while the latter allows for virulence and bacterial resistance to drugs. The genetic plurality is passed horizontally among bacteria in the wound, adding to the resistance to treatment and allowing the bacteria to avoid the defense mechanisms of the host such as bacterial phagocytosis,
neutrophil degranulation, and formation of reactive oxygen species. In some cases, the biofilm allows bacteria to become quiescent and thus become less sensitive to antimicrobials that typically affect dividing bacterial cells.

Biofilms can form and recover from debridement rapidly. Fully mature biofilm colonies can form within 2 to 4 days depending on the species and growth conditions. Common bacterial species such as *Staphylococcus*, *Streptococcus*, and *Pseudomonas* can attach to the surface of the wound in minutes, forming adherent microcolonies in 2 to 4 hours. Bacterial species develops the extracellular polymeric substances (EPS) and resistance to disinfectants, antiseptics, and antibiotics in 6 to 12 hours. The biofilm then develops into mature colonies in 2 to 4 days. Furthermore, it rapidly recovers from mechanical disruption, such as debridement, within 24 hours. The presence of biofilms leads to delayed wound healing by stimulating chronic inflammation in the wound. The host responds to the biofilms by mobilizing macrophages and neutrophils in the biofilm area, resulting in secretion of high levels of reactive oxygen species and proteases that can cause damage to the normal and healing tissue. The resulting increase in exudate production provides a source of nutrients to the biofilms, leading to more resistance to healing.

The best method of treating wounds with biofilms is not well defined. It is believed that frequent debridement to mechanically remove the biofilm remains to be the best method of treatment. The frequency of debridement is not well defined, although a weekly debridement has been suggested to improve healing. More than one method of debridement might be needed in wounds resistant to healing. A few products have been suggested to control and remove biofilms, such as surfactant and some wound cleansing formulas. In addition, topical broad-spectrum antimicrobials such as silver, iodine, honey, and others have been suggested to aid in the treatment of biofilms. Using a combination of debridement methods, cleansing agents, and antimicrobials may be needed in resistant chronic wounds. An effective therapy to combat biofilm should include effective removal of the biofilm, antimicrobial eradication of bacteria/organisms, and prevention of biofilm recurrence, and these treatment options may need to be repeated multiple times to achieve effective therapy. Many agents and devices thought to be effective in eradicating and treating biofilms are under evaluation or development; however, their long-term effect is yet to be proven.

**REFERENCES**

Entries highlighted in bright blue are key references.

As the population ages, oncology is becoming a larger portion of surgical practice. The surgeon often is responsible for the initial diagnosis and management of solid tumors. Knowledge of cancer epidemiology, etiology, staging, and natural history is required for initial patient assessment, as well as to determine the optimal surgical therapy.

Modern cancer therapy is multidisciplinary, involving the coordinated care of patients by surgeons, medical oncologists, radiation oncologists, reconstructive surgeons, pathologists, radiologists, and primary care physicians. **Primary (or definitive) surgical therapy** refers to en bloc resection of tumor with adequate margins of normal tissues and regional lymph nodes as necessary. **Adjuvant therapy** refers to radiation therapy and systemic therapies, including chemotherapy, immunotherapy, hormonal therapy, and, increasingly, biologic therapy. The primary goal of surgical and radiation therapy is local and regional control. On the other hand, the primary goal of adjuvant therapy is systemic control by treatment of distant foci of subclinical disease to prevent distant recurrence. Surgeons must be familiar with adjuvant therapies to coordinate multidisciplinary care and to determine the best sequence of therapy. They must also be aware of the potential for patients to receive effective systemic therapies prior to surgery as a means of reducing tumor volume.

Recent advances in molecular biology are revolutionizing medicine. New information is being translated rapidly into clinical use, with the development of new prognostic and predictive markers and new biologic therapies. Increasingly cancer therapy is becoming personalized, incorporating information about each patient’s tumor characteristics, patient’s own genome, as well as host immune responses and tumor microenvironment, into clinical decision-making. It is therefore essential that surgeons understand the principles of molecular oncology to appropriately interpret these new contributions and incorporate them into practice.
Key Points

1. Modern cancer therapy is multidisciplinary, involving coordinated care by surgeons, medical oncologists, radiation oncologists, reconstructive surgeons, pathologists, radiologists, and primary care physicians.

2. Understanding cancer biology is essential to successfully implement personalized cancer therapy.

3. The following alterations are critical for malignant cancer growth: self-sufficiency of growth signals, insensitivity to growth-inhibitory signals, evasion of apoptosis, potential for limitless replication, angiogenesis, invasion and metastasis, reprogramming of energy metabolism, and evading immune destruction.

Epidemiology

Basic Principles of Cancer Epidemiology

The term incidence refers to the number of new cases occurring. Incidence is usually expressed as the number of new cases per 100,000 persons per year. Mortality refers to the number of deaths occurring and is expressed as the number of deaths per 100,000 persons per year. Incidence and mortality data are usually available through cancer registries. Mortality data are also available as public records in many countries where deaths are registered as vital statistics, often with the cause of death. In areas where cancer registries do not exist, mortality data are used to extrapolate incidence rates. These numbers are likely to be less accurate than registry data, as the relationship between incidence and cause-specific death is likely to vary significantly among countries owing to the variation in health care delivery.

The incidence of cancer varies by geography. This is due in part to genetic differences and in part to differences in environmental and dietary exposures. Epidemiologic studies that monitor trends in cancer incidence and mortality have tremendously enhanced our understanding of the etiology of cancer. Furthermore, analysis of trends in cancer incidence and mortality allows us to monitor the effects of different preventive and screening measures, as well as the evolution of therapies for specific cancers.

The two types of epidemiologic studies that are conducted most often to investigate the etiology of cancer and the effect of prevention modalities are cohort studies and case-control studies. Cohort studies follow a group of people who initially do not have a disease over time and measure the rate of development of a disease. In cohort studies, a group that is exposed to a certain environmental factor or intervention usually is compared to a group that has not been exposed (e.g., smokers vs. nonsmokers). A case-control study compares a group of patients affected with a disease to a group of individuals without the disease and looks back retrospectively to compare how frequently the exposure to a risk factor is present in each group to determine the relationship between the risk factor and the disease. The results are expressed in terms of an odds ratio, or relative risk. A relative risk <1 indicates a protective effect of the exposure, whereas a relative risk >1 indicates an increased risk of developing the disease with exposure.

Cancer Incidence and Mortality in the United States

In the year 2017, it is estimated that 1.7 million new cancer cases will be diagnosed in the United States, excluding carcinoma in situ of any site except bladder, and excluding basal cell and squamous cell carcinomas of the skin. In addition, 63,410 cases of carcinoma in situ of the breast, and 74,680 of melanoma in situ are expected. It is estimated that in 2017 an estimated 600,920 people will die of cancer in the United States, corresponding to about 1650 deaths per day. The estimated new cancer cases and deaths by cancer type are shown in Table 10-1. The most common causes of cancer death in men are cancers of the lung and bronchus, colon and rectum, and prostate; in women, the most common cancers are of the lung and bronchus, breast, and colon and rectum. These four cancers account for almost half of total cancer deaths among men and women.

The annual age-adjusted cancer incidence rates among males and females for selected cancer types are shown in Fig. 10-1. Incidence rates are declining for most cancer sites (Fig. 10-2). Incidence rates for thyroid cancer have begun to stabilize recently, possibly due to changes in clinical practice guidelines that were initiated in 2009 and included more conservative indications for biopsy. The age-adjusted incidence rate of breast cancer started to decrease from 2001 to 2004. This decrease in breast cancer incidence has at least temporally been associated with the first report of the Women’s Health Initiative, which documented an increased risk of coronary artery disease and breast cancer with the use of hormone replacement therapy; this was followed by a drop in the use of hormone replacement therapy by postmenopausal women in the United States. Unfortunately, there was a slight increase in breast cancer incidence from 2004 to 2013. This was driven wholly by nonwhite women; rates increased by about 2% per year among women other than white or black and by 0.5% per year among black women. Thus, rates have risen slightly in women as a whole from 2013 to 2017, although rates remained stable in white women.

Declines in colorectal cancer incidence have been mainly attributed to increased screening that allows for removal of precancerous polyps. Prostate cancer rates rapidly increased and decreased between 1995 and 1998. These trends are thought to be attributable to increased use of prostate-specific antigen (PSA) screening. Due to growing concerns about overdiagnosis and overtreatment, a U.S. Preventive Services Task Force recommended against routine use of PSA testing to screen for prostate cancer. As a result, there was more than 10% annual reduction in prostate cancer incidence from 2010 to 2013. Differences in lung cancer incidence patterns between women and men are thought to reflect historical differences in tobacco use. Differences in smoking prevalence is also thought to contribute to regional differences in lung cancer incidence. Lung cancer incidence is fourfold higher in Kentucky, which has the highest smoking prevalence, compared with Utah, which has the lowest smoking prevalence.

The 5-year survival rates for selected cancers are listed in Table 10-2. From 2010 to 2014, cancer death rates decreased by 1.8% per year in men and by 1.4% per year in women. These declines in mortality have been consistent in the past decade and larger than what was observed in the previous decade. Over the

*Rounded to the nearest 10, cases exclude basal cell and squamous cell skin cancers and in situ carcinoma except bladder. About 63,410 cases of carcinoma in situ of the female breast and 74,680 cases of melanoma in situ were diagnosed in 2017.

Deaths for colon and rectum cancers are combined because a large number of deaths from rectal cancer are misclassified as colon.

More deaths than cases may reflect lack of specificity in recording underlying cause of death on death certificate and/or an undercount in the case estimate.

past 3 decades, the 5-year relative survival rate for all cancers combined has increased by 20% among whites and 24% among blacks. Improvements in survival for the most common cancers have been similar across both sexes but are more pronounced among patients age 50 to 64 years than among those older than 65 years. This difference may reflect reduced efficacy of new therapies in the elderly or perhaps lower utilization. Progress has been rapid for hematopoietic and lymphoid malignancies due to improved treatment protocols and the discovery of targeted therapies. The decrease in lung cancer death rates in men is thought to be due to a decrease in tobacco use, whereas the decreases in death rates from breast, colorectal cancer, and prostate cancer likely reflect advances in early detection and treatment. For instance, there is potential for lung cancer to be diagnosed at an earlier stage through the use of screening with low-dose computed tomography.

Global Statistics on Cancer Incidence and Mortality

The five most common cancers for men worldwide are lung, prostate, colorectal cancer, stomach, and liver and for women are breast, colorectal, cervix, lung, and stomach. Notably, for several cancer types there is wide geographical variability in cancer incidence (Fig. 10-3). The mortality rates for different cancers also vary significantly among countries. This is attributable not only to variations in incidence but also to variations in survival after a cancer diagnosis. The survival rates are influenced by treatment patterns as well as by variations in cancer screening practices, which affect the stage of cancer at diagnosis. For example, the 5-year survival rate for stomach cancer is much higher in Japan, where the cancer incidence is high enough to warrant mass screening, which is presumed to lead to earlier diagnosis. In the case of prostate cancer, on the other
hand, the mortality rates diverge much less than the incidence rates among countries. Survival rates for prostate cancer are much higher in North America than in developing countries. It is possible that the extensive screening practices in the United States allow discovery of cancers at an earlier, more curable stage; however, it is also possible that this screening leads to discovery of more latent, less biologically aggressive cancers, which may not have caused death even if they had not been identified.

In 2008 (the last date for which complete data are available), about 1 million new cases of stomach cancer were estimated to have occurred (988,000 cases, 7.8% of the total), making it the fourth most common malignancy in the world, behind cancers of the lung, breast, and colorectal cancer. The incidence of stomach cancer varies significantly among different regions of the world. The difference in risk by country is presumed to be primarily due to differences in dietary factors. The risk is increased by high consumption of preserved salted foods, such as meats and pickles, and decreased by high intake of fruits and vegetables. There is also some international variation in the incidence of infection with *Helicobacter pylori*, which is known to play a major role in gastric cancer development. Fortunately, a steady decline is being observed in the incidence and mortality rates of gastric cancer. This may be related to improvements in preservation and storage of foods as well as due to changes in the prevalence of *H pylori*. More than 70% of cases (713,000 cases) occur in developing countries, and half the cases in the world occur in Eastern Asia (mainly in China). Age-standardized incidence rates are about twice as high for men as for women, ranging from 3.9 in Northern Africa to 42.4 in Eastern Asia for men, and from 2.2 in Southern Africa to 18.3 in Eastern Asia for women. Stomach cancer is the second leading cause of cancer death in both sexes worldwide.

Overall, the incidence of breast cancer is rising in most countries. Incidence varies from 19.3 per 100,000 women in Eastern Africa to 89.7 per 100,000 women in Western Europe, and are high in developed regions of the world (except Japan) and low in most of the developing regions. Although breast cancer has been linked to cancer susceptibility genes, mutations in these genes account for only 5% to 10% of breast tumors, which suggests that the wide geographic variations in breast cancer incidence are not due to geographic variations in the prevalence of these genes. Most of the differences, therefore, are attributed to differences in reproductive factors, diet, alcohol, obesity, physical activity, and other environmental differences. Indeed, breast cancer risk increases significantly in females

</table>
who have migrated from Asia to America.\textsuperscript{5} The range of breast cancer mortality rates is much less (approximately 6 to 19 per 100,000) because of the more favorable survival of breast cancer in developed regions. As a result, breast cancer ranks as the fifth cause of death from cancer overall (458,000 deaths), but it is still the most frequent cause of cancer death in women in both developing (269,000 deaths, 12.7\% of total) and developed regions (estimated 189,000 deaths).\textsuperscript{4}

There is a 25-fold variation in colon cancer incidence worldwide.\textsuperscript{5} The incidence of colon and rectal cancer is higher in developed countries than in developing countries. The incidence rates are highest in North America, Australia and New Zealand, and Western Europe, and especially in Japanese men.\textsuperscript{5} In contrast, the incidence is relatively low in North Africa, South America, and Eastern, Southeastern, and Western Asia. These geographic differences are thought to reflect environmental exposures and are presumed to be related mainly to dietary differences in consumption of animal fat, meat, and fiber.\textsuperscript{5}

Worldwide liver cancer is the fifth most common cancer in men (523,000 cases, 7.9\% of the total) and the seventh in women (226,000 cases, 6.5\% of the total). Almost 85\% of liver cancer cases occur in developing countries, and particularly in men.\textsuperscript{4} The overall sex ratio of male to female is 2:4. The regions of high incidence are Eastern and Southeastern Asia, Middle and Western Africa, as well as Melanesia and Micronesia/Polynesia (particularly in men). Low rates are estimated in developed regions, with the exception of Southern Europe. There were an estimated 694,000 deaths from liver cancer in 2008 (477,000 in men, 217,000 in women), and because of its high fatality (overall ratio of mortality to incidence of 0.93), liver cancer is the third most common cause of death from cancer worldwide. The geographical distribution of the mortality rates is similar to that observed for incidence. Worldwide, the major risk factors for liver cancer are infection with hepatitis B and C viruses and consumption of foods contaminated with aflatoxin. Hepatitis B immunization in children has recently been shown to reduce the incidence of liver cancer.\textsuperscript{5}

In summary, the incidence rates of many common cancers vary widely by geography. This is due in part to genetic differences, including racial and ethnic differences. It is due also in part to differences in environmental and dietary exposures, factors that can potentially be altered. Therefore, establishment of regional and international databases is critical to improving our understanding of the etiology of cancer and will ultimately assist in the initiation of targeted strategies for global cancer prevention. Furthermore, the monitoring of cancer mortality rates and 5-year cancer-specific survival rates will identify regions where there are inequities of health care, so that access to health care can be facilitated and guidelines for treatment can be established.

### CANCER BIOLOGY

#### Hallmarks of Cancer

Although there are >100 types of cancer, it has been proposed that there are six essential alterations in cell physiology that dictate malignant growth: self-sufficiency of growth signals, insensitivity to growth-inhibitory signals, evasion of apoptosis (programmed cell death), potential for limitless replication, angiogenesis, and invasion and metastasis. Recently two additional hallmarks have emerged—reprogramming of energy metabolism and evading immune destruction. These hallmarks of cancer are being pursued as targets for cancer therapy (Fig. 10-4).

#### Cell Proliferation and Transformation

In normal cells, cell growth and proliferation are under strict control. In cancer cells, cells become unresponsive to normal growth controls, which leads to uncontrolled cell division. Human cells require several genetic changes for neoplastic transformation. Cell type–specific differences also exist in the process by which a normal cell is transformed into a cancerous one. Abnormally proliferating, transformed cells outgrow normal cells in the culture dish (i.e., in vitro) and commonly display several abnormal characteristics. These include loss of contact inhibition (i.e., cells continue to proliferate after a confluent monolayer is formed); an altered appearance and poor adherence to other cells or to the substratum; loss of anchorage dependence for growth; immortalization; and gain of tumorigenicity (i.e., the ability to give rise to tumors when injected into an appropriate host).

#### Cancer Initiation

Tumorigenesis is proposed to have three steps: initiation, promotion, and progression. Initiating events such as gain of function of genes known as oncogenes or loss of function of genes known as tumor-suppressor genes may lead a single cell to acquire a distinct growth advantage. Although tumors usually arise from a single cell or clone, it is thought that sometimes not a single cell but
rather a large number of cells in a target organ may have undergone the initiating genetic event. Thus, many normal-appearing cells may have an increased malignant potential. This is referred to as a field effect. The initiating events are usually genetic and occur as deletions of tumor-suppressor genes or amplification or mutation of oncogenes. Subsequent events can lead to accumulations of additional deleterious mutations in the clone.

Cancer is thought to be a disease of clonal progression as tumors arise from a single cell and accumulate mutations that confer on the tumor an increasingly aggressive behavior. Most tumors go through a progression from benign lesions to in situ tumors to invasive cancers (e.g., atypical ductal hyperplasia to ductal carcinoma in situ to invasive ductal carcinoma of the breast). Fearon and Vogelstein proposed the model for colorectal tumorigenesis presented in Fig. 10-5.9 Colorectal tumors arise from the mutational activation of oncogenes coupled with mutational inactivation of tumor-suppressor genes, the latter being the predominant change.9 Mutations in at least four or five genes are required for formation of a malignant tumor, while fewer changes suffice for a benign tumor. Although genetic mutations often occur in a preferred sequence, a tumor’s biologic properties are determined by the total accumulation of its genetic changes.

Gene expression is a multistep process that starts from transcription of a gene into messenger ribonucleic acid (mRNA) and then translation of this sequence into the functional protein. There are several controls at each level. In addition to alterations at the genome level (e.g., amplifications of a gene), alterations at the transcription level (e.g., methylation of the DNA leading to transcriptional silencing) or at the level of mRNA processing, mRNA stability, mRNA translation, or protein stability, all can alter the levels of critical proteins and thus contribute to tumorigenesis. Alternatively, changes in the genomic sequence can lead to a mutated product with altered function.

**Cell-Cycle Dysregulation in Cancer**

The proliferative advantage of tumor cells is a result of their ability to bypass a quiescent state. Cancer cells often show alterations in signal transduction pathways that lead to proliferation in response to external signals. Mutations or alterations in the expression of cell-cycle proteins, growth factors, growth factor receptors, intracellular signal transduction proteins, and nuclear transcription factors all can lead to disturbance of the basic regulatory mechanisms that control the cell cycle, allowing unregulated cell growth and proliferation.

The cell cycle is divided into four phases (Fig. 10-6).10 During the synthetic or S phase, the cell generates a single copy of its genetic material, whereas in the mitotic or M phase, the cellular components (including copies of DNA) are partitioned between two daughter cells. The G₁ and G₂ phases represent gap phases, during which the cells prepare themselves for
completion of the S and M phases, respectively. When cells cease proliferation, they exit the cell cycle and enter the quiescent state referred to as G0. The two key classes of regulatory molecules that regulate cellular progress through the cell cycle are the cyclins and the cyclin-dependent kinases (CDKs), which associate to form an activated heterodimer. CDKs are expressed constitutively and have a catalytic activity (phosphorylation of downstream proteins), whereas the cyclins serve a regulatory function and are synthesized at specific times during the cell cycle. Two families of genes, the cip/kip (CDK interacting protein/Kinase inhibitory protein) family and the INK4a/ARF (Inhibitor of Kinase 4/Alternative Reading Frame) family

---

**Figure 10-4.** Hallmarks of cancer and their therapeutic implications. Drugs that interfere with each of the acquired capabilities necessary for tumor growth and progression are in clinical trials and in some cases approved for clinical use in treating forms of human cancer. The drugs listed are illustrative examples. (Reproduced with permission from Hanahan D, Weinberg RA. Hallmarks of cancer: the next generation, CCell. 2011 Mar 4;144(5):646-674.)

---

**Figure 10-5.** The adenoma-carcinoma model of human colorectal carcinogenesis. The neoplastic process is initiated by mutations in the adenomatous polyposis coli (APC) or β-catenin genes. Tumor progression results from mutations in other genes (e.g., K-ras, Smad 4 and p53) and the development of genomic instability. Patients with familial adenomatous polyposis inherit mutations in the APC gene and develop multiple aberrant crypt foci. Some of these may progress to cancer as they acquire other genetic mutations. (Reproduced with permission from Li C-J, Zhang, X, Fan G-W. Updates in colorectal cancer stem cell research, J Cancer Res Ther. 2014 Dec;10 Suppl:233-239.)
Normal cellular genes that contribute to cancer when abnormal are called oncogenes. The normal counterpart of such a gene is referred to as a proto-oncogene. Oncogenes are usually designated by three-letter abbreviations, such as myc or ras. Oncogenes are further designated by the prefix “v-“ for virus or “c-“ for cell or chromosome, corresponding to the origin of the oncogene when it was first detected. Proto-oncogenes can be activated (show increased activity) or overexpressed (expressed at increased protein levels) by translocation (e.g., abl), promoter insertion (e.g., c-myc), mutation (e.g., ras), or amplification (e.g., HER2/neu). More than 100 oncogenes have been identified.

 Oncogenes may be growth factors (e.g., platelet-derived growth factor), growth factor receptors (e.g., HER2), intracellular signal transduction molecules (e.g., ras), nuclear transcription factors (e.g., c-myc), or other molecules involved in the regulation of cell growth and proliferation. Growth factors are ubiquitous proteins that are produced and secreted by cells locally and that stimulate cell proliferation by binding specific cell-surface receptors on the same cells (autocrine stimulation) or on neighboring cells (paracrine stimulation). Persistent overexpression of growth factors can lead to uncontrolled autostimulation and neoplastic transformation. Alternatively, growth factor receptors can be aberrantly activated (turned on) through mutations or overexpression (continually presenting cells with growth-stimulatory signals, even in the absence of growth factors), which leads cells to respond as if growth factor levels are altered. The growth-stimulating effect of growth factors and other mitogens is mediated through postreceptor signal transduction molecules. These molecules mediate the passage of growth signals from the outside to the inside of the cell and then to the cell nucleus, initiating the cell cycle and DNA transcription. Aberrant activation or expression of cell-signaling molecules, cell-cycle molecules, or transcription factors may play an important role in neoplastic transformation. Protein tyrosine kinases account for a large portion of known oncogenes. One of the best-studied oncogenes, HER2 is discussed as an example later.

HER2, also known as neu or c-erbB-2, is a member of the epidermal growth factor receptor (EGFR) family and is one of the best-characterized tyrosine kinases. Unlike other receptor tyrosine kinases, HER2/neu does not have a direct soluble ligand. It plays a key role in signaling, however, because it is the preferred partner in heterodimer formation with all the other EGFR family members (EGFR/c-erbB-1, HER2/c-erbB-3, and HER3/c-erbB-4), which bind at least 30 ligands, including epidermal growth factor (EGF), transforming growth factor α (TGFα), heparin-binding EGF-like growth factor, amphiregulin, and heregulin. Heterodimerization with HER2 potentiates recycling of receptors rather than degradation, enhances signal potency and duration, increases affinity for ligands, and increases catalytic activity.

HER2 can interact with different members of the HER family and activate mitogenic and antiapoptotic pathways (Fig. 10-7). The specificity and potency of the intracellular signals are affected by the identity of the ligand, the composition of the receptors, and the phosphotyrosine-binding proteins associated with the erbB molecules. The Ras- and Shc-activated mitogen-activated protein kinase (MAPK) pathway is a target of all erbB ligands, which increase the transcriptional activity of early response genes such as c-myc, c-fos, and c-jun. MAPK-independent pathways such as the phosphoinosito-3 kinase (PI3K) pathway also are activated by most erbB dimers, although the potency and kinetics of activation may differ. Stimulation of the PI3K pathway through HER2 signaling also can lead to activation of survival molecule Akt, which suppresses apoptosis through multiple mechanisms.

The mutant rat neu gene was first recognized as an oncogene in neuroblastomas from carcinogen-treated rats. The HER2 gene is frequently amplified and the protein overexpressed in many cancers, including breast, ovarian, lung, gastric, and oral cancers. Overexpression of HER2 results in ligand-independent activation of HER2 kinase, which leads to mitogenic signaling. HER2 overexpression is associated with increased cell proliferation and anchorage-independent growth as well as resistance to proapoptotic stimuli. Further, overexpression of HER2 increases cell migration and upregulates the activities of matrix metalloproteinases (MMPs) and in vitro invasiveness. In animal models, HER2 increases tumorigenicity, angiogenesis, and metastasis. These results all suggest that HER2 plays a key role in cancer biology. More recently, HER2 mutations have also been reported in human cancer, including 3% of patients with lung cancer. A phase 2 study of the irreversible kinase inhibitor neratinib showed it to have efficacy in HER2-mutated breast cancer lacking HER amplification.

The critical role of HER2 in cancer biology has been leveraged for therapeutics, leading to several HER2-targeted drugs with different mechanism of action approved by the Food and Drug Administration (FDA): monoclonal antibodies trastuzumab and pertuzumab, small molecule inhibitor lapatinib, and antibody-drug conjugate ado-trastuzumab emtansine. Anti-HER2 agents first showed efficacy in the metastatic setting but
are now routinely used as adjuvant therapy of breast cancer and also as neoadjuvant treatments (“up-front chemotherapy”).

**Alterations in Apoptosis in Cancer Cells**

Apoptosis is a genetically regulated program to dispose of cells. Cancer cells must avoid apoptosis if tumors are to arise. The growth of a tumor mass is dependent not only on an increase in proliferation of tumor cells but also on a decrease in their apoptotic rate. Apoptosis is distinguished from necrosis because it leads to several characteristic changes. Soon after undergoing apoptosis, membrane phosphatidylserine translocates from the inner face of the plasma membrane to the cell surface where it can be detected via the use of a fluorescent conjugate of Annexin V, a protein that exhibits a high affinity for phosphatidylserine. Late in apoptosis there are characteristic changes in nuclear morphology, such as chromatin condensation, nuclear fragmentation, and DNA laddering, as well as membrane blebbing. Apoptotic cells are then engulfed and degraded by phagocytic cells. The effectors of apoptosis are a family of proteases called caspases (cysteine-dependent and aspartate-directed proteases). The initiator caspases (e.g., 8, 9, and 10), which are upstream, cleave the downstream executioner caspases (e.g., 3, 6, and 7) that carry out the destructive functions of apoptosis.

Two principal molecular pathways signal apoptosis by cleaving the initiator caspases with the potential for crosstalk: the mitochondrial pathway and the death receptor pathway. In the mitochondrial (or intrinsic) pathway, death results from the release of cytochrome c from the mitochondria. Cytochrome c, procaspase 9, and apoptotic protease activating factor 1 (Apaf-1) form an enzyme complex, referred to as the **apoptosome**, that activates the effector caspases. In addition to these proteins, the mitochondria contain other proapoptotic proteins such as Smac/DIABLO (second mitochondria-derived activator of caspase/direct inhibitor of apoptosis-binding protein with low pI). The mitochondrial pathway can be stimulated by many factors, including DNA damage, reactive oxygen species, or the withdrawal of survival factors. The permeability of the mitochondrial membrane determines whether the apoptotic pathway will proceed. The Bcl-2 family of regulatory proteins includes both proapoptotic proteins (e.g., Bax, BAD, and Bak) and antiapoptotic proteins (e.g., Bcl-2 and Bcl-xL). The activity of the Bcl-2 proteins is centered on the mitochondria, where they regulate...
membrane permeability. Growth factors promote survival signaling through the PI3K/Akt pathway, which phosphorylates and inactivates proapoptotic BAD. In contrast, growth factor withdrawal may promote apoptosis through signaling by unphosphorylated BAD. The heat shock proteins, including Hsp70 and Hsp27, are also involved in inhibition of downstream apoptotic pathways by blocking formation of the apoptosome complex and inhibiting release of cytochrome c from the mitochondria.19

The second principal apoptotic pathway is the death receptor pathway, sometimes referred to as the extrinsic pathway. Cell-surface death receptors include Fas/APO1/CD95, tumor necrosis factor receptor 1, and KILL-ER/DR5, which bind their ligands Fas-L, tumor necrosis factor (TNF), and TNF-related apoptosis-inducing ligand (TRAIL), respectively. When the receptors are bound by their ligands, they form a death-inducing signaling complex (DISC). At the DISC, procaspase 8 and procaspase 10 are cleaved, yielding active initiator caspases.20 The death receptor pathway may be regulated at the cell surface by the expression of “decoy” receptors for Fas (DcR3) and TRAIL (TRID and TRUNDD). The decoy receptors are closely related to the death receptors but lack a functional death domain; therefore, they bind death ligands but do not transmit a death signal. Another regulatory group is the FADD-like interleukin-1 protease-inhibitory proteins (FLIPs). FLIPs have homology to caspase 8; they bind to the DISC and inhibit the activation of caspase 8. Finally, inhibitors of apoptosis proteins (IAPs) block caspase 3 activation and have the ability to regulate both the death receptor and the mitochondrial pathway.

In human cancers, aberrations in the apoptotic program include increased expression of Fas and TRAIL decoy receptors; increased expression of antiapoptotic Bcl-2; increased expression of the IAP-related protein survivin; increased expression of c-FLIP; mutations or downregulation of proapoptotic Bax, caspase 8, APAF1, XAF1, and death receptors CD95, TRAIL-R1, and TRAIL-R2; alterations of the p53 pathway; overexpression of growth factors and growth factor receptors; and activation of the PI3K/Akt survival pathway.20

Autophagy in Cancer Cells

Autophagy (self-eating) is a major cellular pathway for protein and organelle turnover. The autophagic pathway is a mechanism for the delivery of cellular materials to lysosomes for degradation. This process leads to the basal turnover of cell components and provides energy and macromolecular precursors. This process helps maintain a balance between anabolism and catabolism for normal cell growth and development. Inability to activate autophagy in response to nutrient deprivation, or constitutive activation of autophagy in response to stress, can lead to cell death; thus, autophagy is sometimes referred to as a second form of programmed cell death. Autophagy plays an essential role during starvation, cellular differentiation, cell death, and aging. Autophagy is also involved in the elimination of cancer cells by triggering a nonapoptotic cell death program, which suggests a negative role in tumor development. Mouse models that are heterozygotes for the beclin 1 gene, an important gene for autophagy, have altered autophagic response and show a high incidence of spontaneous tumors, which establishes a role for autophagy in tumor suppression.21 This also suggests that mutations in other genes operating in this pathway may contribute to tumor formation through deregulation of autophagy. However, autophagy also acts as a stress response mechanism to protect cancer cells from low nutrient supply or therapeutic insults. Thus, in cancer, autophagy can have opposing and context-dependent roles, and interventions to both stimulate and inhibit autophagy have been proposed as possible anticancer treatments. Studies on the molecular controls of autophagy are ongoing and are expected to generate novel therapeutic strategies. Chloroquin is an antimalarial drug that acts as an autophagic inhibitor by blocking the autophagosome and has been tested for its anticancer properties.

Cancer Invasion

A feature of malignant cells is their ability to invade the surrounding normal tissue. Tumors in which the malignant cells appear to lie exclusively above the basement membrane are referred to as in situ cancer, whereas tumors in which the malignant cells are demonstrated to breach the basement membrane, penetrating into surrounding stroma, are termed invasive cancer. The ability to invade involves changes in adhesion, initiation of motility, and proteolysis of the extracellular matrix (ECM).

Cell-to-cell adhesion in normal cells involves interactions between cell-surface proteins. Calcium adhesion molecules of the cadherin family (E-cadherin, P-cadherin, and N-cadherin) are thought to enhance the cells’ ability to bind to one another and suppress invasion. Migration occurs when cancer cells penetrate and attach to the basal matrix of the tissue being invaded; this allows the cancer cell to pull itself forward within the tissue. Attachment to glycoproteins of the ECM such as fibronectin, laminin, and collagen is mediated by tumor cell integrin receptors. Integrins are a family of glycoproteins that form heterodimeric receptors for ECM molecules. The integrins can form at least 25 distinct pairings of their α and β subunits, and each pairing is specific for a unique set of ligands. In addition to regulating cell adhesion to the ECM, integrins relay molecular signals regarding the cellular environment that influence shape, survival, proliferation, gene transcription, and migration.

Factors that are thought to play a role in cancer cell motility include autocrine motility factor, autotaxin, scatter factor (also known as hepatocyte growth factor), TGFα, EGF, and insulin-like growth factors. Also, serine, cysteine, and aspartic proteinases and MMPs have all been implicated in cancer invasion. Urokinase and tissue plasminogen activators (uPA and tPA) are serine proteinases that convert plasminogen into plasmin. Plasmin, in turn, can degrade several ECM components. Plasmin also may activate MMPs. uPA has been more closely correlated with tissue invasion and metastasis than tPA. Plasminogen activator inhibitors 1 and 2 (PAI-1 and PAI-2) are produced in tissues and counteract the activity of plasminogen activators.

MMPs comprise a family of metal-dependent endopeptidases. Upon activation, MMPs degrade a variety of ECM components. Although MMPs often are referred to by their common names, which reflect the ECM component for which they have specificity, a sequential numbering system has been adopted for standardization. For example, collagenase-1 is now referred to as MMP-1. The MMPs are further classified as secreted and membrane-type MMPs. Most of the MMPs are synthesized as inactivezymogens (pro-MMP) and are activated by proteolytic removal of the propeptide domain outside the cell by other active MMPs or serine proteinases.

MMPs are upregulated in almost every type of cancer. Some of the MMPs are expressed by cancer cells, whereas others are expressed by the tumor stromal cells. Experimental models have demonstrated that MMPs promote cancer progression by
increasing cancer cell growth, migration, invasion, angiogenesis, and metastasis. MMPs exert these effects by cleaving not only structural components of the ECM but also growth factor–binding proteins, growth factor precursors, cell adhesion molecules, and other proteases to provide a growth advantage. The activity of MMPs is regulated by their endogenous inhibitors and tissue inhibitors of MMPs (TIMP-1, TIMP-2, TIMP-3, and TIMP-4).

**Angiogenesis**

Angiogenesis is the establishment of new blood vessels from a preexisting vascular bed. This neovascularization is essential for tumor growth and metastasis. Tumors develop an angiogenic phenotype as a result of accumulated genetic alterations and in response to local selection pressures such as hypoxia. Many of the common oncogenes and tumor-suppressor genes have been shown to play a role in the induction of angiogenesis.

In response to the angiogenic switch, pericytes retract and the endothelium secretes several growth factors such as basic fibroblast growth factor, platelet-derived growth factor (PDGF), and insulin-like growth factor. The basement membrane and stroma around the capillary are proteolytically degraded, a process that is mediated in most part by uPA. The endothelium then migrates through the degraded matrix, initially as a solid cord and later forming lumina. Finally, sprouting tips anastomose to form a vascular network surrounded by a basement membrane.

Angiogenesis is mediated by factors produced by various cells, including tumor cells, endothelial cells, stromal cells, and inflammatory cells. The first proangiogenic factor was identified by Folkman and colleagues in 1971. Since then, several other factors have been shown to be proangiogenic or antiangiogenic. Of the angiogenic stimulators, the best studied are the vascular endothelial growth factors (VEGFs). The VEGF family consists of six growth factors (VEGF-A, VEGF-B, VEGF-C, VEGF-D, VEGF-E, and placental growth factor) and three receptors (VEGFR1 or Flt-1, VEGFR2 or KDR/FLK-1, and VEGFR3 or Flt-4). Neuropilin 1 and 2 also may act as receptors for VEGF. VEGF is induced by hypoxia and by different growth factors and cytokines, including EGF, PDGF, TNF-α, TGFβ, and interleukin-1β. VEGF has various functions, including increasing vascular permeability, inducing endothelial cell proliferation and tube formation, and inducing endothelial cell synthesis of proteolytic enzymes such as uPA, PAI-1, urokinase plasminogen activator receptor, and MMP-1. Furthermore, VEGF may mediate blood flow by its effects on the vasodilator nitric oxide and act as an endothelial survival factor, thus protecting the integrity of the vasculature. The proliferation of new lymphatic vessels, lymphangiogenesis, is also thought to be controlled by the VEGF family. Signaling in lymphatic cells is thought to be modulated by VEGFR3. Experimental studies with VEGF-C and VEGF-D have shown that they can induce tumor lymphangiogenesis and direct metastasis via the lymphatic vessels and lymph nodes.

PDGFs A, B, C, and D also play important roles in angiogenesis. PDGFs are produced by tumor cells as well as supporting cells in the tumor microenvironment. PDGFs can enhance endothelial cell proliferation directly, and they can also upregulate VEGF expression in vascular smooth muscle cells, promoting endothelial cell survival via a paracrine effect. The angiopoietins, angiopoietin-1 and angiopoietin-2 (Ang-1 and Ang-2), are thought to regulate blood vessel maturation. Ang-1 and Ang-2 both bind to the angiopoietin-1 receptor (also known as tyrosine-protein kinase receptor TIE-2), but only the binding of Ang-1 activates signal transduction; thus Ang-2 is an Ang-1 antagonist. Ang-1, via the Tie-2 receptor, induces remodeling and stabilization of blood vessels. Therefore, the balance between these factors determines the angiogenetic capacity of a tumor.

Tumor angiogenesis is regulated by several factors in a coordinated fashion. In addition to upregulation of proangiogenic molecules, angiogenesis also can be encouraged by suppression of naturally occurring inhibitors. Such inhibitors of angiogenesis include thrombospondin 1 and angiostatin. Angiogenesis is a prerequisite not only for primary tumor growth but also for metastasis. Angiogenesis in the primary tumor, as determined by microvessel density, has been demonstrated to be an independent predictor of distant metastatic disease and survival in several cancers. Expression of angiogenic factors such as VEGFs has had prognostic value in many studies. These findings further emphasize the importance of angiogenesis in cancer biology.

**Metastasis**

Metastases arise from the spread of cancer cells from the primary site and the formation of new tumors in distant sites. The metastatic process consists of a series of steps that need to be completed successfully (Fig. 10-8). First, the primary cancer must develop access to the circulation through either the blood circulatory system or the lymphatic system. After the cancer cells are shed into the circulation, they must survive. Next, the circulating cells lodge in a new organ and extravasate into the new tissue. Next, the cells need to initiate growth in the new tissue and eventually establish vascularization to sustain the new tumor. Overall, metastasis is an inefficient process, although the initial steps of hematogenous metastasis (the arrest of tumor cells in the organ and extravasation) are believed to be performed efficiently. Only a small subset of cancer cells is then able to initiate micrometastases, and an even smaller portion goes on to grow into macrometastases.

Metastases can sometimes arise several years after the treatment of primary tumors. For example, although most breast cancer recurrences occur within the first 10 years after the initial treatment and recurrences are rare after 20 years, breast cancer recurrences have been reported decades after the original tumor. This phenomenon is referred to as dormancy, and it remains one of the biggest challenges in cancer biology. Persistence of solitary cancer cells in a secondary site such as the liver or bone marrow is one possible contributor to dormancy. Another explanation of dormancy is that cells remain viable in a quiescent state and then become reactivated by a physiologically perturbing event. Interestingly, primary tumor removal has been proposed to be a potentially perturbing factor. An alternate explanation is that cells establish preangiogenic metastases in which they continue to proliferate but that the proliferative rate is balanced by the apoptotic rate. Therefore, when these small metastases acquire the ability to become vascularized, substantial tumor growth can be achieved at the metastatic site, leading to clinical detection. More recently, it has been proposed that dormancy may be the result of the host losing immunologic control of subclinical metastatic foci of disease either through loss of immune cell populations with antigen-specific capabilities or via the mutation of tumor cells such that their immunogenicity is altered.

Several types of tumors metastasize in an organ-specific pattern. One explanation for this is mechanical and is based on
When different tumor types and their preferred metastasis sites were compared, 66% of organ-specific metastases were explained on the basis of blood flow alone. The other explanation for preferential metastasis is what is referred to as the “seed and soil” theory, the dependence of the seed (the cancer cell) on the soil (the secondary organ). According to this theory, once cells have reached a secondary organ, their growth efficiency in that organ is based on the compatibility of the cancer cell’s biology with its new microenvironment. For example, breast cancer cells may grow more efficiently in bone than in some other organs because of favorable molecular interactions that occur in the bone microenvironment. The ability of cancer cells to grow in a specific site likely depends on features inherent to the cancer cell, features inherent to the organ, and the interplay between the cancer cell and its microenvironment.

Many of the oncogenes discovered to date, such as HER2 and ras, are thought to potentiate not only malignant transformation but also one or more of the steps required in the metastatic process. Experimental models have suggested a role for several molecules, including RhoC, osteopontin and interleukin-11, and Twist, in tumor metastasis. Metastasis also may involve the loss of metastasis-suppressor genes. Laboratory work involving cancer cell lines that have been selected to have a higher metastatic potential have led to the realization that these more highly metastatic cells have a different gene expression profile than their less metastatic parental counterparts. This in turn has led to the currently held belief that the ability of a primary tumor to metastasize may be predictable by analysis of its gene expression profile. Indeed, several studies have focused on identifying a gene expression profile or a molecular signature that is associated with metastasis. It has been shown that such a gene expression profile can be used to predict the probability that the patient will remain free of distant metastasis. This suggests that the metastatic potential of a tumor is already predetermined by the genetic alterations that the cancer cells acquire early in tumorigenesis. Notably, this hypothesis differs from the multistep tumorigenesis theory in that the ability to metastasize is considered an inherent quality of the tumor from the beginning. It is assumed that metastasis develops not from a few rare cells in the primary tumor that acquire the ability to metastasize but that all cells in tumors with such molecular signatures develop the ability to metastasize. The reality probably lies in between since some early genetic changes detectable in the entire tumor can give tumors an advantage in the metastatic process, whereas additional genetic changes can give a clone of cells additional advantages, thus allowing them to succeed in metastasis.

**Epithelial-Mesenchymal Transition**

A regulatory program referred to as epithelial-mesenchymal transition (EMT) is a fundamental event in morphogenesis. During EMT, epithelial cells are converted to migratory and
invasive mesenchymal cells. EMT has also been implicated as the mechanism through which epithelial cells acquire the ability to migrate, invade, resist apoptosis, and metastasize in the setting of cancer. EMT is a developmental process, and a set of pleiotropically acting transcriptional factors, including Snail, Twist, Slug, and Zeb1/2 orchestrate EMT. Several of these transcription factors can directly repress E-cadherin gene expression reducing levels of this key suppressor of motility and invasiveness in cancer cells. This process also entails the induction of mesenchymal markers such as vimentin. It has been proposed that the process of invasion and metastases requires significant plasticity, suggesting that EMT is required for invasion, intravasation, and extravasation. Thus, suppression of EMT regulators (and consequently EMT reversion, or MET) can be important for metastatic outgrowth.

Cancer Stem Cells

Stem cells are cells that have the ability to perpetuate themselves through self-renewal and to generate mature cells of a particular tissue through differentiation. It was first documented for leukemia and multiple myeloma that only a small subset of cancer cells is capable of extensive proliferation. It has subsequently also been shown for many solid cancers that only a small proportion of cells is clonogenic in culture and in vivo. Similarly, in many solid tumor types only a small proportion of cells is clonogenic in culture and in vivo. If indeed tumor growth and metastasis are driven by a small population of cancer stem cells, this may alter our current approaches to cancer therapy. Currently available drugs can shrink metastatic tumors but often cannot eradicate them. The failure of these treatments usually is attributed to the acquisition of drug resistance by the cancer cells; however, the cancer stem cell hypothesis raises the possibility that existing therapies may simply fail to kill cancer stem cells effectively. Therapeutic approaches targeting stem cells specifically are under study.

Figure 10-9. Accumulation of somatic mutations acquired by the cancer cell. Mutations may be acquired while the cell lineage is phenotypically normal, reflecting intrinsic mutations acquired during normal cell division as well as the effects of exogenous mutagens. Other processes such as example DNA repair defects may contribute to the mutational burden. Passenger mutations do not have any effect on the cancer cell, but driver mutations cause clonal expansion. Relapse after chemotherapy can be associated with resistance mutations that may predate the initiation of treatment. (Reproduced with permission from Stratton MR, Campbell PJ, Futreal PA. The cancer genome, Nature. 2009 Apr 9;458(7239):719–724.)

CANCER ETIOLOGY

Cancer Genomics

One widely held opinion is that cancer is a genetic disease that arises from an accumulation of genomic alterations that leads to the selection of cells with increasingly aggressive behavior. These alterations may lead either to a gain of function by oncogenes or to a loss of function by tumor-suppressor genes. These acquired gene alterations present within the tumor are termed somatic mutations to distinguish them from germline mutations that are inherited from parents and transmitted to offspring. Somatic mutations in a cancer genome may consist of several classes of DNA sequence changes. These include substitutions of one base by another; insertions or deletions of small or large segments of DNA; rearrangements, in which the DNA sequence has been broken and then rejoined to another DNA segment; copy number losses that may result in complete absence of a DNA sequence; and copy number gains over and above the two copies present in the normal diploid genome.

Somatic mutations in a cancer cell genome have accumulated over the lifetime of the patient (Fig. 10-9). DNA in normal cells is continuously damaged by internal and external mutagens. Most of this damage is repaired; however, a small fraction may remain as fixed mutations. Mutation rates increase in the presence of substantial exogenous mutagenic exposures, such as tobacco carcinogens or various forms of radiation, including ultraviolet light. These exposures are associated with increased rates of lung and skin cancer, respectively, and somatic mutations within such cancers often exhibit the distinctive mutational signatures known to be associated with the mutagen. The rates of somatic mutations are also increased in several rare inherited diseases, such as Fanconi anemia, ataxia telangiectasia, and xeroderma pigmentosum, which are associated with increased risks of cancer. The rest of the somatic mutations in a cancer cell have been acquired after the cancer cell already shows phenotypic evidence of neoplastic change. Whether the somatic
mutation rate is always higher during this part of the lineage is controversial. This is clearly the case for some cancers. For instance, colorectal and endometrial cancers with defective DNA mismatch repair due to abnormalities in genes such as MLH1 and MSH2, exhibit increased rates of single nucleotide changes and small insertions/deletions at repetitive noncoding polynucleotide tracts known as microsatellites. It has been proposed that one early step in tumor progression is the development of a “mutator phenotype” that is the result of mutations in genes that normally function in the maintenance of genetic stability. This hypothesis was formulated in order to account for the disparity between the low frequency of spontaneous mutations in normal cells as compared to the large number of mutations seen in human tumors.

To date about 300 genes that have been reported to be mutated and causally implicated in cancer development. Ninety percent of cancer genes are mutated at the somatic or tumor level, 20% show germline mutations, and 10% show both. The most common class of genomic alterations among the known cancer genes is a chromosomal translocation that creates a chimeric gene. Many more cancer genes have been found in leukemias, lymphomas, and sarcomas than in other types of cancer; and these genes are usually altered by chromosomal translocation. The most common cancer genes are protein kinases. Several domains that are involved in DNA binding and transcriptional regulation are also common in proteins encoded by cancer genes. Somatic mutations in a cancer genome may be classified according to its consequences for cancer development. “Driver” mutations confer a growth advantage to the cells carrying them and have been positively selected during the evolution of the cancer. The remainder of mutations are “bystanders” or “passengers” that do not confer growth advantage. It is likely that most somatic mutations are passenger mutations. Each tumor may have dozens to hundreds of genomic alterations, making it critical to determine which alterations are indeed drivers, and potentially better therapeutic targets.

There have been many recent advancements in large-scale databases and tools to catalogue and interpret genomic variants in cancer patient populations. Currently, the NCI Genomic Data Commons provides a unified data repository, The Cancer Genome Atlas (TCGA), the NCI Center for Cancer Genomics (CCG), and the childhood cancer initiative entitled Therapeutically Applicable Research to Generate Effective Treatments (TARGET), as well as a suite of tools for users to interact with the GDC data and provide their own data. Other cancer genome repositories include the Catalogue of Somatic Mutations in Cancer (COSMIC) and the International Cancer Genome Consortium (ICGC). The Precision Medicine Initiative launched in 2016 that includes the All of Us Research Program, which will collect genetic data, biologic samples, and other clinical information from at least 1 million volunteer participants. To facilitate the clinical and biologic interpretation of genomic variants in cancer genomes, several open-access tools have been developed and expanded, including MuSiC, MutSigCV, and OncodriveFM. Other curated database resources used to annotate clinical phenotypes to variants observed in cancer genomes include ClinVAR, Clinical Interpretation of Variants in Cancer (CiVic), and the Precision Medicine Knowledgebase (PMKB). These resources and tools are being utilized to conduct pan-cancer analyses to characterize genomic variation and other molecular aberrations observed across tumors to define cancer drivers, clinically actionable targets, and prognostic and predictive signatures. This information is being integrated into clinical practice in many tumor types, such as lung cancer, where molecular drivers are being taken into consideration when selecting systemic therapies (Fig. 10-10). TCGA data was recently leveraged in a study to identify TRK fusions in tumors from six different cancer types, which led to the development of novel TRK inhibitor therapies.

**Tumor Heterogeneity and Molecular Evolution**

There is increasing recognition that tumors are heterogeneous; this represents an important challenge to utilizing genomic alterations to personalize cancer therapy (Fig. 10-11). First,
there may be significant heterogeneity between cancer patients, such that patients with tumors that seem similar histologically, may differ in genomic alterations and in malignant potential.46-48 Second, during cancer progression, subclones frequently arise, resulting in differences in the proportion and pattern of genomic alterations between the primary tumor and the metastases or local-regional recurrences.35 Third, there may also be significant heterogeneity within any one tumor deposit, with spatially separated heterogeneous somatic mutations and chromosomal imbalances.49 Such spatial heterogeneity of subclones within the primary tumor or metastases provides an additional challenge, as it has been proposed that sequencing of a biopsy specimen or only a portion of the tumor could miss therapeutically relevant genomic alterations. The genomic alterations found in a tumor can also change under the selective pressure of a targeted therapy, adding to the challenge of implementing genomically informed personalized therapy.

**Genes Associated With Hereditary Cancer Risk**

Most of our information on human cancer genes has been gained from hereditary cancers. In the case of hereditary cancers, the individual carries a particular germline mutation in every cell. To date, over 70 genes have been associated with hereditary cancers (Table 10-3).43 A few of these hereditary cancer genes are oncogenes, but most are tumor-suppressor genes. Although hereditary cancer syndromes are rare, somatic mutations that occur in sporadic cancer have been found to disrupt the cellular pathways altered in hereditary cancer syndromes, which suggests that these pathways are critical to normal cell growth, cell cycle, and proliferation. Recently, the results of a genome-wide association study of breast cancer in over 120,000 cases and 100,000 controls identified 65 new loci that are associated with overall breast cancer risk.50

The following factors may suggest the presence of a hereditary cancer51:

1. Tumor development at a much younger age than usual
2. Presence of bilateral disease
3. Presence of multiple primary malignancies
4. Presentation of a cancer in the less affected sex (e.g., male breast cancer)
5. Clustering of the same cancer type in relatives
6. Occurrence of cancer in association with other conditions such as mental retardation or pathognomonic skin lesions

It is crucial that all surgeons caring for cancer patients be aware of hereditary cancer syndromes, because a patient’s genetic background has significant implications for patient and family counseling, planning of surgical therapy, and cancer screening and prevention. Some of the more commonly encountered hereditary cancer syndromes are discussed here.

**rb1Gene.** The retinoblastoma gene rb1 was the first tumor suppressor to be cloned. The rb1 gene product, the Rb protein, is a regulator of transcription that controls the cell cycle, differentiation, and apoptosis in normal development.52 Retinoblastoma has long been known to occur in hereditary and nonhereditary forms. Interestingly, although most children with an affected parent develop bilateral retinoblastoma, some develop unilateral retinoblastoma. Furthermore, some children with an affected parent are not affected themselves but then have an affected child, which indicates that they are rb1 mutation carriers. These findings led to the theory that a single mutation is not sufficient for tumorigenesis. Alfred Knudson hypothesized that hereditary retinoblastoma involves two mutations, of which one is germ-line and one somatic, whereas nonhereditary retinoblastoma is due to two somatic mutations (Fig. 10-12).53 Thus, both hereditary and nonhereditary forms of retinoblastoma involve the same number of mutations, a hypothesis known as Knudson’s “two-hit” hypothesis. A “hit” may be a point mutation, a chromosomal deletion referred to as allelic loss, or a loss of heterozygosity, or silencing of an existing gene. Approximately 40% of retinoblastomas are hereditary and due to germline mutations in the RB1 gene. Children with hereditary RB are also at risk for developing a midline intracranial tumor, most commonly pineoblastoma.

**p53 and Li-Fraumeni Syndrome.** Li-Fraumeni syndrome (LFS) was first defined on the basis of observed clustering of malignancies, including early-onset breast cancer, soft tissue sarcomas, brain tumors, adrenocortical tumors, and leukemia.54 Criteria for classic LFS in an individual (the proband) include: (a) a bone or soft tissue sarcoma when younger than 45 years, (b) a first-degree relative with cancer before age 45 years, and (c) another first- or second-degree relative with either a sarcoma diagnosed at any age or any cancer diagnosed before age 45 years.55 Approximately 70% of LFS families have been shown to have germline mutations in the tumor-suppressor gene p53.56 Breast carcinoma, soft tissue sarcoma, osteosarcoma, brain tumors, adrenocortical carcinoma, Wilms’ tumor, and phyllodes tumor of the breast are strongly associated; pancreatic cancer is moderately associated; and leukemia and neuroblastoma are weakly associated with germline p53 mutations.57 Mutations of p53 have not been detected in approximately 30% of LFS families, and it is hypothesized that genetic alterations in other proteins interacting with p53 function may play a role in these families.

Of the known genes in human cancer, p53 is the most commonly mutated within cancer cells. The p53 protein regulates cell-cycle progression as well as apoptotic cell death as part of stress response pathways after exposure to ionizing or ultraviolet (UV) irradiation, chemotherapy, acidosis, growth factor deprivation, or hypoxia. When cells are exposed to stressors, p53 acts as a transcription factor for genes that induce cell-cycle arrest or apoptosis. A majority of p53 mutations are found within a central DNA recognition motif and disrupt DNA binding by p53. Families with germline missense mutations in the DNA-binding domain show a more highly penetrant phenotype than families with other p53 mutations.58 Furthermore, proband cancers are linked with significantly younger age at diagnosis in patients with missense mutations in the DNA-binding domain.59 It has become apparent that children and adults with LFS will benefit from intensive surveillance aimed at early detection of cancers and a modified version of the “Toronto protocol” that includes a combination of physical exams, blood tests, and imaging is recommended.

**BRCA1, BRCA2, and Hereditary Breast-Ovarian Cancer Syndrome.** It is estimated that 5% to 10% of breast cancers are hereditary. Of women with early-onset breast cancer (age 40 years or younger), nearly 10% have a germline mutation in one of the breast cancer genes BRCA1 or BRCA2.59 Mutation carriers are more prevalent among women who have a first- or second-degree relative with premenopausal breast cancer or ovarian cancer at any age. The likelihood of a BRCA mutation is higher in patients who belong to a population in which founder

mutations may be prevalent, such as in the Ashkenazi Jewish population. For a female BRCA1 mutation carrier, the cumulative risks of developing breast cancer and ovarian cancer by age 70 have been estimated to be 87% and 44%, respectively.60 The cumulative risks of breast cancer and ovarian cancer by age 70 in families with BRCA2 mutation have been estimated to be 84% and 27%, respectively.61 Although male breast cancer can occur with either BRCA1 or BRCA2 mutation, the majority of families (76%) with both male and female breast cancer have mutations in BRCA2.64 Besides breast and ovarian cancer, BRCA1 and BRCA2 mutations may be associated with increased risks for several other cancers. BRCA1 mutations confer a fourfold increased risk for colon cancer and threefold increased risk for prostate cancer.65 BRCA2 mutations confer a fivefold increased risk for prostate cancer, sevenfold in men younger than 65 years.62 Furthermore, BRCA2 mutations confer

BASIC CONSIDERATIONS

PART I

demonstrated that they have distinct functions.64,65 In fact, breast cancers arising from \( BRCA1 \) or \( BRCA2 \) mutations are different at the molecular level and have been found to have distinct gene expression profiles.66 \( BRCA1 \)-associated tumors are more likely to be estrogen receptor negative, whereas \( BRCA2 \)-associated tumors are more likely to be estrogen receptor positive. Currently, studies are ongoing to determine whether \( BRCA1 \) and \( BRCA2 \) status can be used to guide systemic therapy choices for breast cancer. Some targeted therapies are showing activity in \( BRCA \) mutation carriers with breast cancer such as PARP - poly(ADP-ribose) polymerase-inhibitors.

**APC Gene and Familial Adenomatous Polyposis**

Patients affected with familial adenomatous polyposis (FAP) characteristically develop hundreds to thousands of polyps in the colon and rectum. The polyps usually appear in adolescence and, if left untreated, progress to colorectal cancer. FAP is associated with benign extracolonic manifestations that may be useful in identifying new cases, including congenital hypertrophy of the retinal pigment epithelium, epidermoid cysts, and osteomas. In addition to colorectal cancer, patients with FAP are at risk for upper intestinal neoplasms (gastric and duodenal polyps, duodenal and periampullary cancer), hepatobiliary tumors (hepatoblastoma, pancreatic cancer, and cholangiocarcinoma), thyroid carcinomas, desmoid tumors, and medulloblastomas.

The product of the adenomatous polyposis coli tumor-suppressor gene (\( APC \)) plays an important role in cell-cell interactions, cell adhesion, regulation of \( \beta \)-catenin, and maintenance of cytoskeletal microtubules. Alterations in \( APC \) lead to dysregulation of several physiologic processes that govern colonic epithelial cell homeostasis, including cell-cycle progression, migration, differentiation, and apoptosis. Mutations in the \( APC \) have been identified in FAP and in 80% of sporadic colorectal cancers.67 Furthermore, \( APC \) mutations are the earliest known genetic alterations in colorectal cancer progression, which emphasizes its importance in cancer initiation. The germline mutations in \( APC \) may arise from point mutations, insertions, or deletions that lead to a premature stop codon and a truncated, functionally inactive protein. The risk of developing specific manifestations of FAP is correlated with the position of the \( APC \) mutations, a phenomenon referred to as genotype-phenotype correlation. For example, desmoids usually are associated with mutations between codons 1403 and 1578.68,69 Mutations in the extreme 5’ or 3’ ends of \( APC \), or in the alternatively spliced region of exon 9, are associated with an attenuated version of FAP. Better understanding of the genotype-phenotype correlations may assist in patient counseling and therapeutic planning.

**Mismatch Repair Genes and Hereditary Nonpolyposis Colorectal Cancer.** Hereditary nonpolyposis colorectal cancer (HNPCC), also referred to as Lynch syndrome, is an autosomal dominant hereditary cancer syndrome that predisposes to a wide spectrum of cancers, including colorectal cancer without polyposis. Some have proposed that HNPCC consists of at least two syndromes: Lynch syndrome 1, which entails hereditary nonpolyposis colorectal cancer, and Lynch syndrome 2, featuring a similar colonic phenotype accompanied by a high risk for carcinoma of the endometrium, transitional cell carcinoma of the ureter and renal pelvis, and carcinomas of the stomach, small bowel, ovary, and pancreas.70 The diagnostic criteria for HNPCC are referred to as the Amsterdam criteria, or the 3-2-1-0 rule. The classic Amsterdam criteria were revised to include other HNPCC-related cancers (Table 10-4).71 These criteria are met when three or more family members have histologically verified, HNPCC-associated cancers (one of whom is a first-degree relative of the other two), two or more generations are involved, at least one individual was diagnosed before age 50 years, and no individuals have FAP.71

During DNA replication, DNA polymerases may introduce single nucleotide mismatches or small insertion or deletion loops. These errors are corrected through a process referred to as mismatch repair. When mismatch repair genes are inactivated, DNA mutations in other genes that are critical to cell growth and proliferation accumulate rapidly. In HNPCC, germline mutations have been identified in several genes that play a key role in DNA nucleotide mismatch repair: \( hMLH1 \) (human mutL homologue 1), \( hMSH2 \) (human mutS homologue 2), \( hMSH6 \), \( hMSH4 \), and \( hMSH5 \).
and hPMS1 and hPMS2 (human postmeiotic segregation 1 and 2), of which hMLH1 and hMSH2 are the most common. The hallmark of HNPCC is microsatellite instability, which occurs on the basis of unpaired mismatches and small insertion or deletion loops. Microsatellite instability can be tested by comparing the DNA of a patient’s tumor with DNA from adjacent normal epithelium, amplifying the DNA with polymerase chain reaction (PCR) using a standard set of markers, comparing the amplified genomic DNA sequences, and classifying the degree of microsatellite instability as high, low, or stable. Such microsatellite instability testing may help select patients who are more likely to have germline mutations. An analysis of patients with early-onset colorectal cancer (age less than 50) showed that 8% had an unsuspected germline mutation in a mismatch repair gene and could be considered as having Lynch syndrome. Thus, genetic counseling and testing with a multigene panel should be considered for such patients.78

PTEN and Cowden Disease

Somatic deletions or mutations in the tumor-suppressor gene PTEN (phosphatase and tensin homologue deleted on chromosome 10) have been observed in a number of glioma breast, prostate, and renal carcinoma cell lines and several primary tumor specimens. PTEN encodes a 403-amino-acid protein, tyrosine phosphatase. PTEN negatively controls the PI3K signaling pathway for the regulation of cell growth and survival by dephosphorylating phosphoinositol 3,4,5-triphosphate; thus, mutation of PTEN leads to constitutive activation of the PI3K/Akt signaling pathway. The “hot spot” for PTEN mutations has been identified in exon 5. Forty-three percent of CD mutations have been identified in this exon, which contains the tyrosine phosphatase core domain. This suggests that the PTEN catalytic activity is vital for its biologic function. PTEN was identified as the susceptibility gene for the autosomal dominant syndrome Cowden disease (CD) or multiple hamartoma syndrome.80 Trichilemmomas, benign tumors of the hair follicle infundibulum, and mucocutaneous papillomatosis are pathognomonic of CD. Other common features include thyroid adenomas and multinodular goiters, breast fibroadenomas, and hamartomatous GI polyps. The diagnosis of CD is made when an individual or family has a combination of pathognomonic major and/or minor criteria proposed by the International Cowden Consortium.81 CD is associated with an increased risk of breast and thyroid cancers. Breast cancer develops in 25% to 50% of affected women.81

p16 and Hereditary Malignant Melanoma. The gene p16, also known as INK4A, CDKN1, CDKN2A, and MTS1, is a tumor suppressor that acts by binding CDK4 and CDK6 and inhibiting the catalytic activity of the CDK4-CDK6/cyclin D complex that is required for phosphorylation of Rb and subsequent cell-cycle progression. Studies suggest that germline mutations in p16 can be found in 20% of melanoma-prone families.82 Mutations in p16 that alter its ability to inhibit the catalytic activity of the CDK4-CDK6/cyclin D complex not only increase the risk of melanoma by 75-fold but also increase the risk of pancreatic cancer by 22-fold.83 Interestingly, p16 mutations that do not appear to alter its function increase the risk of melanoma by 38-fold and do not increase the risk of pancreatic cancer.83 Genomic characterization of primary tumors has revealed that p16 is inactivated through point mutation, promoter methylation, or deletion in a significant portion of sporadic tumors, including cancers of the pancreas, esophagus, head and neck, stomach, breast, and colon, as well as melanomas.

E-cadherin and Hereditary Diffuse Gastric Cancer. E-cadherin is a cell adhesion molecule that plays an important role in normal architecture and function of epithelial cells. The adhesive function of E-cadherin is dependent on interaction of its cytoplasmic domain with β- and γ-catenins and may be regulated by phosphorylation of β-catenin.

Hereditary diffuse gastric carcinoma is an autosomal dominant cancer syndrome that results from germline mutations in the E-cadherin gene, CDH1. Carriers of CDH1 mutations have a 70% to 80% chance of developing gastric cancer.84 Furthermore, mutations of CDH1 have been described in sporadic cancers of the ovary, endometrium, breast, and thyroid. However, frequent mutations have been identified in only two particular tumors: diffuse gastric carcinomas and lobular breast carcinomas. Invasive lobular breast carcinomas often show inactivating mutations in combination with a loss of heterozygosity of the wild-type CDH1 allele.85 Interestingly, in gastric carcinomas the predominant mutations are exon skipping causing in-frame deletions, whereas most mutations identified in lobular breast cancers are premature stop codons; this suggests a genotype-phenotype correlation.

RET Proto-Oncogene and Multiple Endocrine Neoplasia Type 2

The RET (rearranged during transfection) gene encodes for a transmembrane receptor tyrosine kinase that plays a role in proliferation, migration, and differentiation of cells derived from the neural crest. Gain-of-function mutations in the RET gene are associated with medullary thyroid carcinoma in isolation or multiple endocrine neoplasia type 2 (MEN2) syndromes. MEN2A is associated with medullary thyroid carcinoma in isolation or multiple endocrine neoplasia type 2 (MEN2) syndromes. MEN2A is associated with medullary thyroid carcinoma and pheochromocytoma (in 50%) or parathyroid adenoma (in 20%), whereas MEN2B is associated with medullary thyroid carcinoma, marfanoid habitus, mucosal neuromas, and ganglioneuromatosis of the gastrointestinal tract.86 RET mutations lead to uncontrolled growth of the thyroid C cells, and in familial medullary cancer, C-cell hyperplasia progresses to bilateral, multicentric medullary thyroid cancer. Mutations in the RET gene have also been identified in half of sporadic medullary thyroid cancers.

Genetic Modifiers of Risk. Individuals carrying identical germline mutations vary in regard to cancer penetrance (whether cancer will develop or not) and cancer phenotype (the tissues involved). It is thought that this variability may be due to environmental influences or, if genetic, to genetic modifiers...
of risk. Similarly, genetic modifiers of risk also can play a role in determining whether an individual will develop cancer after exposure to carcinogens.

**Chemical Carcinogens**

The first report indicating that cancer could be caused by environmental factors was by John Hill, who in 1761 noted the association between nasal cancer and excessive use of tobacco snuff. Currently, approximately 60% to 90% of cancers are thought to be due to environmental factors. Any agent that can contribute to tumor formation is referred to as a carcinogen and can be a chemical, physical, or viral agent. Chemicals are classified into three groups based on how they contribute to tumor formation. The first group of chemical agents, the genotoxins, can initiate carcinogenesis by causing a mutation. The second group, the cocarcinogens, by themselves cannot cause cancer but potentiate carcinogenesis by enhancing the potency of genotoxins. The third group, tumor promoters, enhances tumor formation when given after exposure to genotoxins.

The International Agency for Research on Cancer (IARC) maintains a registry of human carcinogens that is available through the World Wide Web (http://www.iarc.fr). The compounds are categorized into five groups based on an analysis of epidemiologic studies, animal models, and short-term mutagenesis tests. Group 1 contains what are considered to be proven human carcinogens, based on formal epidemiologic studies among workers who were exposed for long periods (several years) to the chemicals. Group 2A contains what are considered to be probable human carcinogens. Suggestive epidemiologic evidence exists for compounds in this group, but the data are insufficient to establish causality. There is evidence of carcinogenicity, however, from animal studies carried out under conditions relevant to human exposure. Group 2B contains what are considered to be possible carcinogens because these substances are associated with a clear statistically and biologically significant increase in the incidence of malignant tumors in more than one animal species or strain. Group 3 agents are not classifiable, and Group 4 agents are probably not carcinogenic to humans. Selected substances that have been classified as proven carcinogens (group 1) by the IARC in an expert panel review are listed in Table 10-5.

**Physical Carcinogens**

Physical carcinogenesis can occur through induction of inflammation and cell proliferation over a period of time or through exposure to physical agents that induce DNA damage. Foreign bodies can cause chronic irritation that can expose cells to carcinogenesis due to other environmental agents. In animal models, for example, subcutaneous implantation of a foreign body can lead to the development of tumors that have been attributed to chronic irritation from the foreign objects. In humans, clinical scenarios associated with chronic irritation and inflammation such as chronic nonhealing wounds, burns, and inflammatory bowel syndrome have all been associated with an increased risk of cancer. *H. pylori* infection is associated with gastritis and gastric cancer, and thus, its carcinogenicity may be considered physical carcinogenesis. Infection with the liver fluke *Opisthorchis viverrini* similarly leads to local inflammation and cholangiocarcinoma.

The induction of lung and mesothelial cancers by asbestos fibers and nonfibrous particles such as silica are other examples of foreign body-induced physical carcinogenesis. Animal experiments have demonstrated that the dimensions and durability of the asbestos and other fibrous minerals are the key determinants of their carcinogenicity. Short fibers can be inactivated by phagocytosis, whereas long fibers (>10 μm) are cleared less effectively and are encompassed by proliferating epithelial cells. The long fibers support cell proliferation and have been shown to preferentially induce tumors. Asbestos-associated biologic effects also may be mediated through reactive oxygen and nitrogen species. Furthermore, an interaction occurs between asbestos and silica and components of cigarette smoke. Polycyclic aromatic hydrocarbons (PAHs) in cigarette smoke are metabolized by epithelial cells and form DNA adducts. If PAH is coated on asbestos, PAH uptake is increased. Both PAH and asbestos impair lung clearance, potentially increasing uptake further. Therefore, physical carcinogens may be synergistic with chemical carcinogens.

Radiation is the best-known agent of physical carcinogenesis and is classified as ionizing radiation (X-rays, gamma rays, and alpha and beta particles) or nonionizing radiation (UV). The carcinogenic potential of ionizing radiation was recognized soon after Wilhelm Conrad Roentgen’s discovery of X-rays in 1895. Within the next 20 years, a large number of radiation-related skin cancers were reported. Long-term follow-up of survivors of the atomic bombing of Hiroshima and Nagasaki revealed that virtually all tissues exposed to radiation are at risk for cancer. Radiation can induce a spectrum of DNA lesions that includes damage to the nucleotide bases and cross-linking, and DNA single- and double-strand breaks (DSBs). Misrepaired DSBs are the principal lesions of importance in the induction of chromosomal abnormalities and gene mutations. DSBs in irradiated cells are repaired primarily by a nonhomologous end-joining process, which is error prone; thus, DSBs facilitate the production of chromosomal rearrangements and other large-scale changes such as chromosomal deletions. It is thought that radiation may initiate cancer by inactivating tumor-suppressor genes. Activation of oncogenes appears to play a lesser role in radiation carcinogenesis.

Although it has been assumed that the initial genetic events induced by radiation constitute direct mutagenesis from radiation, other indirect effects may contribute to carcinogenesis. For example, radiation induces genomic instability in cells that persists for at least 30 generations after irradiation. Therefore, even if cells do not acquire mutations at initial irradiation, they remain at risk for developing new mutations for several generations. Moreover, even cells that have not been directly irradiated appear to be at risk, a phenomenon referred to as the bystander effect.

Nonionizing UV radiation is a potent DNA-damaging agent and is known to induce skin cancer in experimental animals. Most nonmelanoma human skin cancers are thought to be induced by repeated exposure to sunlight, which leads to a series of mutations that allow the cells to escape normal growth control. Patients with inherited xeroderma pigmentosum lack one or more DNA repair pathways, which confers susceptibility to UV-induced cancers, especially on sun-exposed body parts. Patients with ataxia telangiectasia mutated syndrome also have a radiation-sensitive phenotype.

**Viral Carcinogens**

One of the first observations that cancer may be caused by transmissible agents was by Peyton Rous in 1910 when he demonstrated that cell-free extracts from sarcomas in chickens could transmit sarcomas to other animals injected with these extracts. This was subsequently discovered to represent viral transmission of cancer by the Rous sarcoma virus. At present, several human viruses are known to have oncogenic properties, and several

*Data based on information in the International Agency for Research on Cancer monographs.

*Only tumor types for which causal relationships are established are listed. Other cancer types may be linked to the agents with a lower frequency or with insufficient data to prove causality.*

have been causally linked to human cancers (Table 10-6). It is estimated that 15% of all human tumors worldwide are caused by viruses.

Viruses may cause or increase the risk of malignancy through several mechanisms, including direct transformation, expression of oncogenes that interfere with cell-cycle checkpoints or DNA repair, expression of cytokines or other growth factors, and alteration of the immune system. Oncogenic viruses may be RNA or DNA viruses. Oncogenic RNA viruses are retroviruses and contain a reverse transcriptase. After the viral infection, the single-stranded RNA viral genome is transcribed into a double-stranded DNA copy, which is then integrated into the chromosomal DNA of the cell. Retroviral infection of the cell is permanent; thus, integrated DNA sequences remain in the host chromosome. Oncogenic transforming retroviruses carry oncogenes derived from cellular genes. These cellular genes, referred to as *proto-oncogenes*, usually are involved in mitogenic signaling and growth control, and include protein kinases, G proteins, growth factors, and transcription factors (Table 10-7).

Integration of the provirus upstream of a proto-oncogene may produce chimeric virus-cell transcripts and recombination during the next round of replication that could lead to incorporation of the cellular gene into the viral genome. Then again, many retroviruses do not possess oncogenes but can cause tumors in animals regardless. This occurs by integration of the provirus near a normal cellular proto-oncogene and activation of the expression of these genes by the strong promoter and enhancer sequences in the integrated viral sequence.

Unlike the oncogenes of the RNA viruses, those of the DNA tumor viruses are viral, not cellular, in origin. These genes are required for viral replication using the host cell machinery. In permissive hosts, infection with an oncogenic DNA virus may result in a productive lytic infection, which leads to cell death and the release of newly formed viruses. In nonpermissive cells, the viral DNA can be integrated into the cellular chromosomal DNA, and some of the early viral genes can be synthesized persistently, which leads to transformation of cells to a neoplastic state. The binding of viral oncoproteins to cellular tumor-suppressor proteins p53 and Rb is fundamental to the carcinogenesis induced by most DNA viruses, although some target different cellular proteins.

Like other types of carcinogenesis, viral carcinogenesis is a multistep process. Some retroviruses contain two cellular oncogenes, rather than one, in their genome and are more rapidly tumorigenic than single-gene transforming retroviruses, which emphasizes the cooperation between transforming genes. Furthermore, some viruses encode genes that suppress or delay apoptosis.

Although immunocompromised individuals are at elevated risk, most patients infected with oncogenic viruses do not develop cancer. When cancer does develop, it usually occurs several years after the viral infection. It is estimated, for example, that the risk of hepatocellular carcinoma (HCC) among individuals infected with hepatitis C virus is 1% to 3% after 30 years. There may be synergy between various environmental factors and viruses in carcinogenesis.

Recognition of a viral origin for some tumors has led to the pursuit of vaccination as a preventive strategy. The use of childhood hepatitis B vaccination has already translated into a decrease in liver cancer incidence in the East Asia. Similarly, it is recognized that cervical cancer and its obligate precursors, cervical intraepithelial neoplasia grades 2 and 3, and adenocarcinoma in situ, are caused by oncogenic human papillomavirus (HPV); administration of HPV vaccine to HPV-naive women, substantially reduces the incidence of HPV16/18-related cervical precancers and cervical cancer. Studies suggest that HPV vaccination may also reduce oral HPV infections that are a risk factor for the development of oropharyngeal cancer. The American Cancer Society recommends routine HPV vaccination for girls and boys starting at age 11 or 12. The vaccination series can be started as early as age 9. HPV vaccination is also recommended for females 13 to 26 years old and for males 13 to 21 years old who have not started the vaccines, or who have started but have not completed the series. Males 22 to 26 years old may also be vaccinated. HPV vaccination is also recommended up until age 26 for men who have sex with men and for people with weakened immune systems (including people with HIV infection), if they have not previously been vaccinated. It is important for patients to know that vaccination at older ages is less effective in lowering cancer risk.

**CANCER RISK ASSESSMENT**

Cancer risk assessment is an important part of the initial evaluation of any patient. A patient’s cancer risk not only is an important determinant of cancer screening recommendations but also

may alter how aggressively an indeterminant finding will be pursued for diagnosis. A “probably benign” mammographic lesion, for example, defined as one with <2% probability of malignancy (American College of Radiology category III) is usually managed with a 6-month follow-up mammogram in a patient at baseline cancer risk, but obtaining a tissue diagnosis may be preferable in a patient at high risk for breast cancer.98

Cancer risk assessment starts with taking a complete history that includes history of environmental exposures to potential carcinogens and a detailed family history. Risk assessment for breast cancer, for example, includes obtaining a family history to determine whether another member of the family is known to carry a breast cancer susceptibility gene; whether there is familial clustering of breast cancer, ovarian cancer, thyroid cancer, sarcoma, adenocortical carcinoma, endometrial cancer, brain tumors, dermatologic manifestations, leukemia, or lymphoma; and whether the patient is from a population at increased risk, such as individuals of Ashkenazi Jewish descent. Patients who have a family history suggestive of a cancer susceptibility syndrome such as hereditary breast-ovarian syndrome, Li-Fraumeni Syndrome, or Cowden’s Disease would benefit from genetic counseling and possibly genetic testing.

There are several models that can estimate risk based on complex family histories and assist clinicians in estimating breast cancer risk or the likelihood that a BRCA mutation is present, including the Claus model, Tyrer-Cuzick model, BRCAPRO model, and the Breast and Ovarian Analysis of Disease Incidence and Carrier Estimation Algorithm (BOADICEA) model.99-102 Patients who do have a strong hereditary component of risk can be evaluated on the basis of their age, race, personal history, and exposures. One of the most commonly used models for risk assessment in breast cancer is the Gail model.103 Gail and colleagues analyzed the data from 2852 breast cancer cases and 3146 controls from the Breast Cancer Detection and Demonstration Project, a mammography screening project conducted in the 1970s, and developed a model for projecting breast cancer incidence. The model uses risk factors such as an individual’s age, age at menarche, age at first live birth, number of first-degree relatives with breast cancer, number of previous breast biopsy specimens, and whether the biopsy specimen results revealed atypical ductal hyperplasia (Table 10-8).103 This model has led to the development of a breast cancer risk assessment tool, which is available on the World Wide Web.104 This tool incorporates the risk factors used in the Gail model, as well as race and ethnicity, and allows a health professional to project a woman’s individualized estimated risk for invasive breast cancer over a 5-year period and over her lifetime (to age 90 years). Notably, these risk projections assume that the woman is undergoing regular clinical breast examinations and screening mammograms. Also of note is that this program underestimates the risk for women who have already had a diagnosis of invasive or noninvasive breast cancer and does not take into account specific genetic predispositions such as mutations in BRCA1 or BRCA2. However, risk assessment tools such as this have been validated and are now in widespread clinical use. Similar models are in development or are being validated for...

Early detection is the key to success in cancer therapy. Screening for common cancers using relatively noninvasive tests is expected to lead to early diagnosis, allow more conservative surgical therapies with decreased morbidity, and potentially improve surgical cure rates and overall survival rates. Key factors that influence screening guidelines are how prevalent the cancer is in the population, what risk is associated with the screening measure, and whether early diagnosis actually affects outcome. The value of a widespread screening measure is likely to go up with the prevalence of the cancer in a population, which often determines the age cutoffs for screening and explains why screening is done only for common cancers. The risks associated with the screening measure are a significant consideration, especially with more invasive screening measures such as colonoscopy. The consequences of a false-positive screening test result also need to be considered. For example, when 1000 screening mammograms are taken, only 2 to 4 new cases of cancer will be identified; this number is slightly higher (6 to 10 prevalent cancers per 1000 mammograms) for initial screening mammograms. However, as many as 10% of screening mammograms may be potentially suggestive of an abnormality, which requires further imaging (i.e., a 10% recall rate). Of those women with abnormal mammogram findings, only 5% to 10% will be determined to have a breast cancer. Among women for whom biopsy specimen is recommended, 25% to 40% will have a breast cancer. A false-positive screening result is likely to induce significant emotional distress in patients, leads to unnecessary biopsy specimens, and has cost implications for the health care system.

American Cancer Society guidelines for the early detection of cancer are listed in Table 10-9. These guidelines are updated periodically to incorporate emerging technologies and new data on the efficacy of screening measures. Besides the American Cancer Society, several other professional bodies make recommendations for screening. Although the screening guidelines differ somewhat, most organizations do not emphasize one screening strategy as superior to another, but all emphasize the importance of age-appropriate screening.

Screening guidelines are developed for the general baseline-risk population. These guidelines need to be modified for patients who are at high risk. For example, more intensive colorectal cancer screening is recommended for individuals at increased risk because of a history of adenomatous polyps, a personal history of colorectal cancer, a family history of either colorectal cancer or colorectal adenomas diagnosed in a first-degree relative before age 60 years, a personal history of inflammatory bowel disease of significant duration, or a family history or genetic test result indicating FAP or HNPCC. For some diseases, in higher risk populations, both the screening modality and the screening intensity may be altered. For example, breast magnetic resonance imaging is recommended as an adjunct to

other cancers. For example, a lung cancer risk prediction model, which includes age, sex, asbestos exposure history, and smoking history, has been found to predict risk of lung cancer. There is now growing interest in using each individuals genotype, such as presence or absence of single nucleotide polymorphisms which each may confer low or intermediate cancer risk. Risk models that include biologic as well as environmental factors may accurately predict cancer risk, providing better guidance as to which patients should undergo more intensive screening (e.g., screening with magnetic resonance imaging of the breast, computerized tomography screening of the lung), and should be considered for preventive strategies.

CANCER SCREENING

Early detection is the key to success in cancer therapy. Screening for common cancers using relatively noninvasive tests is expected to lead to early diagnosis, allow more conservative surgical therapies with decreased morbidity, and potentially improve surgical cure rates and overall survival rates. Key factors that influence screening guidelines are how prevalent the cancer is in the population, what risk is associated with the screening measure, and whether early diagnosis actually affects outcome. The value of a widespread screening measure is likely to go up with the prevalence of the cancer in a population, which often determines the age cutoffs for screening and explains why screening is done only for common cancers. The risks associated with the screening measure are a significant consideration, especially with more invasive screening measures such as colonoscopy. The consequences of a false-positive screening test result also need to be considered. For example, when 1000 screening mammograms are taken, only 2 to 4 new cases of cancer will be identified; this number is slightly higher (6 to 10 prevalent cancers per 1000 mammograms) for initial screening mammograms. However, as many as 10% of screening mammograms may be potentially suggestive of an abnormality, which requires further imaging (i.e., a 10% recall rate). Of those women with abnormal mammogram findings, only 5% to 10% will be determined to have a breast cancer. Among women for whom biopsy specimen is recommended, 25% to 40% will have a breast cancer. A false-positive screening result is likely to induce significant emotional distress in patients, leads to unnecessary biopsy specimens, and has cost implications for the health care system.

American Cancer Society guidelines for the early detection of cancer are listed in Table 10-9. These guidelines are updated periodically to incorporate emerging technologies and new data on the efficacy of screening measures. Besides the American Cancer Society, several other professional bodies make recommendations for screening. Although the screening guidelines differ somewhat, most organizations do not emphasize one screening strategy as superior to another, but all emphasize the importance of age-appropriate screening.

Screening guidelines are developed for the general baseline-risk population. These guidelines need to be modified for patients who are at high risk. For example, more intensive colorectal cancer screening is recommended for individuals at increased risk because of a history of adenomatous polyps, a personal history of colorectal cancer, a family history of either colorectal cancer or colorectal adenomas diagnosed in a first-degree relative before age 60 years, a personal history of inflammatory bowel disease of significant duration, or a family history or genetic test result indicating FAP or HNPCC. For some diseases, in higher risk populations, both the screening modality and the screening intensity may be altered. For example, breast magnetic resonance imaging is recommended as an adjunct to

other cancers. For example, a lung cancer risk prediction model, which includes age, sex, asbestos exposure history, and smoking history, has been found to predict risk of lung cancer. There is now growing interest in using each individuals genotype, such as presence or absence of single nucleotide polymorphisms which each may confer low or intermediate cancer risk. Risk models that include biologic as well as environmental factors may accurately predict cancer risk, providing better guidance as to which patients should undergo more intensive screening (e.g., screening with magnetic resonance imaging of the breast, computerized tomography screening of the lung), and should be considered for preventive strategies.

<tr>
<td>Lung</td>
<td>Current or former smokers age 50–74 in good health with at least a 30 pack/year history</td>
<td>LDCT</td>
<td>Clinicians with access to high-volume, high-quality lung cancer screening and treatment centers should initiate a discussion about lung cancer screening with apparently healthy patients age 55–74 y who have at least a 30 pack-y smoking history, and who currently smoke or have quit within the past 15 y. A process of informed and shared decision-making with a clinician related to the potential benefits, limitations, and harms associated with screening for lung cancer with LDCT should occur before any decision is made to initiate lung cancer screening. Smoking cessation counseling remains a high priority for clinical attention in discussions with current smokers, who should be informed of their continuing risk of lung cancer. Screening should not be viewed as an alternative to smoking cessation.</td>

Cancer-related checkup Men and women age ≥20 y On the occasion of a periodic health examination, the cancer-related checkup should include examination for cancers of the thyroid, testicles, ovaries, lymph nodes, oral cavity, and skin, as well as health counseling about tobacco, sun exposure, diet and nutrition, risk factors, sexual practices, and environmental and occupational exposures.

ACS = American Cancer Society; BSE = breast self-examination; CBE = clinical breast examination; Pap = Papanicolaou; HPV = human papillomavirus; gFOBT = guaiac-based fecal occult blood test; FIT = fecal immunochemical test; sDNA, stool DNA; DRE = digital rectal examination; FSIG = flexible sigmoidoscopy; DCBE = double-contrast barium enema; CT = computed tomography; LDCT = low-dose helical CT; PSA = prostate-specific antigen.

mammography for breast cancer screening in BRCA mutation carriers, first-degree relatives of carriers, and women with a lifetime breast cancer risk of 20% to 25% or higher.107

The National Lung Screening Trial demonstrated a 20% reduction in lung cancer deaths in adults age 55 to 74 years who were at high risk of lung cancer and randomized to low-dose helical computed tomography (LDCT) screening compared with screening with annual CXR.108 In 2013, the American Cancer Society updated their lung cancer screening recommendations to emphasize that clinicians with access to high-volume, high-quality lung cancer screening and treatment centers should ascertain the smoking history of their patients 55 to 74 years of age, and should discuss lung cancer screening with those who have at least a 30 pack per year smoking history, currently smoke, or have quit within the past 15 years, and who are in relatively good health.109 It is recommended that this discussion include the benefits, uncertainties, and harms associated with screening for lung cancer with LDCT.

**CANCER DIAGNOSIS**

The definitive diagnosis of solid tumors is obtained by performing a biopsy specimen of the lesion. Biopsy findings determine the tumor histology and grade and thus, assist in definitive therapeutic planning. Biopsy specimens of mucosal lesions usually are obtained endoscopically (e.g., via colonoscope, bronchoscope, or cystoscope). Lesions that are easily palpable, such as those of the skin, can either be excised or sampled by punch biopsy specimen. Deep-seated lesions can be localized with computed tomographic (CT) scan or ultrasound guidance for acquisition of a biopsy specimen.

A sample of a lesion can be obtained with a needle or with an open incisional or excisional biopsy specimen. Fine-needle aspiration is easy and relatively safe, but has the disadvantage of not giving information on tissue architecture. For example, fine-needle aspiration biopsy specimen of a breast mass can make the diagnosis of malignancy but cannot differentiate between an invasive and noninvasive tumor. Therefore core-needle biopsy specimen is more advantageous when the histologic findings will affect the recommended therapy. Core biopsy specimen, like fine-needle aspiration, is relatively safe and can be performed either by direct palpation (e.g., a breast mass or a soft tissue mass) or can be guided by an imaging study (e.g., stereotactic core biopsy specimen of the breast). Core biopsy specimens, like fine-needle aspirations, have the disadvantage of introducing sampling error. For example, 19% to 44% of patients with a diagnosis of atypical ductal hyperplasia based on core biopsy specimen findings of a mammographic abnormality are found to have carcinoma upon excision of the entire lesion.110 It is crucial to ensure that the histologic findings are consistent with the clinical scenario and to know the appropriate interpretation of each histologic finding. A needle biopsy specimen for which the report is inconsistent with the clinical scenario should be either repeated or followed by an open biopsy procedure.

Open biopsy specimens have the advantage of providing more tissue for histologic evaluation and the disadvantage of being an operative procedure. Incisional biopsy specimens are
Cancer staging is a system used to describe the anatomic extent of a malignant process in an individual patient. Staging systems may incorporate relevant clinical prognostic factors such as tumor size, location, extent, grade, and dissemination to regional lymph nodes or distant sites. Accurate staging is essential in designing an appropriate treatment regimen for an individual patient. Staging of the lymph node basin is considered a standard part of primary surgical therapy for most surgical procedures and is discussed later in this chapter. Cancer patients who are considered to be at high risk for distant metastasis usually undergo a preoperative staging work-up. This involves a set of imaging studies of sites of preferential metastasis for a given cancer type. For a patient with breast cancer, for example, a staging work-up would include a chest radiograph, bone scan, and liver ultrasound, or CT scans to evaluate for lung, bone, and liver metastases, respectively. A distant staging work-up usually is performed only for patients likely to have metastasis based on the characteristics of the primary tumor; for example, a staging work-up for a patient with ductal carcinoma in situ of the breast or a small invasive breast tumor is likely to be low yield and not cost effective.

Recently there also is increased usage of molecular imaging with positron emission tomography (PET) scanning, or PET/CT, for cancer staging. Most commonly PET scanning is performed with fluorine 18 incorporated into fluorodeoxyglucose (FDG). FDG PET assesses the rate of glycolysis. FDG uptake is increased in most malignant tissues but also in benign pathologic conditions such as inflammatory disorders, trauma, infection, and granulomatous disease. PET/CT combines a PET scanner and an X-ray CT scanner in a single gantry, in order to acquire sequential images from both devices in the same session. These separate images are combined into a single coregistered image that gives information on the size and shape of abnormal masses in conjunction with their metabolic activity. It has been especially useful in the staging and management of lymphoma, lung cancer, and colorectal cancer. The role of PET scanning in evaluating many other cancers is evolving, and additional molecular tracers, such as 3′-deoxy-3′-(18F)-fluorothymidine, used to assess proliferation, are being actively pursued.

A PET scan can be useful in staging a cancer that potentially can be treated radically, such as small cell lung cancer. In the case of some cancers such as GIST, a PET scan can be used to establish baseline staging before commencing targeted therapy and assessing the overall response to therapy. Another use for PET scanning is the evaluation of an indeterminate lesion as in the case of a solitary pulmonary nodule that is suspected to be malignant in nature. In testicular cancer (seminoma) and lymphoma, this imaging modality has been shown to be effective in assessing suspected disease recurrence, relapse, and/or residual disease. Finally, PET scans have been effective in guiding biopsies in the setting of mesothelioma. Standardization of staging systems is essential to allow comparison of results from different studies from different institutions and worldwide. The staging systems proposed by the American Joint Committee on Cancer (AJCC) and the Union Internationale Contre le Cancer (International Union Against Cancer, or UICC) are among the most widely accepted staging systems. Both the AJCC and the UICC have adopted a shared tumor, node, and metastasis (TNM) staging system that defines the cancer in terms of the anatomic extent of disease and is based on assessment of three components: the size of the primary tumor (T), the presence (or absence) and extent of nodal metastases (N), and the presence (or absence) and extent of distant metastases (M).

The TNM staging applies only to tumors that have been microscopically confirmed to be malignant. Standard TNM staging (clinical and pathologic) is completed at initial diagnosis. Clinical staging (cTNM or TNM) is based on information gained up until the initial definitive treatment. Pathologic staging (pTNM) includes clinical information and information obtained from pathologic examination of the resected primary tumor and regional lymph nodes. Tumor size following neoadjuvant chemotherapy is designated as ypT, and should be based on the largest single focus of residual invasive cancer. Other classifications, such as staging at the time of retreatment for recurrence (rTNM) or autopsy staging (aTNM), should be clearly identified as such.

The clinical measurement of tumor size (T) is the one judged to be the most accurate for each individual case based on physical examination and imaging studies. For example, in breast cancer the size of the tumor could be obtained from a physical examination, mammogram, or ultrasound, and the tumor size is based only on the invasive component.

If even one lymph node is involved by tumor, the N component is at least N1. For many solid tumor types, simply the absence or presence of lymph node involvement is recorded, and the tumor is categorized either as N0 or N1. For other tumor types, the number of lymph nodes involved, the size of the lymph nodes or the lymph node metastasis, or the regional lymph node basin involved also has been shown to have prognostic value. In these cancers, the designations N1, N2, and N3 suggest an increasing abnormality of lymph nodes based on size, characteristics, and location. NX indicates that the lymph nodes cannot be fully assessed.

Cases in which there is no distant metastasis are designated M0, cases in which one or more distant metastases are detected
are designated M1, and cases in which the presence of distant metastasis cannot be assessed are designated MX. In clinical practice, negative findings on clinical history and examination are sufficient to designate a case as M0. However, in clinical trials, routine follow-up often is performed to standardize the detection of distant metastases.

The practice of dividing cancer cases into groups according to stage is based on the observation that the survival rates are higher for localized (lower-stage) tumors than for tumors that have extended beyond the organ of origin. Therefore, staging assists in selection of therapy, estimation of prognosis, evaluation of treatments, and exchange of information among treatment centers. Notably, the AJCC regularly updates its staging system to incorporate advances in prognostic technology to improve the predictive accuracy of the TNM system. Therefore, it is important to know which revision of a staging system is being used when evaluating studies.

**TUMOR MARKERS**

**Prognostic and Predictive Tissue Markers**

Tumor markers are substances that can be detected in higher than normal amounts in the serum, urine, or tissues of patients with certain types of cancer. Tumor markers are produced either by the cancer cells themselves or by the body in a response to the cancer.

Over the past decade, there has been an especially high interest in identifying tissue tumor markers that can be used as prognostic or predictive markers. Although the terms **prognostic marker** and **predictive marker** are sometimes used interchangeably, the term **prognostic marker** generally is used to describe molecular markers that predict disease-free survival, disease-specific survival, and overall survival, whereas the term **predictive marker** often is used in the context of predicting response to certain therapies.

The goal is to identify prognostic markers that can give information on prognosis independent of other clinical characteristics and therefore can provide information to supplement the projections based on clinical presentation. This would allow practitioners to further classify patients as being at higher or lower risk within clinical subgroups and to identify patients who may benefit most from adjuvant therapy. For example, ideal prognostic tumor markers would be able to help determine which patients with node-negative breast cancer are at higher risk of relapse so that adjuvant systemic therapy could be given only to that group. However, although a large number of studies have identified potential novel prognostic markers, most have not been tested with enough vigor to be shown to be of clinical utility. In the 2017, American Society of Clinical Oncology (ASCO) guidelines, it was decided that level of uPA/PAI-1 measured by enzyme-linked immunosorbent assay could be used to determine prognosis in cases of newly diagnosed node-negative, hormone receptor positive breast cancer. In contrast, the data for many other markers, including Ki-67, p27, HER1/EGFR, and p53 were felt to be insufficient to support their use in the management of these breast cancer patients. Similarly, guidelines are available for the management of patients with colorectal cancer and emphasize the processes that need to be in place for accurate measurement of abnormalities in DNA mismatch repair genes as well as EGFR and BRAF mutational status.

Predictive markers are markers that can prospectively identify patients who will benefit from a certain therapy. For example in breast cancer, estrogen receptor (ER), and HER2 assessment can identify patients who can benefit from anti-estrogen therapies (e.g., tamoxifen) and anti-HER2 targeted therapies (e.g., trastuzumab), respectively, and the ASCO guidelines recommend that these markers be routinely assessed. High-throughput techniques such as transcriptional profiling allow for assessment of the relative mRNA levels of thousands of genes simultaneously in a given tumor using microarray technology. With the advent of such molecular profiling technologies, researchers have focused on identifying expression profiles that are prognostic for different cancer types. For breast cancer, although many such multiparameter tests are under development, few have reached the large-scale validation stage. In 2007, ASCO guidelines suggested that one of these, the Oncotype DX assay, can be used to predict recurrence in women with node-negative, ER-positive breast cancer who are treated with tamoxifen. Oncotype DX is a quantitative reverse-transcriptase polymerase chain reaction (RT-PCR) test that used paraffin-fixed tissue. A 21-gene recurrence score (RS) is generated based on the expression of 16 cancer genes and 5 reference genes. The levels of expression are used to derive an RS that ranges from 0 to 100, using a prospectively defined mathematical algorithm. This novel quantitative approach to the evaluation of the best-known molecular pathways in breast cancer has produced impressive results. Use of this multigene assay to predict recurrence was validated in the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-14 trial, in which ER-positive, node-negative patients had received tamoxifen. By multivariate Cox proportional analysis, RS was found to be independently associated with recurrence risk, with a hazard ratio of 3.21 (95% confidence interval of 2.23 to 4.65, \( P < .001 \)). The RS was indeed able to stratify patients by freedom from distant recurrence (Fig. 10-13). The Trial Assessing Individualized Options for Treatment for breast cancer (TAILORx) is evaluating the utility of Oncotype DX for predicting prognosis in patients with ER-positive, node-negative tumors and will focus on women with intermediate RS scores in whom the role of chemotherapy is unclear. Several other multigene predictors for breast cancer are available including MammaPrint, a gene expression profiling platform assessing a
70-gene transcriptional signature. This assay was approved by the Food and Drug Administration (FDA) in February 2007. The usefulness of this assay in making therapy-related decisions was tested prospectively in a large-scale study, the Microarray in Node-Negative Disease May Avoid Chemotherapy (MIND- ACT) trial. Among women with early-stage breast cancer who were determined to be at high clinical risk and low genomic risk for cancer recurrence, the receipt of no adjuvant chemotherapy on the basis of the 70-gene signature result led to a 5-year metastasis survival rate that was 1.5% lower than the rate in patients who had received chemotherapy. In light of these findings, 45% of women with breast cancer who are considered to be at high clinical risk might not require adjuvant chemotherapy.

Multigene profiles to predict prognosis are in development or in validation phases for many other solid tumor types, including lung cancer, ovarian cancer, pancreatic cancer, colorectal cancer, and melanoma. Gene signatures and genomic alterations also are being studied for their ability to predict response to specific chemotherapy regimens or targeted therapies. Many of these multigene marker sets will likely be incorporated into clinical practice in the years to come.

Serum Markers

Serum markers are under active investigation because they may allow early diagnosis of a new cancer or may be used to follow cancer response to therapy or monitor for recurrence. Unfortunately, identification of serum markers of clinical value has been challenging. Many of the tumor markers proposed so far have had low sensitivities and specificities. Tumor marker levels may not be elevated in all patients with cancer, especially in the early stages, when a serum marker would be most useful for diagnosis. Therefore, when a tumor marker is used to monitor recurrence, it is important to be certain that the level of the tumor marker was elevated before primary therapy. Moreover, tumor marker levels can be elevated in benign conditions. Many tumor markers are not specific for a certain type of cancer and can be elevated with more than one type of tumor. Since there may be significant laboratory variability, it is important to obtain serial results from the same laboratory. In spite of these many clinical limitations, several serum markers are in clinical use. A few of the commonly measured serum tumor markers are discussed in the following sections.

Prostate-Specific Antigen. Prostate-specific antigen (PSA) is an androgen-regulated serine protease produced by the prostate epithelium. PSA is normally present in low concentrations in the blood of all adult males. PSA levels may be elevated in the blood of men with benign prostate conditions such as prostatitis and benign prostatic hyperplasia, as well as in men with prostate cancer. PSA levels have been shown to be useful in evaluating the effectiveness of prostate cancer treatment and monitoring for recurrence after therapy. In monitoring for recurrence, a trend of increasing levels is considered more significant than a single absolute elevated value.

Although PSA has been widely used for prostate cancer screening, the utility of PSA screening remains controversial. There is concern that the number of men who avoid dying from prostate cancer due to screening is small, while the harms related to the treatment of screen-detected cancers, including incontinence and erectile dysfunction are at least moderate. In 2012, the U.S. Preventive Services Task Force concluded with moderate certainty that the harms of PSA testing outweigh the benefits and on that basis recommended against PSA-based screening for all men. In 2010, the American Cancer Society updated its guidelines for the early detection of prostate cancer to state that men who have at least a 10-year life expectancy should have an opportunity to make an informed decision with their health care provider about whether to be screened for prostate cancer with digital rectal exam and serum PSA, after receiving information about the benefits, risks, and uncertainties associated with prostate cancer screening; this recommendation was reinforced in their most recent guidelines.

Carcinoembryonic Antigen. Carcinoembryonic antigen (CEA) is a glycoprotein found in the embryonic endodermal epithelium. Elevated CEA levels have been detected in patients with primary colorectal cancer as well as in patients with breast, lung, ovarian, prostate, liver, and pancreatic cancer. Levels of CEA also may be elevated in benign conditions, including diverticulitis, peptic ulcer disease, bronchitis, liver abscess, and alcoholic cirrhosis, especially in smokers and in elderly persons.

CEA measurement is most commonly used in the management of colorectal cancer. However, the appropriate use of CEA testing in patients with colorectal cancer has been debated. Use of CEA level as a screening test for colorectal cancer is not recommended. CEA levels may be useful if obtained preoperatively and postoperatively in patients with a diagnosis of colorectal cancer. Preoperative elevation of CEA level is an indicator of poor prognosis. However, the ASCO clinical practice guidelines state that the data are insufficient to support the use of CEA to determine whether to give a patient adjuvant therapy; the data are stronger for the use of CEA for monitoring for postoperative recurrence. CEA measurement is the most cost-effective approach for detecting metastasis, with over 60% of recurrences being detected first by an elevation in CEA level. Therefore, in cases in which the patient would be a candidate for resection of recurrent colorectal cancer or systemic therapy, the ASCO guidelines recommend that postoperative CEA testing be performed every 3 months in patients with stage II or III disease for at least 3 years. CEA is the marker of choice for monitoring metastatic colorectal cancer during systemic therapy.

Alpha-Fetoprotein. Alpha-fetoprotein (AFP) is a glycoprotein normally produced by a developing fetus. AFP levels decrease soon after birth in healthy adults. An elevated level of AFP suggests the presence of either primary liver cancer or a germ cell tumor of the ovary or testicle. Rarely, other types of cancer such as gastric are associated with an elevated AFP level. Benign conditions that can cause elevations of AFP include cirrhosis, hepatic necrosis, acute hepatitis, chronic active hepatitis, ataxia-telangiectasia, Wiskott-Aldrich syndrome, and pregnancy. The sensitivity of an elevated AFP level for detecting HCC is approximately 60%. AFP is considered to be sensitive and specific enough to be used for screening for HCC in high-risk populations. Current consensus recommendations are to screen healthy hepatitis B virus carriers with annual or semiannual measurement of AFP level and to screen carriers with cirrhosis or chronic hepatitis and patients with cirrhosis of any etiology with twice-yearly measurement of AFP level and liver ultrasonography. Although AFP testing has been used widely for a long time, its efficacy in early diagnosis of HCC is limited. With improvements in imaging technology, a larger proportion of patients diagnosed with HCC are now AFP seronegative.

Cancer Antigen 19-9. Cancer antigen 19-9 (CA 19-9) is a tumor-related antigen that was originally defined by a monoclonal antibody produced by a hybridoma prepared from murine
spleen cells immunized with a human colorectal cancer cell line. The data are insufficient to recommend use of CA 19-9 for screening, diagnosis, surveillance, or monitoring of therapy for colon cancer. Based on the 2006 ASCO guidelines, there are also insufficient data to recommend use of CA 19-9 for screening, diagnosis, or determination of the operability of pancreatic cancer. However, for patients with locally advanced or metastatic cancer receiving active therapy, CA 19-9 can be measured at the start of therapy and every 1 to 3 months while therapy is given; elevations in serial CA 19-9 levels may indicate progressive disease and should be confirmed by additional studies.

**Cancer Antigen 15-3.** Cancer antigen 15-3 (CA 15-3) is an epitope of a large membrane glycoprotein encoded by the MUC1 gene that tumor cells shed into the bloodstream. The CA 15-3 epitope is recognized by two monoclonal antibodies in a sandwich radioimmunoassay. CA 15-3 levels are most useful in following the course of treatment in women diagnosed with advanced breast cancer. CA 15-3 levels are infrequently elevated in early-stage breast cancer. CA 15-3 levels can be increased in benign conditions such as chronic hepatitis, tuberculosis, sarcoidosis, pelvic inflammatory disease, endometriosis, systemic lupus erythematosus, pregnancy, and lactation, and in other types of cancer such as lung, ovarian, endometrial, and GI cancers.

The sensitivity of CA 15-3 is higher for metastatic disease, and in these cases studies have shown sensitivity to be between 54% and 87%, with specificity as high as 96%. This has led to interest in using CA 15-3 for monitoring patients with advanced breast cancer for recurrence. Elevated CA 15-3 levels have been reported before relapse in 54% of patients, with a lead time of 4.2 months. Therefore, detection of elevated CA 15-3 levels during follow-up should prompt evaluation for recurrent disease. However, 6% to 8% of patients without recurrence will have elevated CA 15-3 levels that require evaluation. Furthermore, monitoring with the use of CA 15-3 levels has shown no demonstrated impact on survival. Therefore, the 2007 ASCO guidelines state that the routine use of CA 15-3 for screening, diagnosis, staging, or surveillance of breast cancer is not recommended because available data are insufficient. For monitoring patients during active therapy, CA 15-3 can be used in conjunction with diagnostic imaging and history and physical examination. In the absence of measurable disease, an increase may be interpreted to indicate treatment failure. However, caution is advised when interpreting rising levels in the first 4 to 6 weeks of therapy.

**Cancer Antigen 27-29.** The MUC-1 gene product in the serum may be quantitated by using radioimmunoassay with a monoclonal antibody against the cancer antigen 27-29 (CA 27-29). CA 27-29 levels can be elevated in breast cancer as well as in cancers of the colon, stomach, kidney, lung, ovary, pancreas, uterus, and liver. First-trimester pregnancy, endometriosis, benign breast disease, kidney disease, and liver disease also may be associated with elevated CA 27-29 levels.

CA 27-29 has been reported to have a sensitivity of 57%, a specificity of 98%, a positive predictive value of 83%, and a negative predictive value of 93% in detecting breast cancer recurrences. Although CA 27-29 has been found to predict recurrence an average of 5.3 months before other symptoms or tests, testing of CA 27-29 levels has not been demonstrated to affect disease-free and overall survival rates. Therefore, the ASCO guidelines state that, as with CA 15-3, the routine use of CA 27-29 for screening, diagnosis, staging, or surveillance of breast cancer is not recommended because available data are insufficient. CA 27-29 levels can be used together with diagnostic imaging and history and physical examination to monitor patients during active therapy. When no measurable disease is present, an increase in level may be considered to indicate treatment failure. However, rising levels in the first 4 to 6 weeks of therapy should be interpreted with caution.

**Circulating Tumor Cells**

Circulating tumor cells (CTCs) are cells present in the blood that possess antigenic or genetic characteristics of a specific tumor type. One CTC detection methodology is capture and quantitation of CTCs with immunomagnetic beads coated with antibody specific for cell-surface, epithelial, or cancer antigens. Another methodology used to detect cancer cells in the peripheral blood is RT-PCR. It has been suggested that measurement of CTCs can be an effective tool for selecting patients who have a high risk of relapse and for monitoring efficacy of cancer therapy.

CTCs have probably been most extensively studied in breast cancer. The most promising data come from the use of CTC measures in metastatic breast cancer. In a prospective multicenter trial, the number of CTCs (≥5 CTCs vs. <5 CTCs per 7.5 mL of whole blood) before treatment of metastatic breast cancer was an independent predictor of progression-free and overall survival rates. The presence of >5 CTCs after the first course of therapy predicted lack of response to treatment. This technology, known as CellSearch, has been approved by the FDA for clinical use. In a well-designed single institutional study, detection of one or more CTCs in stage I to III breast cancer patients was associated with both decreased progression-free survival and overall survival. A large clinical trial was launched by the German SUCCESS study group to evaluate the prognostic significance of CTCs in early breast cancer. Blood samples were obtained from over 2000 average-to-high-risk nonmetastatic breast cancer patients before chemotherapy and nearly 1500 patients post chemotherapy and examined for CTCs. Women with detectable CTCs before chemotherapy had significantly worse disease-free and overall survival, and those with five or more CTCs had the highest relapse risk. However, there is limited data to prove that the use of CTC testing leads to improved survival or improved quality of life; thus, the ASCO 2017 guidelines update did not recommend the use of CTC measurement in any clinical setting. The clinical utility of measuring CTC response to initial therapy is now being tested prospectively in multiple clinical trials. The ability to conduct comprehensive analyses of cancer genomes within individual cells is becoming a real possibility, although the clinical utility of such information is still evolving. In addition to CTC, it has become possible in recent years to conduct a so-called “liquid tumor biopsy” by measuring levels of circulating tumor DNA and also circulating microRNAs. These new techniques are investigational but have the potential to provide prognostic and diagnostic information via their presumed correlation with tumor progression and the development of genomic alterations. The prognostic implications of detection of CTCs by RT-PCR have been intensively studied for melanoma. In the recent multicenter Sunbelt Melanoma Trial, serial RT-PCR was performed on peripheral blood samples using four markers—tyrosinase, melanoma antigen reacting to T cell (MART-1), melanoma antigen 3 (MAGE3), and gp 100—to detect occult
melanoma cells in the bloodstream.\textsuperscript{127} Although there were no differences in survival rates among patients in whom at least one marker was detected and those in whom no markers were detected, the disease-free survival and distant disease-free survival rates were worse for patients in whom more than one marker was detected at any time during follow-up.\textsuperscript{127}

**Bone Marrow Micrometastases**

Micrometastatic disease in the bone marrow, also referred to as minimal residual disease, continues to be investigated as a potential prognostic marker. Bone marrow micrometastatic disease usually is detected by staining bone marrow aspirates with monoclonal antibodies to cytokeratin, but other methodologies such as flow cytometry and RT-PCR are in use. Breast cancer patients with bone marrow micrometastasis have larger tumors, tumors with a higher histologic grade, more lymph node metastases, and more hormone receptor-negative tumors than patients without bone marrow micrometastasis. In 4700 patients with stage I, II, or III breast cancer, micrometastasis was a significant prognostic factor associated with poor overall survival, breast cancer-specific survival, disease-free survival, and distant disease-free survival during a 10-year observation period.\textsuperscript{128} The American College of Surgeons Oncology Group Z0010 trial enrolled women with clinical T1 to T2N0M0 invasive breast carcinoma in a prospective observational study to determine the association between survival and metastases detected by immunohistochemical staining of bone marrow specimens from patients with early-stage breast cancer.\textsuperscript{129} Of 3413 bone marrow specimens examined by immunocytochemistry, only 104 (3.0\%) were positive for tumor. Bone marrow involvement was associated with a decreased overall survival, but this association was not significant on multivariable analysis. The prognostic implication of bone marrow involvement continues to be studied by the National Surgical Adjuvant Breast and Bowel Project.

At this time, the routine use of bone marrow testing is not recommended.\textsuperscript{131} Ongoing clinical trials are evaluating the role of routine assessment of bone marrow status in the care of patients with early and advanced breast cancer. The utility of assessment of bone marrow micrometastasis has also been evaluated in other tumor types, including gastric, esophageal, colorectal, lung, cervical, and ovarian cancer.\textsuperscript{130}

**SURGICAL APPROACHES TO CANCER THERAPY**

**Multidisciplinary Approach to Cancer**

Although surgery is an effective therapy for most solid tumors, patients who die from cancer usually die of metastatic disease. Therefore, to improve patient survival rates, a multimodality approach, including systemic therapy and radiation therapy, is key for most tumors. It is important that surgeons involved in cancer care not only know the techniques for performing a cancer operation but also know the alternatives to surgery and be well versed in reconstructive options. It is also crucial that the surgeon be familiar with the indications for and complications of preoperative and postoperative chemotherapy and radiation therapy. Although the surgeon may not be delivering these other therapies, as the first physician to see a patient with a cancer diagnosis, he or she is ultimately responsible for initiating the appropriate consultations. For this reason, the surgeon often is responsible for determining the most appropriate adjuvant therapy for a given patient as well as the best sequence for therapy. In most instances, a multidisciplinary approach beginning at the patient’s initial presentation is likely to yield the best result.

**Surgical Management of Primary Tumors**

The goal of surgical therapy for cancer is to achieve oncologic cure. A curative operation presupposes that the tumor is confined to the organ of origin or to the organ and the regional lymph node basin. Patients in whom the primary tumor is not resectable with negative surgical margins are considered to have inoperable disease. The operability of primary tumors is best determined before surgery with appropriate imaging studies that can define the extent of local-regional disease. For example, a preoperative thin-section CT scan is obtained to determine resectability of pancreatic cancer, which is based on the absence of extrapancreatic disease, the absence of tumor extension to the superior mesenteric artery and celiac axis, and a patent superior mesenteric vein-portal vein confluence.\textsuperscript{130} Disease involving multiple distant metastases is deemed inoperable because it is usually not curable with surgery of the primary tumor. Therefore, patients who are at high risk of having distant metastasis should undergo a staging work-up before surgery for the primary tumor. On occasion, primary tumors are resected in these patients for palliative reasons, such as improving the quality of life by alleviating pain, infection, or bleeding. An example of this is toilet mastectomies for large ulcerated breast tumors. Patients with limited metastases from a primary tumor on occasion are considered surgical candidates if the natural history of isolated distant metastases for that cancer type is favorable or the potential complications associated with leaving the primary tumor intact are significant.

In the past, it was presumed that the more radical the surgery, the better the oncologic outcome would be. Over the past three decades, this has been recognized as not necessarily being true, which has led to more conservative operations, with wide local excisions replacing compartmental resections of sarcomas, and partial mastectomies, skin-sparing mastectomies, and breast-conserving therapies replacing radical mastectomies for breast cancer. The uniform goal for all successful oncologic operations seems to be achieving widely negative margins with no evidence of macroscopic or microscopic tumor at the surgical margins. The importance of negative surgical margins for local tumor control and/or survival has been documented for many tumor types, including sarcoma, breast cancer, pancreatic cancer, and rectal cancer. Thus, it is clear that every effort should be made to achieve microscopically negative surgical margins. Inking of the margins, orientation of the specimen by the surgeon, and immediate gross evaluation of the margins by a pathologist using frozen-section analysis when necessary may assist in achieving negative margins at the first operation. In the end, although radiation therapy and systemic therapy can assist in decreasing local recurrence rates in the setting of positive margins, adjuvant therapy cannot substitute for adequate surgery.

Although it is clear that the surgical gold standard is negative surgical margins, the appropriate surgical margins for optimal local control are controversial for many cancer types. In contrast, in melanoma the optimal margin width for any tumor depth has been better defined, owing to the systematic study of this question in randomized clinical trials.\textsuperscript{132,133} Although such randomized studies may not be possible for all tumor types, it is important to determine optimal surgical margins for each cancer type so that adjuvant radiation and systemic therapy can be offered to patients deemed to be at increased risk for local treatment failure.
Most neoplasms have the ability to metastasize via the lymphatics. Therefore, most oncologic operations have been designed to remove the primary tumor and draining lymphatics en bloc. This type of operative approach usually is undertaken when the lymph nodes draining the primary tumor site lie adjacent to the tumor bed, as is the case for colorectal cancers and gastric cancers. For tumors in which the regional lymph node basin is not immediately adjacent to the tumor (e.g., melanomas), lymph node surgery can be performed through a separate incision. Unlike most carcinomas, soft tissue sarcomas rarely metastasize to the lymph nodes (<5%); therefore, lymph node surgery usually is not necessary.

It is generally accepted that a formal lymphadenectomy is likely to minimize the risk of regional recurrence of most cancers. For example, the introduction of total mesorectal excision of rectal cancer has been associated with a large decline in local-regional recurrence, and this procedure has become the new standard of operative management. On the other hand, there have been two opposing views regarding the role of lymphadenectomy in survival of cancer patients. The traditional Halsted view states that lymphadenectomy is important for staging and survival. The opposing view counters that cancer is systemic at inception and that lymphadenectomy, although useful for staging, does not affect survival. For most cancers, involvement of the lymph nodes is one of the most significant prognostic factors. Interestingly, in some studies removal of a larger number of lymph nodes has been found to be associated with an improved overall survival rate for many tumors, including breast cancer, colon cancer, and lung cancer. Although this seems to support the Halsted theory, the practice of sentinel lymph node biopsy specimens yields the risk of regional recurrence, there may be alternative explanations for the same finding. For example, the surgeon who performs a more extensive lymphadenectomy may obtain wider margins around the tumor or even provide better overall care, such as ensuring that patients receive the appropriate adjuvant therapy or undergo a more thorough staging workup. Alternatively, the pathologist may perform a more thorough examination, identifying more nodes and more accurately staging the nodes. The effect of appropriate staging on survival is twofold. Patients with nodal metastases may be offered adjuvant therapy, which improves their survival chances. Further, the enhanced staging can improve perceived survival rates through a “Will Rogers effect.” Such a phenomenon is observed when moving an element from one set to another set raises the average value of both sets. When commenting on the 1930s migration of poor farmers from a dustbowl state to a more prosperous western state, humorist Will Rogers quipped that this event raised the average intelligence of both states. Thus, identification of small metastases that had formerly been silent and unidentified leads to stage migration for these patients and thus to a perceived improvement in chances of survival for the higher stage. In addition, there is improved survival for the lower stage, which is now minus the patients with low volume nodal disease. Clearly the impact of lymphadenectomy on survival will continue to be a topic of clinical research.

Surgical management of the clinically negative regional lymph node basin has evolved with the introduction of lymphatic mapping technology (Fig. 10-14). Lymphatic mapping and sentinel lymph node biopsy specimen were first reported in 1977 by Cabanas for penile cancer. Now, sentinel node biopsy specimen is the standard of care for the management of melanoma and breast cancer. The utility of sentinel node biopsy is being explored in other cancer types such as head and neck squamous cell cancer and vulvar cancer.

The first node to receive drainage from the tumor site is termed the sentinel node. This node is the node most likely to contain metastases, if metastases to that regional lymph node basin are present. The goal of lymphatic mapping and sentinel lymph node biopsy specimen is to identify and remove the lymph node most likely to contain metastases in the least invasive fashion. The practice of sentinel lymph node biopsy specimen followed by regional lymph node dissection for selected patients with a positive sentinel lymph node avoids the morbidity of lymph node dissections in patients with negative nodes. An additional advantage of the sentinel lymph node technique is that it directs attention to a single node, which allows more careful analysis of the lymph node most likely to have a positive yield and increases the accuracy of nodal staging. Two criteria are used to assess the efficacy of a sentinel lymph node biopsy specimen: the sentinel lymph node identification rate and the false-negative rate. The sentinel lymph node identification rate

**Figure 10-14.** Lymphatic mapping and sentinel lymph node biopsy specimen for breast cancer. A. Peritumoral injection of blue dye. B. Blue dye draining into the sentinel lymph node.
is the proportion of patients in whom a sentinel lymph node was identified and removed among all patients undergoing an attempted sentinel lymph node biopsy specimen. The false-negative rate is the proportion of patients with regional lymph node metastases in whom the sentinel lymph node was found to be negative. False-negative biopsy specimen results may be due to identifying the wrong node or to missing the sentinel node (i.e., surgical error) or they may be due to the cancer cells’ establishing metastases not in the first node encountered but in a second-echelon node (i.e., biologic variation). Alternatively, false-negative biopsy specimen results may be due to inadequate histologic evaluation of the lymph node. The false-negative rates for sentinel lymph node biopsy specimen in study series range between 0% and 11%. Both increases in the identification rate and decreases in the false-negative rate have been observed as surgeons gain experience with the technique.

Lymphatic mapping is performed by using isosulfan blue dye, technetium-labeled sulfur colloid or albumin, or a combination of both techniques to detect sentinel nodes. The combination of blue dye and technetium has been reported to improve the capability of detecting sentinel lymph nodes. The nodal drainage pattern usually is determined with a preoperative lymphoscintigram, and the “hot” and/or blue nodes are identified with the assistance of a gamma probe and careful nodal basin exploration. Careful manual palpation is a crucial part of the procedure to minimize the false-negative rate.

The nodes are evaluated with serial sectioning, hematoxylin and eosin staining, and immunohistochemical analysis with S-100 protein and homatropine methylbromide staining for melanoma and cytokeratin staining for breast cancer. The utility of molecular techniques such as RT-PCR to assess the sentinel nodes is still being explored.

Another area of active investigation is the prognostic value of minimal nodal involvement. For example, in breast cancer, nodes with isolated tumor cell deposits of <0.2 mm are considered to be N0 by the sixth edition of the AJCC staging manual. However, some retrospective studies have suggested that even this amount of nodal disease burden has negative prognostic implications. Molecular ultrastaging with RT-PCR for patients with node-negative disease was assessed in a prospective multicenter trial and was found to not be prognostic in malignant melanoma. However, a recent meta-analysis of 22 studies enrolling 4019 patients found that PCR positivity was associated with worse overall and disease-free survival. Further study of the utility of ultrastaging of nodes in breast cancer, melanoma, and several other tumor types is ongoing.

Until recently, in breast cancer management, when sentinel node mapping revealed a positive sentinel node, this was followed by a completion axillary lymph node dissection. Results of the American College of Surgeons Oncology Group Z0011 trial, challenged this practice. ACOSOG Z11 was a phase 3 multicenter noninferiority trial conducted to determine the effects of completion lymph node dissections in melanoma is under investigation. In the MSLT-II clinical trial, melanoma patients with sentinel-node metastases were randomized to immediate completion lymph-node dissection or nodal observation with ultrasonography. The primary end point of this study was melanoma-specific survival. Immediate completion lymph-node dissection led to increased regional disease control and provided prognostic information but did not increase melanoma-specific survival among patients with intermediate-thickness melanoma and sentinel-node metastases.

Surgical Management of Distant Metastases

The treatment of a patient with distant metastases depends on the number and sites of metastases, the cancer type, the rate of tumor growth, the previous treatments delivered and the responses to these treatments, and the patient’s age, physical condition, and desires. Although once a tumor has metastasized it usually is not curable with surgical therapy, such therapy has resulted in cure in selected cases with isolated metastases to the liver, lung, or brain.

Patient selection is the key to the success of surgical therapy for distant metastases. The cancer type is a major determinant in surgical decision making. A liver metastasis from a colon cancer is more likely to be an isolated and thus resectable lesion than a liver metastasis from a pancreatic carcinoma. The growth rate of the tumor also plays an important role and can be determined in part by the disease-free interval and the time between treatment of the primary tumor and detection of the distant recurrence. Patients with longer disease-free intervals have a higher survival rate after surgical metastasectomy than those with a short disease-free interval. Similarly, patients who have synchronous metastases (metastases diagnosed at the initial cancer diagnosis) do worse after metastasectomy than patients who develop metachronous metastases (metastasis diagnosed after a disease-free interval). The natural history of metastatic disease is so poor for some tumors (e.g., pancreatic cancer) that there is no role at this time for surgical metastasectomy. In cancers with a more favorable outlook, observation for several weeks or months, potentially with initial treatment with systemic therapy, can allow the surgeon to monitor for metastases at other sites.

In curative surgery for distant metastases, as with surgery for primary tumors, the goal is to resect the metastases with negative margins. In patients with hepatic metastases that are unresectable because their location near intrahepatic blood vessels precludes a margin-negative resection, or because they are multifocal or hepatic function is inadequate, tumor ablation with cryotherapy or radiofrequency ablation is an alternative. Curative resections or ablative procedures should be attempted...
only if the lesions are accessible and the procedure can be performed safely.

**CHEMOTHERAPY**

**Clinical Use of Chemotherapy**

In patients with documented distant metastatic disease, chemotherapy is usually the primary modality of therapy. The goal of therapy in this setting is to decrease the tumor burden, thus prolonging survival. It is rare to achieve cure with chemotherapy for metastatic disease for most solid tumors. Chemotherapy administered to a patient who is at high risk for distant recurrence but has no evidence of distant disease is referred to as *adjuvant chemotherapy*. The goal of adjuvant chemotherapy is eradication of micrometastatic disease, with the intent of decreasing relapse rates and improving survival rates.

Adjuvant therapy can be administered after surgery (postoperative chemotherapy) or before surgery (neoadjuvant chemotherapy, or induction therapy). A portion or all of the planned adjuvant chemotherapy can be administered before the surgical removal of the primary tumor. Preoperative chemotherapy has three potential advantages. The first is that preoperative regression of tumor can facilitate resection of tumors that were initially inoperable, or allow more conservative surgery for patients whose cancer was operable to begin with. In the NSABP B-18 project, for example, women were randomly assigned to receive adjuvant doxorubicin and cyclophosphamide preoperatively or postoperatively. More patients treated before surgery than after surgery underwent breast-conserving surgery (68% vs. 60%). The second advantage of preoperative chemotherapy is the treatment of micrometastases without the delay of postoperative recovery. The third advantage is the ability to assess a cancer’s response to treatment clinically, after a number of courses of chemotherapy, and pathologically, after surgical resection. This is especially important if alternative treatment regimens are available to be offered to patients whose disease responded inadequately. Molecular characterization of the residual disease may also give insight into mechanisms of chemoresistance and possible therapeutic targets.

There are some potential disadvantages to preoperative chemotherapy, however. Although disease progression while the patient is receiving preoperative chemotherapy is rare in chemotherapy-sensitive tumors such as breast cancer, it is more frequent in relatively chemotherapy-resistant tumors such as sarcomas. Thus, patient selection is critical to ensure that the opportunity to treat disease surgically is not lost by giving preoperative chemotherapy. Often, rates of postoperative wound infection, flap necrosis, and delays in postoperative adjuvant therapy do not differ between patients who are treated with preoperative chemotherapy and patients who are treated with surgery first. However, preoperative chemotherapy can introduce special challenges to tumor localization, margin analysis, lymphatic mapping, and pathologic staging.

Response to chemotherapy is monitored clinically with imaging studies as well as physical examinations. Response usually is defined as complete response, partial response, stable disease, or progression. Response generally is assessed using the Response Evaluation Criteria in Solid Tumors (RECIST) criteria. Objective tumor response assessment is critical because tumor response is used as a prospective endpoint in clinical trials and tumor response is a guide to clinicians regarding continuation of current therapy.

**Principles of Chemotherapy**

Chemotherapy destroys cells by first-order kinetics, which means that with the administration of a drug a constant percentage of cells is killed, not a constant number of cells. If a patient with $10^{12}$ tumor cells is treated with a dose that results in 99.9% cell kill (3-log cell kill), the tumor burden will be reduced from $10^{12}$ to $10^9$ cells (or 1 kg to 1 g). If the patient is retreated with the same drug, which theoretically could result in another 3-log cell kill, the cells would decrease in number from $10^9$ to $10^6$ (1 g to 1 mg) rather than being eliminated totally.

Chemotherapeutic agents can be classified according to the phase of the cell cycle during which they are effective. Cell-cycle phase nonspecific agents (e.g., alkylating agents) have a linear dose-response curve, such that the fraction of cells killed increases with the dose of the drug. In contrast, the cell-cycle phase-specific drugs have a plateau with respect to cell killing ability, and cell kill will not increase with further increases in drug dose.

**Anticancer Agents**

**Alkylating Agents.** Alkylating agents are cell-cycle–nonspecific agents, that is, they are able to kill cells in any phase of the cell cycle. They act by cross-linking the two strands of the DNA helix or by causing other direct damage to the DNA. The damage to the DNA prevents cell division and, if severe enough, leads to apoptosis. The alkylating agents are composed of three main subgroups: classic alkylators, nitrosoureas, and miscellaneous DNA-binding agents (Table 10-10).

**Antitumor Antibiotics.** Antitumor antibiotics are the products of fermentation of microbial organisms. Like the alkylating agents, these agents are cell-cycle nonspecific. Antitumor antibiotics damage the cell by interfering with DNA or RNA synthesis, although the exact mechanism of action may differ by agent.

**Antimetabolites.** Antimetabolites are generally cell-cycle–specific agents that have their major activity during the S phase of the cell cycle and have little effect on cells in G0. These drugs are most effective, therefore, in tumors that have a high growth fraction. Antimetabolites are structural analogues of naturally occurring metabolites involved in DNA and RNA synthesis. Therefore, they interfere with normal synthesis of nucleic acids by substituting for purines or pyrimidines in the metabolic pathway to inhibit critical enzymes in nucleic acid synthesis. The antimetabolites include folate antagonists, purine antagonists, and pyrimidine antagonists.

**Plant Alkaloids.** Plant alkaloids are derived from plants such as the periwinkle plant, *Vinca rosea* (e.g., vincristine, a vinca alkaloid), or the root of American mandrake, *Podophyllum peltatum* (e.g., etoposide, a podophyllotoxin). Vinca alkaloids affect the cell by binding to tubulin in the S phase. This blocks microtubule polymerization, which results in impaired mitotic spindle formation in the M phase. Taxanes such as paclitaxel, on the other hand, cause excess polymerization and stability of microtubules, which blocks the cell cycle in mitosis. The epipodophyllotoxins (e.g., etoposide) act to inhibit a DNA enzyme called topoisomerase II by stabilizing the DNA-topoisomerase II complex. This results in an inability to synthesize DNA, and thus the cell cycle is stopped in the G1 phase.
Combination Chemotherapy

Combination chemotherapy may provide greater efficacy than single-agent therapy by three mechanisms: (a) it provides maximum cell kill within the range of toxicity for each drug that can be tolerated by the host, (b) it offers a broader range of coverage of resistant cell lines in a heterogeneous population, and (c) it prevents or delays the emergence of drug-resistant cell lines. When combination regimens are devised, drugs known to be active as single agents usually are selected. Drugs with different mechanisms of action are combined to allow for additive or synergistic effects. Combining cell-cycle–specific and cell-cycle–nonspecific agents may be especially advantageous. Drugs with differing dose-limiting toxic effects are combined to allow for each drug to be given at therapeutic doses. Drugs with different patterns of resistance are combined whenever possible to minimize cross-resistance. The treatment-free interval between cycles is kept to the shortest possible time that will allow for recovery of the most sensitive normal tissue.

Drug Toxicity

Tumors are more susceptible than normal tissue to chemotherapeutic agents, in part because they have a higher proportion of dividing cells. Normal tissues with a high growth fraction, such as the bone marrow, oral and intestinal mucosa and hair follicles are sensitive to chemotherapeutic effects. Therefore, treatment with chemotherapeutic agents can produce toxic effects such as bone marrow suppression, stomatitis, ulceration of the GI tract, and alopecia. Toxic effects usually are graded from 0 to 4 on the basis of World Health Organization standard criteria. Significant drug toxicity may necessitate a dosage reduction. A toxic effect requiring a dose modification or change in dose intensity is referred to as a dose-limiting toxic effect. Because maintaining dose intensity is important to preserve as high a tumor cell kill as possible, several supportive strategies have been developed, such as administration of colony-stimulating factors and erythropoietin to treat poor bone marrow reserve and administration of cytoprotectants such as mesna and amifostine to prevent renal dysfunction. Some toxicities, such as neuropathy, are not as easily reversible, and their potential effects on lifestyle must be considered when evaluating a patient prior to the initiation of chemotherapy.

Administration of Chemotherapy

Chemotherapy usually is administered systemically (IV, IM, SC, or PO). Systemic administration treats micrometastases at widespread sites and prevents systemic recurrence. However, it increases the drug’s toxicity to a wide range of organs throughout the body. One method to minimize systemic toxicity while enhancing target organ delivery of chemotherapy is regional administration of chemotherapy. Many of these approaches require surgical access, such as intrahepatic delivery of chemotherapy for hepatic carcinomas or metastatic colorectal cancer using a hepatic artery infusion pump, limb perfusion for extremity melanoma and sarcoma, and intraperitoneal hyperthermic

HORMONAL THERAPY

Some tumors, most notably breast and prostate cancers, originate from tissues whose growth is under hormonal control. The first attempts at hormonal therapy were through surgical ablation of the organ producing the hormones involved, such as oophorectomy for breast cancer. Currently, hormonal anticancer agents include androgens, antiandrogens, antiestrogens, estrogens, glucocorticoids, gonadotropin inhibitors, progestins, aromatase inhibitors, and somatostatin analogues. Hormones or hormone-like agents can be administered to inhibit tumor growth by blocking or antagonizing the naturally occurring substance, such as with the estrogen antagonist tamoxifen. Other substances that block the synthesis of the natural hormone can be administered as alternatives. Aromatase inhibitors, for example, block the peripheral conversion of endogenous androgens to estrogens in postmenopausal women. Hormonal therapy provides a highly tumor-specific form of therapy in sensitive tissues. In breast cancer, estrogen and progesterone receptor status is used to predict the success of hormonal therapy. Androgen receptor is also being pursued as a therapeutic target for breast cancer treatment.

TARGETED THERAPY

Over the past decade, increased understanding of cancer biology has fostered the emerging field of molecular therapeutics. The basic principle of molecular therapeutics is to exploit the molecular differences between normal cells and cancer cells to develop targeted therapies. Thus, targeted therapies usually are directed at the processes involved in tumor growth rather than directly targeting the tumor cells. The ideal molecular target would be exclusively expressed in the cancer cells, be the driving force of the proliferation of the cancer cells, and be critical to their survival. A large number of molecular targets are currently being explored, both preclinically and in clinical trials. The major groups of targeted therapy agents are inhibitors of growth factor receptors, inhibitors of intracellular signal transduction, cell-cycle inhibitors, apoptosis-based therapies, and anti-angiogenic compounds.

Protein kinases have come to the forefront as attractive therapeutic targets with the success of imatinib mesylate (Gleevec) in treating chronic myelogenous leukemia and GI stromal tumors, and trastuzumab (Herceptin) in treating breast cancer, and vemurafenib in treating melanoma. These drugs work by targeting bcr-abl and c-kit (imatinib) and HER2 and BRAF, respectively. For example, a phase 3 randomized trial demonstrated that, compared with dacarbazine, standard of care chemotherapy option for patients with metastatic melanoma with a V600E BRAF mutation, the BRAF inhibitor vemurafenib led to significantly higher response rates (48% vs. 5%). At 6 months, overall survival was 84% (95% CI, 78–89) in the vemurafenib group and 64% (95% CI, 56–73) in the dacarbazine group. The hazard ratio for tumor progression in the vemurafenib group was 0.26 (95% CI, 0.20–0.33; P<0.001). The estimated median progression-free survival was 5.3 months in the vemurafenib group and 1.6 months in the dacarbazine group. This trial highlights the fact that in at least some tumor types targeted therapies that inhibit a genomic alteration that is a driver is likely to be more effective than an unselected therapeutic option.

Sequencing of the human genome has revealed approximately 500 protein kinases. Several tyrosine kinases have been shown to have oncogenic properties and many other protein kinases have been shown to be aberrantly activated in cancer cells. Therefore, protein kinases involved in these aberrantly activated pathways are being aggressively pursued in molecular therapeutics. Potential targets like HER2 can be targeted via different strategies, such as transcriptional downregulation, targeting of mRNA, RNA inhibition, antisense strategies, direct inhibition of protein activity, and induction of immunity against the protein. Most of the compounds in development are monoclonal antibodies like trastuzumab or small-molecule kinase inhibitors like imatinib or vemurafenib. Some other agents, such as sunitinib, are multitargeted kinase inhibitors. Selected FDA-approved targeted therapies are listed in Table 10-11. Many of the promising pathways, such as the PI3K/Akt/mTOR pathway, are being pursued as therapeutic targets with several drugs in development, targeting different aspects of the pathway (Fig. 10-15).

Development of molecularly targeted agents for clinical use presents several unique challenges. Once an appropriate compound is identified and confirmed to have activity in preclinical testing, predictive markers for activity in the preclinical setting must be defined. Expression of a target may not be sufficient to predict response because the pathway of interest may not be activated or critical to the cancer’s survival. Although in traditional phase 1 trials the goal is to identify the maximum tolerated dosage, the maximum dosage of biologic agents may not be necessary to achieve the desired biologic effect. Thus, assays to verify modulation of the target need to be developed to determine at what dosage the desired effect is achieved. When phases 2 and 3 clinical trials are initiated, biomarker modulation studies should be integrated into the trial to determine whether clinical response correlates with target modulation and thus to identify additional parameters that impact response. Rational dose selection and limitation of study populations to patients most likely to respond to the molecular therapy as determined by predictive markers are most likely to lead to successful clinical translation of a product. Finally, most biologic agents are cytostatic, not cytotoxic. Thus, rational combination therapy mixing new biologic agents with either established chemotherapeutic agents that have synergy or with other biologic agents is more likely to lead to cancer cures.

IMMUNOTHERAPY

The aim of immunotherapy is to induce or potentiate inherent antitumor immunity that can destroy cancer cells. Central to the process of antitumor immunity is the ability of the immune system to recognize tumor-associated antigens present on human cancers and to direct cytotoxic responses through humoral or T-cell–mediated immunity. Overall, T-cell–mediated immunity appears to have the greater potential of the two for eradicating tumor cells. T cells recognize antigens on the surfaces of target cells as small peptides presented by class I and class II MHC molecules.

Several antitumor strategies are under investigation. One approach to antitumor immunity is nonspecific immunotherapy, which stimulates the immune system as a whole through administration of bacterial agents or their products, such as bacille

Calmette-Guérin. This approach is thought to activate the effectors of antitumor response such as natural killer cells and macrophages, as well as polyclonal lymphocytes. Another approach to nonspecific immunotherapy is systemic administration of cytokines such as interleukin-2, interferon-α, and interferon-γ. Interleukin-2 stimulates proliferation of cytotoxic T lymphocytes and maturation of effectors such as natural killer cells into lymphokine-activated killer cells. Interferons, on the other hand, exert antitumor effects directly by inhibiting tumor cell proliferation and indirectly by activating host immune cells, including macrophages, dendritic cells, and natural killer cells, and by enhancing human leukocyte antigen (HLA) class I expression on tumor cells.

Antigen-specific immunotherapy can be active, as is achieved through antitumor vaccines, or passive. In passive immunotherapy, antibodies to specific tumor-associated antigens can be produced by hybridoma technique and then administered to patients whose cancers express these antigens, inducing antibody-dependent cellular cytotoxicity.

The early attempts at vaccination against cancers used allogeneic cultured cancer cells, including irradiated cells, cell lysates, and shed antigens isolated from tissue culture supernatants. An alternate strategy is the use of autologous tumor vaccines. These have the potential advantage of being more likely to contain antigens relevant for the individual patient but have the disadvantage of requiring a large amount of tumor tissue for preparation, which restricts eligibility of patients for this modality. Strategies to enhance immunogenicity of tumor cells include the introduction of genes encoding cytokines or chemokines, and fusion of the tumor cells to allogeneic MHC class II-bearing cells. Alternatively, heat shock proteins derived from a patient’s tumor can be used because heat shock protein peptide complexes are readily taken up by dendritic cells for presentation to T cells.

Identification of tumor antigens has made it possible to perform antigen-specific vaccination. For example, in the case of melanoma, several antigens have been identified that can be recognized by both CD8+ cytotoxic T cells and CD4+ helper T cells, including MART-1, gp 100, MAGE1, tyrosinase, TRP-1, TRP-2, and NY-ESO-1. Antigens tested usually are overexpressed or mutated in cancer cells. Tissue specificity and immunogenicity are important determinants in choosing an appropriate target. Vaccines directed at defined tumor antigens aim to combine selected tumor antigens and appropriate routes for delivering these antigens to the immune system to optimize antitumor immunity. Several different vaccination approaches have been studied, including tumor cell-based vaccines, peptide-based vaccines, recombinant virus-based vaccines, DNA-based vaccines, and dendritic cell vaccines.

In adoptive transfer, antigen-specific effector cells (i.e., cytotoxic T lymphocytes) or antigen-nonspecific effector cells
(i.e., natural killer cells) can be transferred to a patient. These effector cells can be obtained from the tumor (tumor-infiltrating lymphocytes) or the peripheral blood.

Clinical experience in patients with metastatic disease has shown objective tumor responses to a variety of immunotherapeutic modalities. It is thought, however, that the immune system is overwhelmed with the tumor burden in this setting, and thus adjuvant therapy may be preferable, with immunotherapy reserved for decreasing tumor recurrences. Trials to date suggest that immunotherapy is a potentially useful approach in the adjuvant setting. How to best select patients for this approach and how to integrate immunotherapy with other therapies are not well understood for most cancer types.

Tolerance to self-antigens expressed in tumors is a limitation in generating antitumor responses. Recently, several pathways that modulate tolerance and approaches to manipulating these pathways have been identified: pathways that activate professional antigen-presenting cells such as Toll-like receptors, growth factors, and the CD40 pathway; cytokines to enhance immunostimulation; and pathways that inhibit T-cell inhibitory signals or block the activity of immune-suppressive regulatory T cells (Tregs).

A new and highly effective strategy to activate the T-cell arm of anticancer immunity is the use of monoclonal antibodies to block inhibitory signaling pathways employed by the immune system to prevent T cell overactivation and the development of autoimmunity. CTLA-4 and PD-1 are two important inhibitory T-cell checkpoints that can be blocked with neutralizing antibodies and result in an effective antigen-specific anti-tumor response.

CTLA-4 is an inhibitory receptor expressed by activated T cells that belongs to the immunoglobulin superfamily. CTLA4 is related to the T-cell costimulatory receptor, CD28, and both are bound by CD80 and CD86 (also known as B7-1 and B7-2) which are expressed on antigen-presenting cells. CTLA4 conveys an inhibitory signal to the T cell, whereas engagement of CD28 with ligand sends a stimulatory signal. CTLA-4 is able to outcompete CD28 for CD80 and CD86 ligands and therefore is able to dominate immune signaling in the setting of antigen recognition. CTLA-4 is also expressed by regulatory T cells, which contributes to their ability to inhibit T-cell function.

Programmed death ligand 1 (PD-L1) is a 40 kDa type 1 transmembrane protein that is thought to play an important role in suppressing the immune system. PD-L1 binds to its receptor, PD-1, which is found on activated T cells. The PD1/PDL1 pathway is increasingly recognized as a key contributor to tumor-mediated immune suppression. The interaction between PD-1 leads to reduced proliferation, altered production of stimulatory cytokines, and reduced T-cell lytic activity. Thus, both anti-PD1 and anti-PD-L1 strategies are actively being pursued for cancer therapy.

The FDA-approved CTLA-4 blocking antibody ipilimumab has shown efficacy in patients with metastatic melanoma. Nivolumab and pembrolizumab are antibodies that target PD-1, whereas blockade of PD-L1 is accomplished with agents such as atezolizumab. Cancers for which checkpoint inhibitors have found utility include melanoma, renal cell carcinoma, bladder carcinoma, squamous cell carcinoma of the head and neck, and carcinoma of the lung. These agents produce durable shrinkage of advanced disease in 20% to 40% of patients, and combination strategies that employ checkpoint inhibitors with cytokines, vaccines, cellular therapies, and other targeted agents are under active investigation.

**GENE THERAPY**

Gene therapy is being pursued as a possible approach to modifying the genetic program of cancer cells as well as treating metabolic diseases. The field of cancer gene therapy uses a variety of strategies, ranging from replacement of mutated or deleted tumor-suppressor genes to enhancement of immune responses to cancer cells. Indeed, in preclinical models, approaches such as replacement of tumor-suppressor genes leads to growth arrest or apoptosis. However, the translation of these findings into clinically useful tools presents special challenges.

One of the main difficulties in getting gene therapy technology from the laboratory to the clinic is the lack of a perfect delivery system. An ideal vector would be administered through a noninvasive route and would transduce all of the cancer cells and none of the normal cells. Furthermore, the ideal vector would have a high degree of activity, that is, it would produce an adequate amount of the desired gene product to achieve target cell kill. Unlike genetic diseases in which delivery of the gene of interest into only a portion of the cells may be sufficient to achieve clinical effect, cancer requires either that the therapeutic gene be delivered to all of the cancer cells or that a therapeutic effect be achieved on nontransfected cells as well as transfected cells through a bystander effect. However, treatment of a metabolic disease requires prolonged gene expression, whereas transient expression may be sufficient for cancer therapy.

Several vector systems are under study for gene therapy; however, none is considered ideal. One of the promising approaches to increase the number of tumor cells transduced is the use of a replication-competent virus like a parovirus, human reovirus, or vesicular stomatitis virus that selectively replicates within malignant cells and lysed them more efficiently than it does normal cells. Another strategy for killing tumor cells with suicide genes exploits tumor-specific expression elements, such as the MUC-1, PSA, CEA, or VEGF promoters, that can be used to achieve tissue-specific or tumor-specific expression of the desired gene.

Because the goal in cancer therapy is to eradicate systemic disease, optimization of delivery systems is the key to success for gene therapy strategies. Gene therapy is likely to be most successful when combined with standard therapies, but it will provide the advantage of customization of therapy based on the molecular status of an individual’s tumor.

**MECHANISMS OF INTRINSIC AND ACQUIRED DRUG RESISTANCE**

Several tumor factors influence tumor cell kill. Tumors are heterogeneous, and, according to the Goldie-Coldman hypothesis, tumor cells are genetically unstable and tend to mutate to form different cell clones. This has been used as an argument for giving chemotherapy as soon as possible in treatment to reduce the likelihood that resistant clones will emerge. Tumor size is another important variable. Larger tumors may have greater heterogeneity, although heterogeneity may also differ based on biologic subtype. Tumor growth may be described by a Gompertz curve, named after Benjamin Gompertz, which has the form of a sigmoid function. Gompertzian models have thus been used to describe changes in tumor cell numbers over time where growth is slowest at the start and end of a time period, but are quite rapid in the middle. Theoretically, for any tumor, there is a period of time where cancer cells grow rapidly (exponential growth...
Cancer cells demonstrate adaptive responses to targeted therapy, like activating alternate pathways of survival; thus, these alterations may blunt therapeutic efficacy. Cancer cells also acquire resistance upon prolonged treatment with targeted therapy through a variety of mechanisms. One mechanism is through the loss of the target. For example, this was observed in a study of patients with HER2-positive breast cancer patients who were treated with neoadjuvant trastuzumab-based chemotherapy. Post neoadjuvant treatment, a third of the samples from patients who did not have a complete pathologic response displayed loss of the HER2 amplification that had been present in their pretreatment-biopsy specimens. Another means by which cancers develop resistance is the acquisition of additional genetic aberrations. In lung cancer, a second mutation in EGFR (T790M) and MET amplification have been described as two main mechanisms of drug resistance to EGFR inhibitors erlotinib and gefitinib. Other mechanisms like novel genetic changes, including HER2 and EGFR amplification, PIK3CA mutations, and markers of epithelial-to-mesenchymal transition have also been reported in EGFR inhibitor resistant lung. Analysis of metastases from patients with colorectal cancer who developed resistance to cetuximab or panitumumab showed the emergence of KRAS amplification in one sample and acquisition of secondary KRAS mutations in 60% of the cases. These studies emphasize the utility of repeat tumor biopsy specimens at the time of relapse or progression to identify mechanisms of resistance and best combinatorial therapies.

### RADIATION THERAPY

#### Physical Basis of Radiation Therapy

**Ionizing radiation** is energy strong enough to remove an orbital electron from an atom. This radiation can be electromagnetic, like a high-energy photon, or particulate, such as an electron, proton, neutron, or alpha particle. Radiation therapy is delivered primarily as high-energy photons (gamma rays and X-rays) and charged particles (electrons). Gamma rays are photons that are released from the nucleus of a radioactive atom. X-rays are photons that are created electronically, such as with a clinical linear accelerator. Currently, high-energy radiation is delivered to tumors primarily with linear accelerators. X-rays traverse the tissue, depositing the maximum dose beneath the surface, and thus spare the skin. Electrons are used to treat superficial skin lesions, superficial tumors, or surgical beds to a depth of 5 cm. Gamma rays typically are produced by radioactive sources used in brachytherapy.

The dose of radiation absorbed correlates with the energy of the beam. The basic unit is the amount of energy absorbed per unit of mass (joules per kilogram) and is known as a gray (Gy). One gray is equivalent to 100 rads, the unit of radiation measurement used in the past.

#### Biologic Basis of Radiation Therapy

Radiation deposition results in DNA damage manifested by single- and double-strand breaks in the sugar phosphate backbone of the DNA molecule. Cross-linking between the DNA strands and chromosomal proteins also occurs. The mechanism of DNA damage differs by the type of radiation delivered. Electromagnetic radiation is indirectly ionizing through the actions of short-lived hydroxyl radicals, which are produced primarily by the ionization of cellular hydrogen peroxide ($H_2O_2$). Protons and other heavy particles are directly ionizing and directly damage DNA.
Radiation damage is manifested primarily by the loss of cellular reproductive integrity. Most cell types do not show signs of radiation damage until they attempt to divide, so slowly proliferating tumors may persist for months and appear viable. Some cell types, however, undergo apoptosis.

The extent of DNA damage after radiation exposure is dependent on several factors. The most important of these is cellular oxygen. Hypoxic cells are significantly less radiosensitive than aerated cells. The presence of oxygen is thought to prolong the half-life of free radicals produced by the interaction of X-rays and cellular H$_2$O$_2$, and thus indirectly ionizing radiation is less efficacious in tumors with areas of hypoxia. In contrast, radiation damage from directly ionizing radiation is independent of cellular oxygen levels.

The extent of DNA damage from indirectly ionizing radiation is dependent on the phase of the cell cycle. The most radiation-sensitive phases are G$_1$ and M, whereas G$_2$ and late S phases are less sensitive. Thus, irradiation of a population of tumor cells results in killing of a greater proportion of cells in G$_2$ and M phases. However, delivery of radiation in divided doses, a concept referred to as fractionation, allows the surviving G$_1$ and S phase cells to progress to more sensitive phases, a process referred to as reassortment. In contrast to DNA damage after indirectly ionizing radiation, that after exposure to directly ionizing radiation is less dependent on the cell-cycle phase.

Several chemicals can modify the effects of ionizing radiation. These include hypoxic cell sensitizers such as metronidazole and misonidazole, which mimic oxygen and increase cell kill of hypoxic cells. A second category of radiation sensitizers are the thymidine analogues iododeoxyuridine and bromodeoxyuridine. These molecules are incorporated into the DNA in place of thymidine and render the cells more susceptible to radiation damage; however, they are associated with considerable acute toxicity. Several other chemotherapeutic agents sensitize cells to radiation through various mechanisms, including 5-fluorouracil, actinomycin D, gemcitabine, paclitaxel, topotecan, doxorubicin, and vinorelbine. The development of novel radiosensitizers is an active area of research and multiple small molecules as well as novel nanomaterials are under investigation.

Radiation Therapy Planning

Radiation therapy is delivered in a homogeneous dose to a well-defined region that includes tumor and/or surrounding tissue at risk for subclinical disease. The first step in planning is to define the target to be irradiated as well as the dose-limiting organs in the vicinity. Treatment planning includes evaluation of alternative treatment techniques, which is done through a process referred to as simulation. Once the beam distribution that will best achieve homogeneous delivery to the target volume and minimize the dose to the normal tissue is determined, immobilization devices and markings or tattoos on the patient’s skin are used to ensure that each daily treatment is given in the same way. Conventional fractionation is 1.8 to 2 Gy/d, administered 5 days each week for 3 to 7 weeks.

Radiation therapy may be used as the primary modality for palliation in certain patients with metastatic disease, primarily patients with bony metastases. In these cases, radiation is recommended for symptomatic metastases only. However, lytic metastases in weight-bearing bones such as the femur, tibia, or humerus also are considered for irradiation. Another circumstance in which radiation therapy might be appropriate is spinal cord compression due to metastases to the vertebral body that extend posteriorly to the spinal canal.

The goal of adjuvant radiation therapy is to decrease local-regional recurrence rates. Adjuvant radiation therapy can be given before surgery, after surgery, or in selected cases, during surgery. Preoperative radiation therapy has several advantages. It may minimize seeding of the tumor during surgery and it allows for smaller treatment fields because the operative bed has not been contaminated with tumor cells. Also, radiation therapy for inoperable tumors may achieve adequate reduction to make them operable. The disadvantages of preoperative therapy are an increased risk of postoperative wound healing problems and the difficulty in planning subsequent radiation therapy in patients who have positive surgical margins. If radiation therapy is given postoperatively, it is usually given 3 to 4 weeks after surgery to allow for wound healing. The advantage of postoperative radiation therapy is that the surgical specimen can be evaluated histologically and radiation therapy can be reserved for patients who are most likely to benefit from it. Further, the radiation therapy can be modified on the basis of margin status. The disadvantages of postoperative radiation therapy are that the volume of normal tissue requiring irradiation may be larger owing to surgical contamination of the tissue planes and that the tumor may be less sensitive to radiation owing to poor oxygenation. Postlaparotomy adhesions may decrease the mobility of the small bowel loops, increasing the risk for radiation injury in abdominal or pelvic irradiation. Given the potential advantages and disadvantages of both approaches, the roles of preoperative and postoperative radiation therapy are being actively evaluated and compared for many cancer types.

Another mode of postoperative radiation therapy is brachytherapy. In brachytherapy, unlike in external beam therapy, the radiation source is in contact with the tissue being irradiated. The radiation source may be cesium, gold, iridium, or radium. Brachytherapy is administered via temporary or permanent delivery implants such as needles, seeds, or catheters. Temporary brachytherapy catheters are placed either during open surgery or percutaneously soon after surgery. The implants are loaded interstitially, and treatment usually is given postoperatively for a short duration, such as 1 to 3 days. Although brachytherapy has the disadvantages of leaving scars at the catheter insertion site and requiring special facilities for inpatient brachytherapy, the advantage of patient convenience owing to the shorter treatment duration has made intracavitary treatment approaches popular for the treatment of breast cancer.

Another short delivery approach is intraoperative radiotherapy (IORT), often used in combination with external beam therapy. The oncologic consequences of the limited treatment volume and duration associated with brachytherapy and IORT are not well understood. Accelerated partial breast irradiation with interstitial brachytherapy, intracavitary brachytherapy (MammoSite), IORT, and three-dimensional conformal external beam radiotherapy is being compared with whole breast irradiation in an intergroup phase 3 trial (NSABP B-39/Radiation Therapy Oncology Group 0413). Several additional studies of adjuvant IORT also are ongoing internationally. There has also been increased interest in utilizing intensity-modulated radiation therapy (IMRT). IMRT is a complex technique for the delivery of radiation therapy preferentially to target structures while minimizing doses to adjacent normal critical structures. It is widely utilized for the treatment of a variety of tumor types, including
the central nervous system, head and neck, breast, prostate, gastrointestinal tract, and gynecologic organs, as well as in patients where previous radiation therapy has been delivered. Stereotactic radiosurgery uses extremely accurate image-guidance and patient positioning to deliver a high dose of radiation to a small tumor with well-defined margins. In this manner, the dose of radiation being applied to normal tissues can be minimized. It is most commonly used for the treatment of brain and spinal tumors. Protons are a charged particle that can be also used in external beam radiation therapy. Proton therapy employs a beam of protons as a means of delivering radiation to a tumor. In contrast to photons, which deposit energy continuously during their passage through tissue, protons deposit a large amount of their energy near the end of their path (known as the Bragg peak) and release less energy along the way. Thus, proton therapy could theoretically reduce the exposure of normal tissue to radiation, allowing the delivery of higher doses of radiation to a tumor. It is thought that chemoradiation given concurrently with radiation improves survival rates. Chemotherapy before radiation has the advantage of reducing the tumor burden, which facilitates radiation therapy. On the other hand, some chemotherapy regimens, when given concurrently with radiation, may sensitize the cells to radiation therapy. Chemoradiation is being investigated in many tumor types, including rectal cancer, pancreatic cancer, and esophageal cancer. In a Cochrane review of six randomized controlled trials, it was demonstrated that in patients with T3/4 rectal cancer, chemoradiation was associated with a significantly lower local recurrence rate compared with radiation therapy alone (OR 0.56, 95% CI 0.42–0.75, \( P < 0.0001 \)) but was not associated with improved survival.

**Side Effects**

Both tumor and normal tissue have radiation dose-response relationships that can be plotted as a sigmoidal curve (Fig. 10-16). A minimum dose of radiation must be given before any response is seen. The response to radiation then increases slowly with an increase in dose. At a certain dose level the curves become exponential, with increases in tumor response and normal tissue toxicity with each incremental dose increase. The side effects of radiation therapy can be acute, occurring during or 2 to 3 weeks after therapy, or chronic, occurring weeks to years after therapy. The side effects depend on the tissue included in the target volume. Some of the major acute and chronic sequelae of radiation are summarized in Table 10-13. In addition to these effects, a small increase in the risk for secondary malignancies is attributable to radiation therapy.

**CANCER PREVENTION**

The truth of the old axiom “An ounce of prevention is worth a pound of cure” is being increasingly recognized in oncology. Cancer prevention can be divided into three categories: (a) primary prevention (i.e., prevention of initial cancers in healthy individuals), (b) secondary prevention (i.e., prevention of cancer in individuals with premalignant conditions), and (c) tertiary prevention (i.e., prevention of second primary cancers in patients cured of their initial disease).

The systemic or local administration of therapeutic agents to prevent the development of cancer, called chemoprevention, is being actively explored for several cancer types. In breast cancer, the NSABP Breast Cancer Prevention Trial demonstrated that tamoxifen administration reduces the risk of breast cancer by one half and reduces the risk of estrogen receptor-positive tumors by 69% in high-risk patients. Therefore, tamoxifen has been approved by the FDA for breast cancer chemoprevention. The subsequent NSABP P-2 trial demonstrated that raloxifene is as effective as tamoxifen in reducing the risk of invasive breast cancer and is associated with a lower risk of thromboembolic events and cataracts but a nonstatistically significant higher risk of noninvasive breast cancer; these findings led the FDA to approve raloxifene for prevention as well. Several other agents are also under investigation. Celecoxib (a cyclooxygenase 2 [COX-2] inhibitor) has been shown to reduce polyp number and polyp burden in patients with FAP, which led to its approval by the FDA for these patients. However, celecoxib is no longer widely used as a primary preventative treatment in this setting due to the association between COX-2 inhibitors and coronary artery disease. In head and neck cancer, 13-cis-retinoic acid has been shown both to reverse oral leukoplakia and to reduce second primary tumor development. However, a large phase 3 clinical trial that utilized low-dose 13-cis-retinoic acid in patients with early stage squamous cell carcinoma of the head and neck showed no significant difference in the incidence of tumor recurrence or the second primary tumors between the placebo and chemoprevention arms. Thus, the chemoprevention trials completed so far have had mixed results. Much remains to be done over the next few years to improve outcomes and decrease therapy-related toxic effects. It is important for surgeons to be aware of these preventive options because they are likely to be involved in the diagnosis of premalignant and malignant conditions and will be the ones to counsel patients about their chemopreventive options.

In selected circumstances, the risk of cancer is high enough to justify surgical prevention. These high-risk settings include hereditary cancer syndromes such as hereditary breast-ovarian cancer syndrome, hereditary diffuse gastric cancer, multiple endocrine neoplasia type 2, FAP, and hereditary nonpolyposis colorectal cancer, as well as some nonhereditary...
conditions such as chronic ulcerative colitis. Most prophylactic surgeries are large ablative surgeries (e.g., bilateral risk-reducing mastectomy or total proctocolectomy). Therefore, it is important that the patient be completely informed about potential surgical complications as well as long-term lifestyle consequences. Further, the conservative options of close surveillance and chemoprevention need to be discussed. The patient’s cancer risk needs to be assessed accurately and implications for survival discussed. Ultimately, the decision to proceed with surgical prevention should be individualized and made with caution.

### TRENDS IN ONCOLOGY

#### Cancer Screening and Diagnosis

It is clear that the practice of oncology will change dramatically over the next few decades because our understanding of the molecular basis of cancer and available technologies are evolving rapidly. One of the critical changes expected is earlier detection of cancers. With improvements in available imaging modalities and development of newer functional imaging techniques, it is likely that many tumors will be detected at earlier, more curable stages in the near future.

Another area of rapid development is the identification of serum markers. High-throughput technologies such as matrix-assisted laser desorption ionization time-of-flight mass spectrometry and liquid chromatography ion-spray tandem mass spectrometry have revolutionized the field of proteomics and are now being used to compare the serum protein profiles of patients with cancer with those of individuals without cancer. Identification of unique proteins as well as unique proteomic profiles for most cancer types is being pursued actively by many researchers and, if successful, could dramatically enhance our ability to detect cancers early.

DNA fragments that are derived from tumors and are circulating in the blood stream are referred to as circulating tumor DNA (ctDNA). Analysis of ctDNA can potentially provide information on the entire tumor genome and has potential clinical utility as a so-called “liquid biopsy” when blood samples are obtained during important junctures of a clinical scenario. ctDNA may originate directly from the tumor or from circulating tumor cells, which refers to intact tumor cells that are shed from primary tumors and enter the bloodstream. The precise mechanism of ctDNA release has not been determined; however, there is evidence to show that the length of the DNA fragments are similar to those seen during the process of apoptosis. ctDNA can be reliably procured from peripheral blood and analyzed via a number of advanced techniques, including next generation sequencing. The main advantages of using ctDNA in genomic studies is the ability to obtain information on the entire tumor genome, thus avoiding the difficulties of tumor heterogeneity that are encountered with needle biopsies, and the ability to obtain multiple samples with much less risk to the patient.

#### Surgical Therapy

The current trend in surgery is toward more conservative resections. With earlier identification of tumors, more conservative operations may be possible. The goal, however, is always to remove the tumor en bloc with wide negative margins. Another interesting area being explored is the destruction of tumors by techniques such as radiofrequency ablation, cryoablation, and heat-producing technologies like lasers, microwaves, or focused ultrasound.

The debate over how to manage the regional lymph node basins for certain cancer types continues. With an increasing understanding of the metastatic process, surgeons may be able to stratify patients on the basis of the likelihood that their disease will spread metastatically, based on the gene expression profile of their primary tumors, and offer regional therapy accordingly. There is also a growing interest in minimally invasive surgical treatments for a variety of cancer types.

#### Systemic Therapy

The current trend in systemic therapy is toward individualized therapy. Therefore, the intent is to determine the underlying biology of each tumor to tailor therapy accordingly. Genomic, transcriptional, and proteomic profiling approaches are being used to identify molecular signatures that correlate

with response to certain agents. It is likely that in the near future all tumors can be tested and treatments individualized. Patients who will respond to conventional therapies can be treated with these regimens, whereas patients who will not respond will not, which spares them the toxicity. Instead, the latter patients can be offered novel therapies. Furthermore, with the advent of effective immune-based therapies, it is likely that patients may be given treatments that can specifically target the alterations driving tumor growth in combination with drugs that can enhance the anticancer immune response. Patients can be genotyped for critical alleles that may affect drug metabolism and thus, may influence the efficacy as well as the side effects of the drugs given. Finally, stratification of patients by gene expression profile for prognosis may assist in determining which patients are at higher risk of relapse so that patients whose tumors have less aggressive biologic characteristics can be spared further therapy.

BACKGROUND

Organ transplantation is a relatively novel field of medicine that has made significant progress since the second half of the 20th century. Advances in surgical technique and a better understanding of immunology are the two main reasons that transplants have evolved from experimental procedures, just several decades ago, to a widely accepted treatment today for patients with end-stage organ failure. Throughout the world, for a variety of indications, kidney, liver, pancreas, intestine, heart, and lung transplants are now the current standard of care.

But the success of transplantation has created new challenges. A better understanding of the pathophysiology of end-stage organ failure as well as advances in critical care medicine and in the treatment of various diseases led to expanding the criteria for, and decreasing the contraindications to, transplants. As a result, the discrepancy between the ever-growing number of patients awaiting a transplant and the limited number of organs available is one of the field’s biggest challenges (Fig. 11-1). In 2017 alone, according to the United Network for Organ Sharing (UNOS), about 115,000 patients in the United States were awaiting a transplant, yet the number of transplants performed approached only about 35,000 (Fig. 11-2).

DEFINITIONS

In addition to being the overall name of this relatively new field of medicine, transplantation is the process of transferring an organ, tissue, or cell from one place to another. An organ transplant is a surgical procedure in which a failing organ is replaced by a functioning one. The organ is transplanted either orthotopically (implanted in the same anatomic location in the recipient as it was in the donor) or heterotopically (implanted in...
Key Points

1. The field of transplantation has made tremendous advances in the last 50 years, mainly due to refinements in surgical technique and development of effective immunosuppressive medications.

2. Although immunosuppressive medications are essential for transplantation, they are associated with significant short- and long-term morbidity.

3. Opportunistic infections can be significantly lowered by the use of appropriate antimicrobial agents.

4. Kidney transplantation represents the treatment of choice for almost all patients with end-stage renal disease. The gap between demand (patients on the waiting list) and supply (available kidneys) continues to widen.

5. Pancreas transplantation represents the most reliable way to achieve euglycemia in patients with poorly controlled diabetes.

6. The results of islet transplantation continue to improve but still trail those of pancreas transplantation.

7. Liver transplantation has become the standard of care for many patients with end-stage liver failure and/or liver cancer.

Another anatomic location. Orthotopic transplants require the removal of the diseased organ (heart, lungs, liver, or intestine); in heterotopic transplants, the diseased organ is kept in place (kidney, pancreas).

According to the degree of immunologic similarity between the donor and recipient, transplants are divided into three main categories: (a) an autotransplant is the transfer of cells, tissue, or an organ from one part of the body to another part in the same person, so no immunosuppression is required; this type of transplant includes skin, artery or vein, bone, cartilage, nerve, and islet cell transplants; (b) an allotransplant is the transfer of cells, tissue, or an organ from one person to another of the same species; with the exception of identical twins, the immune system of the recipient recognizes the donated organ as a foreign body, so immunosuppression is required in order to avoid rejection; and (c) a xenotransplant is the transfer of cells, tissue, or an organ from one organism to another of a different species. To date, animal-to-human transplants are still experimental procedures, given the very complex immunologic and infectious issues that have yet to be solved.

HISTORY

Over the centuries, many different references to transplantation can be found in the world’s literature, yet transplantation as a recognized scientific and medical field began to emerge only in the middle of the 20th century. Two major events led to the rise of transplantation.

First, the surgical technique of the vascular anastomosis was developed by the French surgeon Alexis Carrel.1 This led to increased transplant activity, especially in animal models. Russian surgeon Yu Yu Voronoy was the first to report a series of human-to-human kidney transplants in the 1940s.2 But the outcomes were dismal, mainly because of the lack of understanding of the underlying immunologic processes.

Second, the findings of British scientist Sir Peter B. Medawar in the 1940s were also key.3 In his work with skin grafts in animal models and in human burn patients, he learned that the immune system plays a crucial role in the failure of skin grafts. His research led to a better understanding of the immune system and is considered to be the birth of transplant immunobiology.

The first human transplant with long-term success was performed by Joseph Murray in Boston, Massachusetts, in 1954.4 Because it was a living related kidney transplant between identical twins, no immunosuppression was required; the recipient lived for another 8 years before he died of issues unrelated to the transplanted kidney. Other centers performed similar transplants and could reproduce similar good results.

Ultimately, attempts were made to perform kidney transplants between nonidentical individuals. For immunosuppression, total-body radiation and an anticancer agent called # Waiting # Transplanted Figure 11-1. Patients on the waiting list and the number of organ transplants performed, 2000 to 2009. (U.S. data from the Scientific Registry of Transplant Recipients Annual Report, http://srtr.org)
6-mercaptopurine were used, but given the profound toxicity of both those methods of immunosuppression, results were discouraging. A breakthrough was achieved in the early 1960s with the introduction of maintenance immunosuppression through a combination of corticosteroids and a less toxic derivative of 6-mercaptopurine, azathioprine.\(^5,6\)

Increasing experience with kidney transplants and the better results achieved with maintenance immunosuppression paved the way for the era of nonrenal transplants (Table 11-1). In 1963, the first liver transplant was performed by Thomas Starzl in Denver, Colorado, and the first lung transplant was performed by James Hardy in Jackson, Mississippi. In 1966, the first pancreas transplant was performed by William Kelly and Richard Lillehei in Minneapolis, Minnesota. In 1967, the first successful heart transplant was performed by Christiaan Barnard in Cape Town, South Africa. The early years of transplantation were marked by high mortality, mainly because of irreversible rejection. However, dramatic advances occurred with the further development of new forms of immunosuppression. The groundbreaking event was the introduction of the first anti-T lymphocyte (T cell) drug, cyclosporine, in the early 1980s.\(^7\) Since then, with an even better understanding of immunologic processes, many other drugs have been introduced that target specific pathways that lead to rejection. As a result, rejection rates have decreased substantially, allowing a 1-year graft survival rate in excess of 80% in all types of transplants.

The gradual increase in the organ shortage led to innovative surgical techniques. For example, deceased donor split-liver transplants and living donor liver transplants have helped expand the liver donor pool. Similarly, living donor intestine and pancreas techniques have been developed. The evolution of donor nephrectomy from an open to a minimally invasive procedure (laparoscopic or robotic) has helped increase the pool of living kidney donors.

## TRANSPLANT IMMUNOBIOLOGY

The outcomes of early transplants were less than satisfactory. The limiting factor was the lack of understanding of immunologic processes, and irreversible rejection was the reason for graft loss in the vast majority of recipients. A better understanding of transplant immunobiology led to significant improvements in patient and graft survival rates.\(^8,9\) The immune system is designed as a defense system to protect the body from foreign pathogens, such as viruses, bacteria, and fungi, but it also acts to reject transplanted cells, tissues, and organs, recognizing them as foreign. It mediates other complex processes as well, such as the body’s response to trauma or to tumor growth. No matter what type of agent, the immune system recognizes it as foreign and triggers a strong response that is designed to either eradicate pathogenic organisms or reject foreign cells or tissue.

**TRANSPORT ANTIGENS**

Transplants between genetically nonidentical persons lead to recognition and rejection of the organ by the recipient’s immune system, if no intervention is undertaken. The main antigens responsible for this process are part of the major histocompatibility complex (MHC). In humans, these antigens make up the human leukocyte antigen (HLA) system. The antigen-encoding genes are located on chromosome 6. Two major classes of HLA antigens are recognized. They differ in their structure, function, and tissue distribution. Class I antigens (HLA-A, HLA-B, and HLA-C) are expressed by all nucleated cells. Class II antigens (HLA-DR, HLA-DP, and HLA-DQ) are expressed by antigen-presenting cells (APCs) such as B lymphocytes, dendritic cells, macrophages, and other phagocytic cells.

The principal function of HLA antigens is to present the fragments of foreign proteins to T lymphocytes. This leads to recognition and elimination of the foreign antigen with great specificity. HLA molecules play a crucial role in transplant recipients as well. They can trigger rejection of a graft via two different mechanisms. The most common mechanism is cellular rejection, in which the damage is caused by activated T lymphocytes. The process of activation and proliferation is triggered by exposure of T lymphocytes to the donor’s HLA molecules. The other mechanism is humoral rejection, in which the damage is mediated by circulating antibodies against the donor’s HLA molecules. The donor-specific antibodies can be present either pretransplant, due to previous exposure (because of a previous transplant, pregnancy, blood transfusion, or immunization), or posttransplant. After antibody binding to the donor’s HLA molecules, the complement cascade is activated, leading to cellular lysis.

**ALLORECOGNITION AND LYMPHOCYTE ACTIVATION**

The immune system of each person is designed to discriminate between self and nonself cells and tissues. This process is called allore cognition, with T cells playing the crucial role. The recognition of foreign HLA antigens by the recipient’s T cells may occur by either a direct or an indirect pathway. Direct recognition occurs when the recipient’s T cells are activated by direct interaction with the donor’s HLA molecules. Indirect recognition occurs when the recipient’s T cells are activated by interaction with APCs that have processed and presented the foreign antigen. The foreign antigen can be shed from the graft into the circulation, or it can be identified by the APCs within the graft itself.

Independent of the pathway of foreign HLA antigen presentation, the ensuing activation of T cells is similar and involves complex cell surface receptors and markers, i.e., the T-cell receptor (TCR) and an array of cluster differentiation markers (CDs). A two-signal model, T-cell activation begins with the engagement of the TCR/CD3 complex with the foreign molecule. This interaction causes transmission of the signal into the cell, namely signal 1. However, this signal alone is not sufficient to activate the T cell. An additional costimulatory signal is required, i.e., signal 2. Two well-characterized costimulatory interactions are the CD40/CD154 and B7/CD28 pathways. The “master switch” is turned on by the interaction of CD40 protein with APCs, along with the interaction of CD154 protein with T cells; this ligation induces the upregulation of other costimulatory molecules. Transmission of signal 1 and signal 2 into the cell nucleus leads to upregulation of the transcription of genes for several cytokines, including the T-cell growth factor interleukin-2 (IL-2). In turn, IL-2 activates a number of pathways, leading to proliferation and differentiation of T cells. Rejection is the result of an attack of activated T cells on the transplanted organ.

Although T-cell activation is the main culprit in rejection, B-cell activation and subsequent antibody production also play a role. After the foreign HLA antigen is processed by B cells, it interacts with activated helper T cells, leading to differentiation of B cells into plasma cells and subsequently to their proliferation and antibody production.

**CLINICAL REJECTION**

Graft rejection is due to a complex interaction of different components of the immune system, including B and T lymphocytes, APCs, and cytokines. The end result is graft damage caused by inflammatory injury. According to its onset and pathogenesis, rejection is divided into three main types: hyperacute, acute, and chronic, and each is described in the following sections.

**Hyperacute**

Hyperacute rejection, a very rapid type of rejection, results in irreversible damage and graft loss within minutes to hours after organ reperfusion. It is triggered by preformed antibodies against the donor’s HLA or ABO blood group antigens. These antibodies activate a series of events that result in diffuse intravascular coagulation, causing ischemic necrosis of the graft. Fortunately, pretransplant blood group typing and cross-matching (in which the donor’s cells are mixed with the recipient’s serum, and then the cells are observed for any destruction) have virtually eliminated the incidence of hyperacute rejection.

**Acute**

Acute rejection, the most common type of rejection, usually occurs within a few days or weeks posttransplant. According to the mechanism involved, it is further divided into cellular (T-cell–mediated) rejection, humoral (antibody-mediated) rejection, or a combination of both. The diagnosis is based on the results of biopsies of the transplanted organ, special immunologic stains, and laboratory tests (such as elevated creatinine levels in kidney transplant recipients, elevated liver test values in liver transplant recipients, and elevated levels of glucose, amylase, and lipase in pancreas transplant recipients).

**Chronic**

Chronic rejection occurs slowly and usually is progressive. It can manifest within the first year posttransplant but most often takes place gradually over several years. The mechanisms are not well understood, but the pathologic changes eventually lead to tissue fibrosis and loss of graft function. As advances in immunosuppression have diminished the incidence of acute rejection, this form of rejection is becoming more common.

**CLINICAL IMMUNOSUPPRESSION**

A successful transplant hinges upon a balance between the extent of the recipient’s immune response, the health and viability of the donor allograft, and pharmacologic immunosuppression. Immunosuppressive regimens are critical to graft and
patient survival posttransplant. Immunosuppression has evolved from the use of azathioprine and steroids in the 1960s and 1970s to the development in the 1980s of cyclosporine, the latter which markedly increased allograft survival. \(^2\) The introduction of tacrolimus and mycophenolate mofetil (MMF) in the 1990s further advanced the field of transplantation, enabling a variety of combinations to be used for immunosuppression often “tailored” for each recipient (Table 11-2).

Presently, immunosuppressants are used in multidrug regimens aimed at increasing efficacy by targeting multiple pathways to lower the immune response and to decrease the toxicity of individual agents. Certain regimens may involve withdrawal, avoidance, or minimization of certain classes of drugs. Transplant centers generally institute their immunosuppressive protocols based on experience, risk profiles, cost considerations, and outcomes. Immunosuppression is delivered in two phases: induction (starting immediately posttransplant, when the risk of rejection is highest) and maintenance (usually starting within days posttransplant and usually continuing for the life of the graft and the recipient). Thus, the degree of immunosuppression is highest in the first 3 to 6 months posttransplant; during this time, prophylaxis against a number of different bacterial, viral, or even antifungal opportunistic pathogens is administered. \(^12\) \(^13\)

A conventional immunosuppressive protocol might include (a) induction with anti-T-lymphocyte–depleting or nondepleting antibodies and (b) maintenance with calcineurin inhibitors, antiproliferative agents, and corticosteroids. Characteristics of the most common immunosuppressive agents are listed in Table 11-3.

**INDUCTION**

Induction includes the use of depleting (polyclonal) antibodies or nondepleting antibodies within the first month posttransplant. Studies have shown that induction with antibody regimens may prevent acute rejection, potentially leading to improved graft survival and the use of less maintenance immunosuppression.

**Depleting Antibodies**

Rabbit antithymocyte globulin (Thymoglobulin) is a purified gamma globulin obtained by immunizing rabbits with human thymocytes. Atgam, which has largely been replaced by Thymoglobulin, is a purified gamma globulin obtained by immunizing horses with human thymocytes. These agents contain antibodies to T cells and B lymphocytes (B cells), integrins, and other adhesion molecules, thereby resulting in rapid depletion of peripheral lymphocytes. Typically, the total dose of Thymoglobulin is roughly 6 mg/kg, a dose that has been shown to confer adequate lymphocyte depletion and better allograft survival. Doses of 3 mg/kg may not effectively prevent acute rejection, but more doses and prolonged administration increase the risk of infection and the potential occurrence of lymphoma. Thymoglobulin administration causes a cytokine release syndrome, so premedications (acetaminophen and diphenhydramine) are usually given. The principal side effects of Thymoglobulin include fever, chills, arthralgias, thrombocytopenia, leukopenia, and an increased incidence of a variety of infections. \(^14\) \(^15\)

**Nondepleting Antibodies**

Basiliximab (Simulect) is an anti-CD25 monoclonal antibody. The alpha subunit of the IL-2 receptor, also known as Tac or CD25, is found exclusively on activated T cells. Blockade of this component by this monoclonal antibody selectively prevents IL-2–induced T-cell activation. No lymphocyte depletion occurs with basiliximab; thus, it is not designed to be used to treat acute rejection. Its selectivity in blocking IL-2–mediated responses makes it a powerful induction agent without the added risks of infections, malignancies, or other major side effects. Currently, basiliximab is the only available anti-CD25 monoclonal antibody approved for clinical use. Usually, it is followed by the use of calcineurin inhibitors, corticosteroids, and MMF as maintenance immunosuppression. \(^16\)

Alemtuzumab (Campath, Lemtrada), another anti-CD52 monoclonal antibody, was initially used to treat chronic lymphocytic leukemia. The use of alemtuzumab has grown in the field of transplantation, given its profound lymphocyte-depleting effects. It causes cell death by complement-mediated cytolsis, antibody-mediated cytotoxicity, and apoptosis. One dose alone (30 mg) depletes 99% of lymphocytes. Monocyte recovery can be seen at 3 months posttransplant; B-cell recovery at 12 months; and T-cell recovery, albeit only to 50% of baseline, at 36 months. Alemtuzumab causes a significant cytokine release reaction and often requires premedications (steroids and antihistamines). Because of the long-lasting T-cell depletion, the risks of infection and posttransplant lymphoproliferative disorder remain. Initially, alemtuzumab was available only through a limited distribution program, but more recently has been studied in a number of clinical trials. \(^17\) \(^18\)

**MAINTENANCE**

**Corticosteroids**

Corticosteroids have had a role in immunosuppression since the beginning of the field of transplantation. Despite numerous

FKBP = FK506-binding protein; GI = gastrointestinal; IL = interleukin; IV = intravenous; LDL = low-density lipoprotein; PO = oral

Attempts to limit or discontinue their use, they remain an integral component of most immunosuppressive protocols, for both induction and maintenance. Moreover, they are often the first-line agents in the treatment of acute rejection. Steroids bind to glucocorticoid-responsive elements in DNA that prevent the transcription of cytokine genes and cytokine receptors. In addition, steroids have an impact on lymphocyte depletion, on the transcription of cytokine genes and cytokine receptors. In glucocorticoid-responsive elements in DNA that prevent calcineurin activity and decreases antibody production. It has been used as a first-line agent in transplant recipients for more than 40 years, but it became an adjunctive agent after the introduction of cyclosporine. With the development of newer agents such as MMF, the use of AZA has decreased significantly. However, it is preferred in recipients who are considering conceiving a child because MMF is teratogenic and can cause birth defects. Use of AZA remains an option for recipients who cannot tolerate the gastrointestinal (GI) side effects of MMF.

**Azathioprine**

An antimetabolite, azathioprine (AZA) is converted to 6-mercaptopurine and inhibits both the de novo purine synthesis and salvage purine synthesis. AZA decreases T-lymphocyte activity and decreases antibody production. It has been used as a first-line agent in transplant recipients for more than 40 years, but it became an adjunctive agent after the introduction of cyclosporine. With the development of newer agents such as MMF, the use of AZA has decreased significantly. However, it is preferred in recipients who are considering conceiving a child because MMF is teratogenic and can cause birth defects. Use of AZA remains an option for recipients who cannot tolerate the gastrointestinal (GI) side effects of MMF.

The most significant side effect of AZA, often dose-related, is bone marrow suppression. Leukopenia is often reversible with dose reduction or temporary cessation of the drug. Other significant side effects include hepatotoxicity, pancreatitis, neoplasia, anemia, and pulmonary fibrosis. Its most significant drug interaction is with allopurinol, which blocks AZA metabolism, increasing the risk of pancytopenia. Recommendations are to not use AZA and allopurinol together, or if doing so is unavoidable, to decrease the dose of AZA by 75%.
Mycophenolate Mofetil

Approved in May 1995 by the U.S. Food and Drug Administration (FDA) for preventing acute rejection after kidney transplants, MMF has now been incorporated into routine maintenance regimens after many solid organ transplants. Mycophenolate is the prodrug of mycophenolate acid, derived from Penicillium fungi. Mycophenolate acid is an inhibitor of inosine monophosphate dehydrogenase (IMPDH) involved in the de novo pathway of purine synthesis. MMF is available in capsules (250 and 500 mg); the starting dose is 1 g twice daily. In hopes of decreasing the GI side effects, an enteric-coated formulation called Myfortic was developed; its benefits have not been clearly demonstrated in studies, but in some conversion studies patients did report less GI intolerance. The pharmacokinetics of MMF are complex; mycophenolic acid (MPA) levels are not routinely performed at most transplant centers. Studies have shown that MPA levels and the incidence of rejection are not significantly correlated. The most common side effects of MMF are GI in nature, most commonly diarrhea, nausea, dyspepsia, and bloating. Esophagitis and gastritis occur in roughly 5% of recipients and may represent a cytomegalovirus (CMV) or herpesvirus family infection. The other important side effects are leukopenia, anemia, and thrombocytopenia (Table 11-4). Leukopenia can sometimes be reversed by lowering the MMF dose and discontinuing other agents like valganciclovir. MMF does not have any significant drug interactions, but clinicians should be careful to avoid additive toxicities with other medications that might lead to leukopenia and thrombocytopenia.

Sirolimus

The first mammalian target of rapamycin (mTOR) inhibitors to enter clinical use was sirolimus (Rapamune). A key regulatory kinase, mTOR changes cells from the G1 to S phase in the cell cycle, in response to proliferation signals provided by cytokines like IL-2. The mTOR inhibitors bind to FK506-binding protein (FKBP), and the sirolimus-FKBP complex binds to mTOR. Sirolimus also inhibits proliferation of vascular smooth muscle cells, possibly easing the vasculopathy and progressive fibrosis that can affect allografts. Sirolimus is a substrate for CYP3A4/4 and has many significant drug interactions (see Table 11-4).

To date, sirolimus has been used in a variety of combinations for maintenance immunosuppression, alone or in

conjunction with one of the calcineurin inhibitors. In such combinations, sirolimus usually is used to help withdraw from, or completely avoid, the use of steroids. It also has been used as an alternative to tacrolimus or cyclosporine, in a calcineurin-sparing protocol. One of the most significant side effects of sirolimus is hypertriglyceridemia, a condition that may be resistant to statins and fibrates. Impaired wound healing (immediately posttransplant in particular), thrombocytopenia, leukopenia, and anemia also are associated with sirolimus, and these problems are exacerbated when it is used in combination with MMF.25,26

### Cyclosporine

The introduction of cyclosporine in the early 1980s dramatically altered the field of transplantation by significantly improving outcomes after kidney transplantation. Cyclosporine binds with its cytoplasmic receptor protein, cyclophilin, which subsequently inhibits the activity of calcineurin, thereby decreasing the expression of several critical T-cell activation genes, the most important being for IL-2. As a result, T-cell activation is suppressed.27

Many formulations of cyclosporine exist, so it is important to know which one the transplant recipient is taking. Sandimmune, an older, oil-based formulation, has poor bioavailability and variable absorption. The newer formulations, Gengraf and Neoral, are microemulsified with improved bioavailability. Cyclosporine can be given intravenously or orally to maintain trough levels of 250 to 350 ng/mL for the first 3 months posttransplant; then it can be tapered to 150 to 250 ng/mL.28

The metabolism of cyclosporine is via the cytochrome P450 system, resulting in many significant drug interactions (see Table 11-4). Calcineurin inhibitors are nephrotoxic and constrict the afferent arteriole in a dose-dependent, reversible manner (Table 11-5). They also can cause hyperkalemia and hypomagnesemia. Several neurologic complications, including headaches, tremor, and seizures, also have been reported.29

Cyclosporine has several undesirable cosmetic effects, including hirsutism and gingival hyperplasia. It is associated with a higher incidence of hypertension and hyperlipidemia than is tacrolimus.

### Tacrolimus

The calcineurin inhibitor tacrolimus (Prograf) is now the backbone of most immunosuppressive regimens. Tacrolimus acts by binding FKBP, causing roughly 10 to 100 times more potent inhibition of IL-2 production than cyclosporine (which acts by binding cyclophilins). It can be given intravenously, orally, or sublingually to maintain trough levels of 8 to 12 ng/mL for the first 3 months posttransplant; then it can be tapered to 6 to 10 ng/mL. The metabolism of tacrolimus is via the cytochrome P450 system, resulting in many significant drug interactions (see Table 11-4).

Tacrolimus causes a higher incidence of new-onset diabetes posttransplant than does cyclosporine. Other side effects include alopecia, nephrotoxicity, neurotoxicity, hypertension, hyperkalemia, hypomagnesemia, and an increased incidence of certain types of infection.30

### Belatacept

The best-characterized pathway of T-cell costimulation includes CD28; its homologue, the cytotoxic T-lymphocyte–associated protein 4 (CTLA4); and their ligands, CD80 and CD86. Belatacept (also known as LEA29Y) was developed through two amino acid substitutions to abatacept (also known as CTLA4-Ig), a fusion protein consisting of the extracellular domain of CTLA4 and the Fc domain of immunoglobulin G (IgG). It is a high-avidity molecule with slower dissociation rates.

Clinical trials have compared the use of belatacept vs. a standard cyclosporine protocol in recipients of living donor, deceased donor, and extended-criteria donor kidneys. Belatacept was not inferior to cyclosporine in both patient and allograft survival rates, but was associated with a higher rate of biopsy-proven acute cellular rejection.

In terms of adverse effects, belatacept differs from standard calcineurin-based regimens because of an increased risk of posttransplant lymphoproliferative disorder (PTLD); the greatest risk is in recipients who are Epstein-Barr virus (EBV)-seronegative pretransplant. The FDA recommends the use of belatacept only in seropositive recipients. Studies in liver transplant recipients were halted early because of increased mortality rates.

However, belatacept does have a lower incidence of cardiovascular risk factors including metabolic lipid disorders, hypertension, neurotoxicity, glucose abnormalities, and adverse cosmetic effects. Except for the increased risk of malignancy, the more favorable adverse effect profile of belatacept and its convenient monthly dosing schedule may make it an attractive option for maintenance of immunosuppression, possibly improving compliance.31,32

### HUMORAL REJECTION

#### Rituximab

A chimeric anti-CD20 (anti-B cell) monoclonal antibody, rituximab is currently FDA approved for treating several types of lymphoma. The CD20 antigen is expressed early in the B-cell cycle but is absent on mature plasma cells. The variable region binds to CD20 through three different mechanisms: (a) antibody-dependent cell cytotoxicity, (b) complement-dependent cell killing, and (c) induction of apoptotic cell death. The use of

rituximab has grown to include the treatment of antibody-mediated rejection and use in desensitization protocols. Studies so far have been small, with rituximab usually used in conjunction with plasmapheresis, steroids, and intravenous immunoglobulin (IVIG).\textsuperscript{33,35}

**Bortezomib**

A proteasome inhibitor, bortezomib is FDA approved for treating multiple myeloma. It can directly target plasma cells. Traditional treatments have been successful in removing antibodies, inhibiting antibody activity, or lowering antibody production; however, targeting mature antibody production in plasma cells has not met with success. Bortezomib has been shown to cause apoptosis of normal plasma cells, thereby decreasing alloantibody production in sensitized patients. Several case reports and series have described the use of bortezomib for the treatment of antibody-mediated rejection and in desensitization protocols.\textsuperscript{34,36,37}

**Eculizumab**

A humanized monoclonal antibody with high affinity for C5, eculizumab is a first-in-class, FDA-approved agent for treating paroxysmal nocturnal hemoglobinuria, hemolytic uremic syndrome, and generalized myasthenia gravis. It blocks the activation of the terminal complement cascade. Most antibody-mediated rejection episodes are associated with early complement activation as evidenced on renal transplant biopsies by the presence of C4d\textsuperscript{+} staining of the peritubular capillaries. Given its highly selective mechanism of action, this agent is predicted to be useful to treat antibody-mediated rejection and to desensitize patients pretransplant. However, its serious adverse effects include an increased risk of infections, especially due to encapsulated bacteria such as Neisseria meningitidis. Patients should be immunized with meningococcal vaccine at least 2 weeks before the administration of eculizumab.\textsuperscript{34,38,39}

**INFECTIONS AND MALIGNANCIES**

Advances in immunosuppression have led to improved graft survival rates. However, the growing population of immunosuppressed patients, in turn, has led to an increased incidence of opportunistic infections and malignancies. Such posttransplant complications have become important barriers to long-term disease-free survival.

**Infections**

Transplant recipients are predisposed to a variety of infections. Immunosuppression is the obvious reason. Moreover, such patients have already endured end-stage organ disease pretransplant and then the stress of an invasive transplant operation. Posttransplant, they continue to have significant comorbid conditions.

**Early.** Early infections (i.e., infections occurring within 1 month posttransplant) can be due to a wide spectrum of pathogens (bacterial, viral, and fungal). In the immediate postoperative period, recipients are significantly compromised from the stress of the operation, from induction immunosuppression, and often from initially impaired graft function. Infections during this period can be devastating.

It is imperative to differentiate between medical and surgical infections. Surgical infections are the most common and require expedient surgical intervention. Typical examples include generalized peritonitis, intra-abdominal abscesses, and wound infections.

In liver and pancreas recipients, surgical infections are most severe. The incidence of intra-abdominal infections is decreasing, but they remain a significant problem: they are the second most common reason (after vascular thrombosis) for graft loss in pancreas recipients.

Lengthy operations with significant blood loss, prolonged warm and cold ischemic times, and spillage of contaminated fluid (bile, urine, or bowel contents) predispose patients to intra-abdominal infections. Other prominent risk factors are the high level of induction immunosuppression immediately posttransplant and anastomotic leaks. Furthermore, pretransplant infections can reemerge or worsen.

The signs and symptoms of intra-abdominal infections are those of peritonitis: fever, hypotension, ileus, and abdominal pain, although the latter can be masked by immunosuppression. Treatment entails a prompt return to the operating room. Intra-abdominal infections are usually polymicrobial, involving several bacterial and fungal species. Common bacterial isolates include Escherichia coli, as well as Enterococcus, Klebsiella, and Pseudomonas species. Common fungal isolates are Candida albicans, Candida krusei, and Candida glabrata. Localized infections or abscesses can be treated with percutaneous drainage and antibiotics.

Medical infections include respiratory, urinary tract, and bloodstream infections. Medical treatment should also be aggressive, often including empiric antibiotics and antifungal medications even before culture results are available. Recipients of organs from infected donors should be treated per the results of donor culture speciation and the antibiotic sensitivity profile.

**Late.** Late infections primarily are due to chronic immunosuppression, specifically the depression of cell-mediated immunity that renders recipients susceptible to viruses, fungi, and parasites.

Members of the herpesvirus group are the most common etiologic agents of viral infections posttransplantation, with herpes simplex virus (HSV), CMV, and EBV being the most prominent. Pretransplant exposure to viruses may confer immunity. Recipients who are seronegative for HSV, CMV, and/or EBV have a higher incidence of posttransplant infections, especially if they receive donor allografts from seropositive donors.

CMV is a latent infection that can be transmitted to seronegative recipients by donor organs from seropositive individuals, can reactivate during immunosuppression, or both. Infections usually occur 3 to 6 months posttransplant or during treatment for rejection. The incidence of CMV has been greatly reduced with 12-week acyclovir prophylaxis.\textsuperscript{40} CMV infections range from an asymptomatic or mild flu-like syndrome to tissue-invasive disease resulting in pneumonitis, hepatitis, and GI ulcerations. Symptomatic infections and all tissue-invasive CMV disease should be treated with intravenous (IV) ganciclovir, a reduction in immunosuppression, or both, although successful treatment of mild to moderate rejection and concurrent mild to moderate CMV disease has been described.

EBV infections range from a mild mononucleosis syndrome to severe hepatitis and highly morbid PTLD. PTLD ranges from a localized tumor to a progressive, diffuse infiltration of various organs including the brain. It results from the proliferation of EBV-positive B cells in immunosuppressed patients. The main risk factors are a high degree of immunosuppression and...
a predisposing EBV serostatus (seronaive recipient, seropositive donor). Among patients with early lesions, the first line of treatment is to reduce immunosuppression. For those with more advanced PTLD, rituximab is used.

After 6 months posttransplant, the risk of invasive fungal infections is closely associated with environmental exposures. Blastomyces dermatitidis grows in moist soil in the Midwest and Southeast regions of the United States. Diagnosis is confirmed by biopsy; the preferred treatment is IV amphotericin B.

Coccidioides immitis can cause invasive coccidioidomycosis after inhalation of aerosolized infectious particles. It is endemic in the Southwest, Northern Mexico, and various parts of Central and South America. This infection can be resilient and difficult to treat. The first line of treatment is high-dose amphotericin B.

Histoplasma capsulatum is found in chicken, pidgeon, and bat droppings in the Ohio River and Mississippi River valleys. Dissemination is commonplace; up to a quarter of patients have central nervous system (CNS) involvement. Treatment consists of prolonged (3 to 13 months) administration of oral itraconazole.

Opportunistic infections with Aspergillus, Cryptococcus, Mucor, and Rhizopus species are rare but can cause serious infections. Patients with invasive Candida or Aspergillus infections exhibit a 20% mortality rate. Prophylaxis with fluconazole has been shown to reduce invasive fungal infections in liver recipients.41

Pneumocystis jiroveci (also known as PCP) is ubiquitous and can cause pulmonary disease in immunocompromised patients. However, trimethoprim-sulfamethoxazole (TMP-SMX) is effective prophylaxis against PCP, and daily, lifelong administration has virtually eliminated this infection among transplant recipients.

Malignancies
Chronic immunosuppression increases the risk of developing certain types of malignancies. The most extensive data, from a cohort study involving more than 175,000 solid organ transplant recipients, showed that 10,656 of them developed malignancies. The standardized incidence ratio was 2:10 (as compared with the general population). Recipients had at least a fivefold increase (as compared with the general population) in these types of malignancies: Kaposi’s sarcoma, nonmelanoma skin cancer, non-Hodgkin’s lymphoma, and cancer of the liver, anus, vulva, and lip. In addition, recipients had a statistically significant increase (as compared with the general population) in melanoma, Hodgkin’s lymphoma, and cancer of the lung, kidney, colon, rectum, and pancreas.42

ORGAN PROCUREMENT AND PRESERVATION
Organ procurement is a key element in organ transplantation. Currently, over 100 organ procurement organizations (OPOs) exist in the United States, all members of the Organ Procurement and Transplantation Network (OPTN), which is a federally mandated network created by and overseen by UNOS. Each OPO is responsible for evaluating and procuring deceased donor organs for transplantation in a specific geographic region. Hospitals receiving any type of federal reimbursement for their services (whether transplant-related or not) are required to report all deaths to their OPO in a timely manner. Each OPO then determines the medical suitability of the deceased for organ donation; requests consent for donation from family members; if consent is given, contacts the OPTN to analyze and identify potential recipients whose HLA antigens most closely match those of the donor; and arranges for the recovery and transport of any donated organs.

Strategies to increase organ donation and utilization have been successfully implemented in the last 10 to 15 years. The nationwide “Organ Donation Breakthrough Collaborative,” sponsored by the U.S. Department of Health and Human Services in 2003, brought the OPOs and transplant communities into a single concerted program to develop best practices guidelines. However, a severe donor shortage remains. The number of living organ donors peaked in 2007 and has declined since.

Alternative options include tissue engineering and stem cell research, but those fields are in their infancy in terms of producing fully functional and vascularized human organs. With the development of genetic “knockout” pigs, xenotransplantation still shows promise, but two problems in particular—immunologic barriers and xenosis (also known as zoonosis) of endogenous porcine retroviruses—have yet to be satisfactorily addressed.

Today, the gap between patients waiting for organ transplants and the number of organs available continues to widen. More than 118,000 patients are on the waiting list for solid organ transplants, but only 33,611 transplants were performed in 2016.

Deceased Donors
Most transplants today utilize organs from deceased donors. Formerly, death was determined by the cessation of both cardiac and respiratory function.

Donation After Brain Death. In 1968, the concept of “irreversible coma” was introduced by an ad hoc committee report at Harvard Medical School; that concept was pivotal to the final acceptance, in 1981, of “brain death” as a legal definition in the United States. The legal language states that the declaration of brain death should be in accordance with acceptable medical standards but does not specify clinical methodology. It is customary for hospitals to establish their own policies to declare brain death, according to their standards of care and local regulations.

Typically, brain death is defined as the irreversible cessation of brain function, including the brainstem. The presence of medical conditions that mimic brain death—such as drug overdose, medication side effects, severe hypothermia, hypoglycemia, induced coma, and chronic vegetative state—need to be excluded. The latest evidence-based guideline on determining brain death in adults reaffirmed the validity of current clinical practice.43 Briefly, the clinical diagnosis of brain death consists of four essential steps: (a) establishment of the proximate cause of the neurologic insult; (b) clinical examinations to determine coma, absence of brainstem reflexes, and apnea; (c) utilization of ancillary tests, such as electroencephalography (EEG), cerebral angiography, or nuclear scans, in patients who do not meet clinical criteria; and (d) appropriate documentation. A similar guideline on determining brain death in pediatric patients was recently developed.44

Once the diagnosis of brain death has been established, the local OPO assumes the care of the potential donor and initiates the process of donor evaluation and organ donation, and the potential donor is screened for contraindications to donation. The medical history and social history are obtained from the available family members. A battery of tests, including serologic
or molecular detection of human immunodeficiency virus (HIV) and viral hepatitis, are performed. The exact medical conditions that preclude donation vary; nonetheless, in the United States, infections and other medical conditions that determine eligibility are dictated by UNOS bylaws and routinely reviewed and updated.

The OPO focuses on preserving organ function and optimizing peripheral oxygen delivery until organ procurement commences. In all deceased donors, core temperature, systemic arterial blood pressure, arterial oxygen saturation, and urine output must be determined routinely and frequently. Arterial blood gases, serum electrolytes, blood urea nitrogen, serum creatinine, liver enzyme, hemoglobin, and coagulation tests need to be monitored regularly. In all brain-dead donors, elevated intracranial pressure triggers a compensatory catecholamine response to maintain cerebral perfusion pressure. Ischemic injury to the spinal cord and the sympathetic system may lead to a profound vasodilation. As a result, brain-dead donors frequently have severe hemodynamic and metabolic derangements, so aggressive monitoring and intervention are required to prevent loss of precious organs.

Previous studies of deceased donor care focused on organ-specific resuscitation protocols that resulted in only marginal gains in the number of organs transplanted. The latest developments center on multisystem protocols to increase the number of organs transplanted per donor (OTPD). The goals are to maintain a core temperature between 36.0°C and 37.5°C, a mean arterial pressure >70 mmHg or a systolic pressure >100 mmHg, and a hemoglobin level between 7 and 10 g/dL; hormonal therapy and aggressive treatment of arrhythmias and metabolic derangements are also called for.

Surgical Technique. Procurement of multiple organs (heart, lungs, kidney, liver, pancreas, and/or small bowel), or multivisceral procurement, was first described by the Pittsburgh group in 1987. Since then, most centers have incorporated changes, especially with regard to the timing and location of dissection and flushing. The basic steps involve a long incision to provide wide exposure of all thoracic and abdominal organs (Fig. 11-3). A Cattell-Braasch maneuver (complete mobilization of the distal small bowel, right colon, and duodenum) is performed to allow for identification of the distal aorta, iliac bifurcation, and distal inferior vena cava (IVC). The infrarenal aorta is the site for inserting the cannula that will allow for flushing of the organs with cold preservation solution. Sometimes, division of the inferior mesenteric artery is necessary to facilitate the exposure of the distal aorta. The third portion of the duodenum is retracted cephalad to expose the root of the superior mesenteric artery (SMA). Limited dissection is performed at the root of the SMA, which is encircled with a vessel loop to enable its temporary occlusion at the time of flushing, thus reducing the incidence of overperfusion injury to the pancreas.

A large anomalous or replaced right hepatic artery typically rises from the SMA, and this should be identified and preserved. Lateral to the SMA is the inferior mesenteric vein (IMV), which can be cannulated for portal flushing. Dissection of the hepatic hilum and the pancreas should be limited to the common hepatic artery (CHA), and branches of the CHA (e.g., splenic, left gastric, and gastroduodenal arteries) are exposed. The gastrohepatic ligament is carefully examined to preserve a large anomalous or replaced left hepatic artery, if present. The supraceliac aorta can be exposed by dividing the left triangular ligament of the liver and the gastrohepatic ligament.

The common bile duct is transected at the superior margin of the head of the pancreas. The gallbladder is incised and flushed with ice-cold saline to clear the bile and sludge. If the pancreas is to be procured, the duodenum is flushed with antimicrobial solution. Before the cannulation of the distal aorta, systemic heparinization (300 units/kg) is administered. The supraceliac aorta is clamped; cold preservation fluid is infused via the aortic (systemic) and IMV (portal) cannulas. The thoracic organs, liver, pancreas, and kidneys are then removed.

Donation After Cardiac Death. Given the severe shortage of donor organs, donation after cardiac death (DCD)—also known as donation by non–heart-beating donors (NHBDs)—was introduced to the transplant community in the 1990s. The category of DCD (Maastricht classification) was initially proposed at an international workshop and is now widely adopted for organ procurement. Currently, most NHBDs in the United States meet Maastricht classification III; that is, they have suffered a devastating injury with no chance of a meaningful recovery but do not meet the criteria for brain death. After consent for donation is obtained from the next of kin, the donor’s life support is removed. After the cessation of cardiac and respiratory function, organ procurement commences. DCD procurement protocols vary between states; religious and cultural differences need to be taken into consideration. The surgical team must be familiar with, and respect, the local protocol.

With cardiac death (as opposed to brain death), warm ischemic injury to organs can occur during the period between circulatory cessation and rapid core cooling through perfusion of preservation solution. However, the difference in long-term outcomes is negligible for recipients of organs from either type of donor. Still, a significant percentage of liver grafts procured after cardiac death, especially those with more than 25 minutes of warm ischemic time, develop devastating ischemic cholangiopathy and fail.

A new development to minimize ischemic injury to organs procured after cardiac death has been the application of extracorporeal membrane oxygenation (ECMO). With ECMO, DCD differs in two key ways: (a) cannulation occurs before withdrawal of life support and (b) organs are perfused via ECMO with warm oxygenated blood after declaration of cardiac death.

Figure 11-3. Exposure for thoracic and abdominal organ procurement.
The initial experience with organs procured using ECMO has been encouraging.

**Surgical Technique.** Surgeons who perform multiple organ retrieval should be familiar and experienced with the super-rapid technique described by the Pittsburgh group. Preferably, NHBDs undergo withdrawal of life support in the operating room after the surgical site is prepped and draped, as soon as the surgical team is ready. Alternatively, the NHBD is transported to the operating room after declaration of cardiac death.

A midline incision is used to rapidly gain entry into the abdominal cavity. An assistant retracts the small bowel and the sigmoid colon laterally, so that the bifurcation of the aorta can be easily identified on the left side of the vertebral column. A short segment of the distal aorta is dissected out from the retroperitoneum. A moist umbilical tape is passed around the aorta, which is used to secure a cannula. The distal aorta is clamped. Next, a cannula is passed cephalad through an aortotomy and secured. Flushing with cold preservation solution is started at once, followed by cross-clamping the aorta proximally (thoracic aorta) and venting through the vena cava. The portal flush is then instituted.

The rest of the procedure is similar to procurement after brain death, with two noticeable differences. First, to avoid injury to a large anomalous or replaced left hepatic artery, the gastrohepatic ligament and the left gastric artery are separated from the stomach at the lesser curvature. Second, to avoid injury to a large anomalous or replaced right hepatic artery, the SMA is examined before it is divided. If the pancreas is not procured, a common aortic patch encompassing both the SMA and the celiac artery can be procured with the liver.

**Living Donors**

The maxim of medical ethics is “primum non nocere” (first, do no harm), and for that reason, living organ donation presents unique ethical and legal challenges. Performing potentially harmful operations to remove organs from healthy individuals seems, at first glance, to contradict that maxim. But in fact, the ethical framework of living organ donation rests on three guiding principles respected in all discussions of medical practice: beneficence to the recipient, nonmaleficence to the donor, and the donor’s right to autonomy. In order to achieve optimal outcomes (the common good), transplant professionals should focus on maximizing the benefits for the recipient and minimizing the damage to the donor. The Uniform Anatomical Gift Act adopted by all states in the United States (with slight variations) provides the legal framework for competent adult living donors to decide whether or not to donate. It is the fiduciary duty of transplant professionals to explain the risks of organ donation. Any decision to donate should be uncoerced, and no enticements should be offered.

The use of living donors offers numerous advantages for recipients in need. First and foremost is the availability of lifesaving organs for those who would otherwise succumb to the progression of their end-stage disease. In certain parts of the world, such as East Asia, the concept of brain death and the use of deceased donors conflict with the prevailing culture or religion. Even in countries where the use of deceased donors is accepted, the use of living donors may significantly shorten the waiting time for recipients. A shorter waiting time generally implies a healthier recipient—one whose body has not been ravaged by prolonged end-stage organ failure. Moreover, with the use of living donors, transplants are planned (rather than emergency) procedures, allowing for better preoperative preparation of the recipient. Receiving an organ from a closely matched relative may also have immunologic benefits. And long-term results may be superior with the use of living donors, as is certainly the case with kidney transplants.

The major disadvantage is the risk to the living donor. Medically, there is no possibility of benefit to the donor, only the potential for harm. The risk of death associated with donation depends on the organ being removed. For a nephrectomy, the estimated mortality risk is less than 0.05%; for a partial hepatectomy, about 0.2%. The risk of surgical and medical complications also depends on the procedure being performed. In addition, long-term complications may be associated with a partial loss of organ function after donation. The guiding principle should be minimization of risk to the donor. All potential risks must be carefully explained to the potential donor, and written informed consent must be obtained.

**Surgical Technique.** The kidney, the first organ to be transplanted from living donors, is still the most common organ donated by these individuals. The donor’s left kidney is usually preferable because of the long vascular pedicle. Use of living donor kidneys with multiple renal arteries should be avoided in order to decrease the complexity of the vascular reconstruction and to help avoid graft thrombosis. Most donor nephrectomies are now performed via minimally invasive techniques, that is, laparoscopically, whether hand-assisted or not. With laparoscopic techniques, an intraperitoneal approach is most common: it involves mobilizing the colon, isolating the ureter and renal vessels, mobilizing the kidney, dividing the renal vessels and the distal ureter, and removing the kidney (Fig. 11-4). Extensive dissection around the ureter should be avoided, and the surgeon should strive to preserve as much length of the renal artery and vein as possible.

Liver transplants with living donors are not as commonly performed, given the significantly higher rates of donor mortality and morbidity. Initially, only adult donors for pediatric recipients were selected, but now, living donor liver transplants also involve adult donors for adult recipients. In dual graft living donor liver transplants, segmental grafts from two living donors augment the recipient’s graft size. The donor hepatectomy is similar to a major lobar hepatectomy, except that it is important to preserve the integrity of the vascular structure until graft resection (Fig. 11-5).

Living donor transplants of organs other than the kidney and liver are fairly uncommon, but certain centers do perform such transplants. Living donor pancreas transplants involve performing a distal pancreatectomy, with the graft consisting of the body and tail of the pancreas; vascular inflow and outflow are provided by the splenic artery and splenic vein. Living donor intestinal transplants usually involve removal of about 200 cm of the donor’s ileum, with inflow and outflow provided by the ileocolic vessels. Living donor lung transplants involve removal of one lobe of one lung from each of two donors; both grafts are then transplanted into the recipient.

**Organ Preservation**

The development and continuing refinement of organ preservation methods have completely revolutionized the transplant field. Extending the time that organs can be safely stored after procurement has enabled better organ utilization and better recipient outcomes. Hypothermia and pharmacologic inhibition are the two most frequent methods. Both slow—yet cannot
Figure 11-4. Laparoscopic left donor nephroureterectomy. A. Takedown of splenic flexure of colon to expose the left renal hilum. B. Dissection of left ureter off the psoas muscle. C. Dissection of left renal vein and gonadal vein. Left ureter seen lateral to the dissection. D. Dissection of left renal artery. Lumbar veins clipped and divided. E. Endo-TA stapler transection of the left renal artery. F. Placement of ports and Pfannenstiel incision for the donor kidney extraction.

Figure 11-5. Donor hepatectomy (right hepatectomy). A. The liver parenchymal transection line (c, the Cantlie line) marked with cautery. Right portal vein (p) and right hepatic artery (a) isolated. b = bile duct. Cystic duct was cannulated for intraoperative cholangiography. B. Exposure of hepatic veins after transection of the parenchyma. IVC = inferior vena cava; L = left hepatic vein; M = middle hepatic vein; R = right hepatic vein.
completely shut down—the removed organ’s metabolic activity, so both have adverse effects, such as cellular swelling and degradation. Cold storage solutions were introduced to mitigate some of the adverse effects of hypothermia or pharmacologic inhibition alone. Such solutions help prevent cellular swelling and the loss of cellular potassium.

One, and perhaps the most effective, preservation solution was developed at the University of Wisconsin and remains in wide use. Its ingredients include lactobionate (which helps prevent cellular swelling and reperfusion injury), raffinose, and hydroxyethyl starch (which helps reduce swelling of endothelial cells, thereby decreasing edema). Histidine-tryptophan-ketoglutarate solution is also currently in wide use.

Despite enhancements in preservation methods, the amount of time that an organ can be safely stored remains relatively short (hours, not days), particularly with organs from marginal donors. Among kidney recipients, delayed graft function becomes significantly more frequent after cold ischemic times of more than 24 hours, necessitating temporary dialysis, which is associated with increased risks of graft loss and higher costs. Among liver recipients, primary nonfunction and biliary complications ensue after prolonged cold ischemic times. In the case of heart and lung recipients, ischemic times should be under 6 hours. All of those times assume the use of normal donors.

There is revived interest in the use of the pulsatile perfusion pump, a kidney graft preservation method that has been available for more than 40 years. With the increasing shortage of available donor organs and the rise in the use of organs after cardiac death, the pulsatile perfusion pump is garnering renewed enthusiasm as an adjunct method of preservation, even for donor organs other than kidneys.

**KIDNEY TRANSPLANTATION**

**Introduction**

Ullman reported the first attempted human kidney transplant in 1902. For the next 50 years, sporadic attempts all ended in either technical failure or in graft failure from rejection. Joseph Murray performed the first successful kidney transplant in 1954, an epochal event in the history of organ transplantation. In that first case, the immunologic barrier was circumvented by transplanting a kidney between identical twins. For his pivotal contribution, Murray shared the Nobel Prize in Physiology or Medicine in 1990 with E. Donnall Thomas for their discoveries concerning “organ and cell transplantation in the treatment of human disease.”

The introduction of AZA (Imuran) in 1960 marked the beginning of a new era in kidney transplantation. With the combination of steroids and AZA for maintenance immunosuppression, the 1-year graft survival rate with a living related donor kidney approached 80%; with a deceased donor kidney, the rate was 65%. In the ensuing years, major milestones included the introduction of more effective immunosuppressive medications with lower toxicity profiles, such as polyclonal antilymphocyte globulin in the 1970s, cyclosporine in the 1980s, tacrolimus in the 1990s, and biologics in the first decade of the 21st century, as previously mentioned.

Parallel to the developments in medical science were the transplant community’s concerted efforts to improve use of healthcare resources. In the United States, the Social Security amendments of 1972 provided Medicare coverage for patients with end-stage renal disease (ESRD). The National Organ Transplant Act of 1984 initiated the process of creating what later became UNOS, an umbrella organization to ensure access to organs by patients in need, to enhance organ procurement and allocation, and to improve posttransplant outcomes. This infrastructure later became the blueprint for other countries to follow. As a result, organ transplantation is the most transparent field of medicine. Data such as transplant center performance are readily available on public websites; penalties for violation of regulations and for underperformance often result in transplant programs being shut down.

Today, a kidney transplant remains the most definitive and durable renal replacement therapy for patients with ESRD. It offers better survival and improved quality of life and is considerably more cost-effective than dialysis. According to the 2016 Scientific Registry of Transplant Recipients (SRTR) annual report, nearly 100,000 adult patients were on the kidney transplant waiting list, while nearly 20,000 patients underwent renal transplantation. Trends over the past decade indicated that living related transplants remained relatively stable, while the number of deceased donor transplants rose. Posttransplant outcomes have continued to improve: in 2015, the 1-year graft survival rate with a living donor kidney was nearly 98%; with a deceased donor kidney, the rate was approximately 95.0%.

The advantages of a living donor kidney transplant include better posttransplant outcomes, avoidance of prolonged waiting time and dialysis, and the ability to coordinate the donor and recipient procedures in a timely fashion. Living donor kidney recipients enjoy better long-term outcomes, a low incidence of delayed graft function, and reduced risks of posttransplant complications. Furthermore, the elective nature of living donor kidney transplants provides unique opportunities for recipient desensitization treatment if the donor and recipient are ABO-incompatible or if the HLA cross-match results are positive.

Some of the challenges transplant professionals face today are closing the growing gap between supply and demand and thereby reducing the current prolonged waiting times; refining immunosuppressive medications to achieve better outcomes with reduced toxicity; and caring for patients who develop rejection, especially antibody-mediated rejection.

**Pretransplant Evaluation**

Active infection or the presence of a malignancy, active substance abuse, and poorly controlled psychiatric illness are the few absolute contraindications to a kidney transplant. Studies have demonstrated the overwhelming benefits of kidney transplants in terms of patient survival, quality of life, and cost-effectiveness, so most patients with ESRD are referred for consideration of a kidney transplant. However, to achieve optimal transplant outcomes, the many risks (such as the surgical stress to the cardiovascular system, the development of infections or malignancies with long-term immunosuppression, and the psychosocial and financial impacts on compliance) must be carefully balanced.

Any problems detected during the evaluation of transplant candidates are communicated to their referring physician and/or to a specialist if advanced evaluation and treatment are needed, ultimately improving overall care. Essentially, the pretransplant evaluation is a multifaceted approach to patient education and disease management.

Before the pretransplant medical evaluation begins, kidney transplant candidates are encouraged to attend a group meeting.
focused on patient education. The meeting is coordinated by a transplant physician or surgeon. The intent is to familiarize patients with the pretransplant evaluation process and with pertinent medical concepts and terms. In an open forum format, important decisions such as type of donor (living vs. deceased) are discussed. The group meeting empowers patients to fully participate in their care and serves as an impetus for a meaningful dialogue with healthcare professionals.

Medical Evaluation

Cardiovascular Disease. Diabetes and hypertension are the leading causes of chronic renal disease. Concomitant cardiovascular disease (CVD) is a common finding in this population. An estimated 30% to 42% of deaths with a functioning kidney graft are due to CVD.72,73 Therefore, assessment of the potential kidney transplant candidate’s cardiovascular status is an important part of the pretransplant evaluation.

In fact, the American Heart Association and the American College of Cardiology Foundation recently published their expert consensus on CVD evaluation and management for solid organ transplant candidates.74 The process should focus on careful screening for the presence of significant cardiac conditions (e.g., angina, valvular disease, and arrhythmias) and for a prior history of congestive heart failure, coronary interventions, or valvular surgery. The perioperative risk assessment is based on patient symptoms and exercise tolerance. For all kidney transplant candidates, a resting 12-lead electrocardiogram (ECG) should be obtained. In addition, in this population, the use of echocardiography to analyze left ventricular function and to assess for pulmonary hypertension is useful.

Stress testing may be considered in patients with no active cardiac condition but with risk factors such as diabetes, hemodialysis for more than 1 year, left ventricular hypertrophy, age greater than 60 years, smoking, hypertension, and dyslipidemia. The utility of noninvasive stress testing (as compared with angiographic studies) for evaluating coronary artery disease is controversial; an additional prognostic marker is the troponin T (cTN T) level.

Malignancies. Because of the long-term use of immunosuppressive medications, transplant recipients are at increased risk for development of malignancies. Untreated and/or active malignancies are absolute contraindications to a transplant (with two exceptions: nonmelanocytic skin cancer and incidental renal cell cancer identified at the time of concurrent nephrectomy [i.e., for polycystic kidney disease] and renal transplantation). For most patients who have undergone treatment of low-grade tumors with a low risk of recurrence (e.g., completely locally excised low-grade squamous cell cancer of the skin, colon cancer in a polyp absent stalk invasion), a wait of at least 2 years after successful treatment is recommended before a kidney transplant can be considered. However, for certain types of tumors, especially at advanced stages or those with a high risk of recurrence (e.g., melanoma, lymphoma, renal cell cancer, breast cancer, colon cancer), a delay of at least 5 years is advisable. According to the Israel Penn International Transplant Tumor Registry, tumor recurrence posttransplant is not infrequent: the recurrence rate is 67% in patients with multiple myeloma, 53% in nonmelanocytic skin cancer, 29% in bladder cancer, and 23% in breast cancer.75

Infections. A thorough history of infections and immunizations should be obtained from transplant candidates, who need all recommended age-appropriate vaccinations according to the Centers for Disease Control and Prevention (CDC) guidelines. Ideally, vaccinations should be completed at least 4 to 6 weeks before the kidney transplant takes place. Immunosuppressive medications blunt the immune response and reduce the effectiveness of vaccinations; even more important, with attenuated vaccines, vaccine-derived infections could occur. If a splenectomy is anticipated (e.g., in recipients whose donor is ABO-incompatible or whose HLA cross-match results are positive), then they should be immunized against encapsulated organisms (such as Neisseria meningitidis, Haemophilus influenzae, and Streptococcus pneumoniae) well in advance of the splenectomy.

Transplant candidates should undergo routine tuberculosis (TB) screening. According to the Centers for Disease Control (CDC), in 2016, 9272 TB cases were diagnosed in the United States with 68.5% of cases occurring in foreign-born persons.76 Serologic screening combined with a chest roentgenogram for fungal infections such as coccidioidomycosis or histoplasmosis, in patients who either have a history of those infections or are from an endemic area, are recommended. Chronic infections such as osteomyelitis or endocarditis must be fully treated; a suitable waiting period after successful treatment must occur, in order to ensure that relapse does not occur.

Hepatitis can be caused by five different type of viruses, hepatitis virus A, B, C, D, and E, with the first three being the most common. Acute viral hepatitis is a contraindication to a kidney transplant; however, chronic viral hepatitis (most commonly caused by hepatitis B [HBV] or C [HCV]) does not preclude a recipient from undergoing a kidney transplant. In such candidates, obtaining a liver biopsy is essential to assess the disease severity. Recipients infected with HBV should undergo antiviral treatment (e.g., lamivudine) to prevent reactivation and progression of liver disease. Note that HBV is a noncytopathic virus; the liver damage is the result of an immune-mediated process.77 Moreover, the presence of normal liver enzymes in patients with HBV antigenemia does not predict the severity of parenchymal damage.

Transplant candidates with chronic HCV infection often have HCV-related glomerulonephritis. As with HBV infection, the clinical presentation and biochemical findings with HCV infection are often unreliable in predicting liver damage. In such patients who also exhibit evidence of cirrhosis, a combined liver-kidney transplant should be considered. In appropriate candidates, pretransplant antiviral treatment with interferon-α may be considered. However, after a kidney transplant, interferon treatment is not recommended because it is an immunosuppressive agent, and thus HIV may precipitate graft rejection.

Thanks to the excellent outcomes of highly active antiretroviral therapy (HAART), infection with HIV is no longer considered a contraindication to a kidney transplant. Kidney transplant candidates with HIV must have an undetectable HIV viral load and a CD4 lymphocyte count greater than 200/mm3; in addition, they must not have developed any opportunistic infection in the previous year.78 Latent viral infections such as CMV and EBV are of particular interest in the field of transplantation, given the risks of reactivation posttransplant and their detrimental effects on graft and patient survival. Knowing the CMV and EBV serologic status of the recipient and donor helps transplant professionals gauge the risk of immunosuppressive regimens in relation to potential infection, thereby guiding plans for posttransplant antiviral prophylaxis treatment or, as noted earlier,
avoiding transplants between a seropositive donor and a seronegative recipient.

**Kidney Disease.** The third most common cause of graft loss in kidney transplant recipients is recurrence of glomerular diseases such as focal segmental glomerulosclerosis (FSGS), immunoglobulin A (IgA) nephropathy, hemolytic uremic syndrome, systemic lupus erythematosus, and membranoproliferative glomerulonephritis. FSGS deserves special mention due to its frequent occurrence and dramatic presentation of early graft loss. An estimated 30% to 40% of FSGS patients develop recurrent disease posttransplant; of those, up to half eventually lose their graft. In recipients with a history of FSGS, posttransplant nephrotic proteinuria should be promptly investigated; if diagnosis is confirmed by transplant kidney biopsy, rescue plasmapheresis should be instituted at once. Adjuvant therapy with rituximab has been proposed.

**Hypercoagulopathy.** Kidney transplant candidates with a history of thrombotic events, repeated miscarriages, or a family history of thrombophilia should be screened for the following coagulopathic disorders: activated protein C resistance ratio, factor V Leiden mutation, factor II 20210 gene mutation, antiphospholipid antibody, lupus anticoagulant, protein C or S deficiency, antithrombin III deficiency, and hyperhomocysteinemia. In recipients at risk for hypercoagulopathy, pediatric kidney grafts and any kidney allografts with a complex vascular anatomy should be avoided. A perioperative anticoagulation protocol is recommended in this population.

**Surgical Evaluation**

**Urologic Evaluation.** Kidney transplant candidates (pediatric patients, in particular) with chronic kidney disease as a result of congenital or genitourinary abnormalities should undergo a thorough urologic evaluation. A voiding cystourethrogram and a complete lower urinary tract evaluation to rule out outlet obstruction are essential. Indications for a native nephrectomy include chronic pyelonephritis, large polycystic kidneys with loss of intra-abdominal domain, significant vesicoureteral reflux, or uncontrollable renovascular hypertension.

**Vascular Evaluation.** The potential implant sites for a kidney graft include the recipient’s iliac vessels and, less commonly, the aorta and vena cava. Careful physical examination often reveals significant central and/or peripheral vascular disease. Findings such as a pulsatile intra-abdominal mass, diminished or absent peripheral pulse, claudication, rest pain, and tissue loss in lower extremities should be further evaluated by abdominal computed tomography scan or ultrasound, Doppler studies, and/or angiography. With the popularity of endovascular interventions, transplant surgeons also should be familiar with such technology and obtain detailed anatomic studies of patients with vascular stents.

**Immunologic Evaluation.** ABO blood typing and HLA typing (HLA-A, -B, and -DR) are required before a kidney transplant. The method of screening for preformed antibodies against HLA antigens (because of prior transplants, blood transfusions, or pregnancies) continues to evolve. The panel-reactive antibody (PRA) assay is a screening test that examines the ability of serum from a kidney transplant candidate to lyse lymphocytes from a panel of HLA-typed donors. A numeric value, expressed as a percentage, indicates the likelihood of a positive crossmatch with a donor. A higher PRA level identifies patients at high risk for a positive cross-match and therefore serves as a surrogate marker to measure the difficulty of finding a suitable donor and the subsequent risk of graft rejection.

An important development in anti-HLA antibody screening is Luminex technology, using HLA-coated fluorescent microbeads and flow cytometry, which is considered the “gold standard.” This technology pinpoints donor-specific antibodies (DSAs) in the serum of a kidney transplant candidate with a high PRA level. Since all organ donors must undergo HLA typing, a negative cross-match for recipients with a high PRA level can be ensured by avoiding the selection of donors carrying unacceptable antigens (i.e., a virtual cross-match). Kidney transplant candidate data (including ABO blood types, HLA types, and DSAs) are entered into a nationwide central database to facilitate deceased donor kidney allocation, as described earlier.

**Psychosocial Evaluation.** Psychiatric disorders have been recognized as important contributing factors to poor outcomes posttransplant. Patients with uncontrolled psychiatric disorders are at high risk for noncompliance with drug treatment, impaired cognitive function, and the development of substance abuse. A robust psychosocial evaluation is essential to ensure that transplant candidates understand the risks and benefits of the procedure and that they adhere to the lifetime immunosuppressive medication regimen.

**Recipient Operation**

Kidney allografts usually are transplanted heterotopically. The iliac fossa is recognized as the ideal position because of its proximity to the recipient’s bladder and iliac vessels.

Retroperitoneal allograft placement also allows easy access for percutaneous biopsies and interventions for ureteral complications. The right iliac fossa is the preferred site because of its easy access to the recipient’s iliac vessels. However, if a pancreas transplant is anticipated in the future or if now failed kidney grafts have been placed at the right iliac fossa, then the left iliac fossa is used for implantation. The current surgical technique for kidney transplants was developed and popularized in the 1950s and 1960s and has changed little since.

A large-bore three-lumen urinary catheter is inserted after the recipient is anesthetized, and it is occluded with a clamp beneath the surgical drapes. Recipients whose native kidneys produce urine will naturally fill up the urinary bladder; those individuals whose kidneys do not will require insufflation of saline prior to creation of the ureteral anastomosis.

Exposure of the operative field starts with a curvilinear skin incision, one to two finger widths above the midline pubic bone and the lateral edge of the rectus sheath. Superiorly, the extension of the incision depends on the recipient’s body habitus and the size of the donor kidney. The anterior rectus sheath is incised, medially to laterally, until the lateral edge of the rectus sheath is exposed. The posterior rectus sheath is missing below the arcuate line, thus providing direct access to the extraperitoneal space. The rectus muscle can be easily mobilized medially without being divided. The remainder of the fascial incision is along the lateral edge of the rectus sheath until the desired exposure is achieved (Fig. 11-6).

The retroperitoneal space of the iliac fossa is entered by mobilizing the peritoneum medially. The inferior epigastric vessels, the round ligament (in females), and the spermatic cord and its vasculature (in males) are encountered in this space; the former two structures are divided, while the latter is retracted with a vascular loop. A self-retained retractor is used to expose
the surgical field. The iliac vessels should be dissected with great care. To minimize the risk of lymphocele development postoperatively, dissection of the iliac artery should be limited; the intertwining lymphatics around the iliac vessels should be ligated. In general, the donor’s renal artery and vein are anastomosed to the recipient’s external iliac vessels in an end-to-side fashion (Fig. 11-7). In recipients with a severely calcified iliac artery, the internal iliac artery can be used as an alternative, and in select cases, an endarterectomy must be performed.

After restoring the circulation to the donor’s kidney, urinary continuity can be established via several approaches. The approach chosen depends on such factors as the length of the donor ureter and a recipient history of bladder surgery, native nephrectomy, or pelvic radiation. The two most common procedures to restore urinary continuity are the Leadbetter-Politano and a modification of the Lich (e.g., extravesical) ureteroneocystostomy.

During the former procedure, a large cystotomy is created in the dome of the bladder, and the donor ureter is brought through a lateral and somewhat inferior 1-cm submucosal tunnel into the bladder, the end of which is spatulated and then sewn in place without tension with interrupted absorbable sutures placed through the mucosa and submucosa on the inside of the bladder.

An extravesical ureteroneocystostomy is performed by careful dissection of a 1-cm portion of the muscular layers on the anterolateral portion of the bladder until a “bubble” of mucosa is exposed. The donor ureter is spatulated in a diamond-shaped fashion, the bladder mucosa is incised, absorbable interrupted sutures are placed in four quadrants, and a mucosa-to-mucosa anastomosis is created using running absorbable sutures with a temporary ureteral stent in place of the first three-quarters of the anastomosis. The muscular layers of the bladder are then carefully approximated over the anastomosis to prevent reflux.

The decision to place a ureteral stent depends on the surgeon, who must try to balance the risk of infectious complications with the possible technical complications of a ureteral anastomosis, but in general, this is not required except during the rarely performed donor ureter to recipient ureter anastomosis or in the case of a pediatric kidney transplant. Fixation of the donor’s kidneys is not necessary, except in the case of small kidneys (usually from a pediatric donor) or en bloc kidneys.

Figure 11-6. Incision and exposure for kidney transplant. A. Mark for the skin incision. B. Anterior rectus sheath incised obliquely. The abdominal muscle transected lateral to the rectus muscle. C. External iliac artery and vein dissected.

Figure 11-7. Vascular anastomoses of kidney transplant. A. Arterial anastomosis: donor renal artery with Carrel patch to recipient external iliac artery, end-to-side. B. Venous anastomosis: donor renal vein with caval extension conduit to recipient external iliac vein, end-to-side.
Figure 11-8. Arterial and venous reconstruction. A. Two renal arteries combined into a single Carrel patch (arrow). Right renal vein extension conduit constructed with stapled caval patch. IVC = inferior vena cava; R = right renal vein. B. Three renal arteries anastomosed to external iliac artery separately.

Grafts With Multiple Renal Arteries
In 10% to 30% of donor kidneys, multiple renal arteries are encountered. Unless kidney transplant candidates have hypercoagulopathy, grafts with multiple renal arteries fare as well as those with single vessels. Vascular reconstruction options include implanting the donor’s arteries separately, reconstructing the multiple arteries into a common channel, or combining multiple arteries into a common Carrel patch (Fig. 11-8).

En Bloc Grafts
Debate persists about whether to implant kidneys obtained from young donors (<5 years or whose body weight is under 20 kg) as a single en bloc unit into one recipient or separately into two recipients. The underlying issues are the shortage of donor organs, the complexity of the surgical procedure, the risks of graft thrombosis, ureteral complications, and long-term outcomes.

In en bloc kidney transplants, the donor aorta and vena cava are used as the vascular inflow and outflow conduits. Therefore, reconstruction of the en bloc graft pretransplant is key to a successful transplant. The donor’s suprarenal vena cava and aorta are oversewn. The lumbar branches of the cava and aorta are ligated. Dissection around the renal hilum should be avoided. The orientation of the cava and aorta should be clearly marked, in order to avoid torsion of the anastomosis. If the color of the two kidneys looks different after reperfusion, repositioning should be attempted to rule out vascular torsion; fixation of the en bloc kidneys to the retroperitoneum is often necessary. The donor’s ureters are implanted to the recipient’s bladder, either as two separate anastomoses or as a common patch (Fig. 11-9). Only a handful of centers have performed en bloc kidney transplants, but the long-term outcomes are encouraging.

Figure 11-9. En bloc kidney transplant (3-month-old donor kidneys). A. En bloc kidneys benched. Vascular integrity tested with methylene blue (blue hue look of the kidneys). B. En bloc kidneys transplanted into a 62-year-old woman. Donor aorta anastomosed to recipient’s external iliac artery; donor cava, to recipient’s external iliac vein.
Perioperative Care

Preoperatively, a thorough history and physical examination should be performed. Any changes in transplant candidates’ recent medical history should be investigated in great detail. In those recipients with a historically negative PRA level who have recently undergone blood transfusions, a prospective tissue cross-match is necessary to avoid graft rejection. Electrolyte panels should be checked. Emergency dialysis may be necessary for transplant candidates experiencing hyperkalemia or fluid overload.

For dialysis-dependent transplant candidates, the catheter sites should be examined preoperatively to rule out infections. Vascular access for hemodialysis is essential to avoid complications related to posttransplant acute tubular necrosis (ATN). Vascular evaluation is mandatory; any changes in results should be investigated by appropriate imaging studies.

As is routine for other major surgical procedures, transplant candidates should preoperatively undergo a chest X-ray, a 12-lead ECG, blood typing, cross-match tests, and prophylaxis against surgical site infection (by administration of a nonnephrotoxic antibiotic with activity against both common skin microflora and gram-negative pathogens); candidates should receive nothing to eat or drink.

Intraoperatively, transplant recipients should be kept well hydrated to avoid ATN and should receive heparin prior to vascular occlusion. Before reperfusion of the transplanted kidney, the desired central venous pressure should be maintained at around 10 mmHg, and the systolic blood pressure should be above 120 mmHg. In pediatric recipients of an adult graft, a superphysiologic condition may be necessary to avoid ATN or graft thrombosis. Mannitol often is administered before reperfusion as a radical scavenger and diuretic agent, and a diuretic such as furosemide is administered as well.

Postoperatively, the guiding principles for the care of kidney transplant recipients are the same as for other surgical patients. The crucial elements include hemodynamic stability and fluid and electrolyte balance. To achieve a euvolemic state, the recipient’s urine output is replaced with either an equal or a reduced volume of IV fluid on an hourly basis, depending on the medical status. In recipients undergoing brisk diuresis, aggressive replacement of electrolytes (including calcium, magnesium, and potassium) may be necessary. In recipients experiencing ATN, fluid overload, or hyperkalemia, however, fluid restriction, treatment for hyperkalemia, and even hemodialysis may be necessary.

Hypotension is an unusual event immediately posttransplant. The differential diagnoses include hypovolemia, vasodilation, and myocardial infarction with cardiac failure. Immediate action should be taken to avoid life-threatening complications. Posttransplant hypertension can be mediated by catecholamines, fluid overload, or immunosuppressive agents.

Postoperatively, urine output is used as a surrogate marker to monitor graft function. Among recipients whose native kidneys produce significant amounts of urine, normal or increased urine output can be misleading; for them, serum blood urea nitrogen and creatinine levels are more reliable indicators of kidney graft function.

Suddenly decreased or minimal urine output requires immediate attention. A change in volume status is the most common cause, but other culprits include blockage of the urinary catheter, urinary leak, vascular thrombosis, hypotension, drug-related nephrotoxicity, ATN, and rejection (all of which must be thoroughly investigated). Diagnostic studies such as Doppler ultrasound, nuclear renograms, or biopsies should be considered.

Postoperative bleeding is an uncommon event after a kidney transplant. Recipients on anticoagulation or antiplatelet treatments are at increased risk. Signs and symptoms (such as an expanding hematoma over the surgical site, increased pain over the graft, a falling hemoglobin level, hypotension, and tachycardia) should arouse suspicion of hemorrhage. Doppler ultrasound is useful to establish the underlying cause. Surgical exploration seldom is required because the accumulated hematoma tamponades the bleed. Indications for surgical exploration include ongoing transfusion requirement, hemodynamic instability, and graft dysfunction from hematoma compression. For recipients on anticoagulation or antiplatelet treatments, the threshold for surgical exploration is lower. Small unligated vessels at the donor’s renal hilum or recipient’s retroperitoneum are likely sources of bleeding.

One of the most devastating postoperative complications in kidney recipients is graft thrombosis. It is rare, occurring in fewer than 1% of recipients. The recipient risk factors include a history of recipient hypercoagulopathy and severe peripheral vascular disease; donor-related risk factors include the use of en bloc or pediatric donor kidneys, procurement damage, technical factors such as intimal dissection or torsion of vessels, and hyperacute rejection. Graft thrombosis usually occurs within the first several days posttransplant. Acute cessation of urine output in recipients with brittle posttransplant diuresis and the sudden onset of hematuria or graft pain should arouse suspicion of graft thrombosis. Doppler ultrasound may help confirm the diagnosis. In cases of graft thrombosis, an urgent thrombectomy is indicated; however, it rarely results in graft salvage.

Urologic complications are seen in up to 5% of recipients. The cause is often related to ureteral ischemia, damage during procurement of the donor’s distal ureter, or technical errors. Symptoms of urine leak include fever, pain, swelling at the graft site, increased creatinine level, decreased urine output, and cutaneous urinary drainage. Diagnosis can be confirmed by a combination of ultrasound, nuclear renography, drainage of perinephric fluid collection, and comparison of serum and fluid creatinine levels. Depending on the location and volume of the urine leak, satisfactory results can be achieved by surgical exploration and repair or by percutaneous placement of a nephrostomy and ureteral stenting.

Early urinary obstruction can be due to edema, blood clots, torsion of the ureter, or compression from a hematoma. Late urinary obstruction is often related to ischemia. The appearance of hydronephrosis on ultrasound is a good initial indicator. Treatment includes percutaneous placement of a nephrostomy and ureteral stenting. If transmural intervention fails, surgical intervention (such as ureteral reimplantation or a ureteropyelostomy) can be undertaken.

Results

A kidney transplant remains the most common solid organ transplant in the world today. With the introduction of induction immunosuppressive therapy and ever-improving, less toxic immunosuppressive medications, posttransplant outcomes have become better and better. And, as noted above, posttransplant outcomes have continued to improve: in 2014 allograft and patient survival rates were well over 90%, and in 2015, the 1-year graft survival rate with a living donor kidney was nearly
98%; with a deceased donor kidney, the rate was approximately 95%. The biggest improvements have been in the reduction of 1-year graft failure. With a deceased donor kidney, the 1-year graft failure rate dropped from approximately 20% in 1989 to less than 7% in 2009 to 4.8% in 2015; with a living donor kidney, the rate dropped from 8.5% in 1989 to less than 3% in 2015. Furthermore, steroid-free protocols and calcineurin-free protocols have been validated and implemented in the last several decades, further reducing medication-related side effects and vastly improving the quality of life for tens of thousands of recipients.

Currently, the most common cause of graft loss is recipient death (usually from cardiovascular causes) with a functioning graft. The second most common cause is chronic allograft nephropathy; characterized by a slow, unrelenting deterioration of graft function, it likely has multiple causes (both immunologic and nonimmunologic). The graft failure rate due to complications related to surgical technique has remained at about 1% to 2%.

**PANCREAS TRANSPLANTATION**

A successful pancreas transplant currently is the only definitive long-term treatment for patients with insulin-dependent diabetes mellitus (IDDM) that (a) restores normal glucose hemostasis without exposing patients to the risk of severe hypoglycemia and (b) prevents, halts, or, in some cases, reverses the development or progression of secondary complications of diabetes.

Given its vast medical, social, and financial implications, diabetes mellitus is a huge burden to patients and to society as a whole. An estimated 10% to 15% of the U.S. population is affected by it; of all diabetic patients, 10% have early-onset disease. In the United States, diabetes mellitus is the most common cause of end-stage kidney disease, blindness, impotence, major limb amputations, and coronary or peripheral vascular bypass procedures. It is one of the most common causes of death, along with myocardial infarction and stroke. Diabetes significantly decreases not only the quality of life but also life expectancy.

Despite improvements in exogenous insulin administration (including the use of devices such as insulin pumps), wide fluctuations in glucose levels and the risk of hypoglycemic episodes are common. The Diabetes Control and Complications Trial (DCCT) demonstrated in the late 1990s that intensive insulin therapy may slow the rate of secondary complications of diabetes—yet at the expense of (life-threatening) iatrogenic hypoglycemia. The annual mortality rate of patients with insulin-induced inadvertent hypoglycemia is estimated to be as high as 2% to 3%.

Since the first pancreas transplant in December 1966, performed by William Kelly and Richard Lillehei at the University of Minnesota, more than 25,000 pancreas transplants in the United States and more than 10,000 pancreas transplants from all over the world have been reported to the International Pancreas Transplant Registry (IPTR).

Pancreas transplants are performed in three recipient categories:

- **Simultaneous pancreas and kidney (SPK) transplant in diabetic and uremic patients.** Almost 80% of pancreas transplants are performed in this category. The recipient is already obligated to lifelong immunosuppressive therapy, due to the need for a kidney transplant, so only the surgical risk of a pancreas transplant is added. A successful SPK transplant renders the recipient dialysis-free and insulin-independent.
- **Pancreas after kidney (PAK) transplant in diabetic and posturemic patients.** Approximately 15% of all pancreas transplants fall into this category. These patients previously underwent a kidney transplant with either a living or deceased donor, but are candidates for a subsequent pancreas transplant because of poor glucose control or because of progression of secondary diabetic complications (which may include the development of diabetic nephropathy in the transplanted kidney).
- **Pancreas transplant alone (PTA) in nonuremic patients with brittle diabetes mellitus.** Only about 5% of all pancreas transplants are in this category. These patients have not yet developed advanced diabetic nephropathy, but their glucose levels are extremely labile despite best efforts of control. Because of the lifelong need for immunosuppressive therapy, the surgical risk has to be balanced with the medical risks of brittle diabetes (e.g., frequent episodes of hypoglycemia and hypoglycemic unawareness).

In SPK recipients, a plethora of literature exists that demonstrates significant improvements in secondary diabetic complications (across all organ systems) posttransplant. Improvements have been reported in diabetic nephropathy, neuropathy (autonomic and peripheral), micro- and macrovascular disease, retinopathy, gastroparesis, and other secondary complications. Currently, more than 1000 pancreas transplants are performed annually in the United States, with the goal of conferring the following benefits: excellent glucose control (similar to that of a functioning native pancreas), prevention or improvement of secondary diabetic complications, and increased quality of life and life expectancy. In addition, pancreas transplants can be successfully performed in patients who have undergone a total pancreatectomy for benign disease (such as chronic pancreatitis) to treat both endocrine and exocrine deficiency after surgery.

**Donor Operation**

The general criteria for selecting deceased donors for pancreas procurement are similar to those for other solid organs; a history of type 1 diabetes mellitus obviously is a contraindication. Relative contraindications include previous pancreatic procedure(s), as well as pancreatic disorders, such as chronic pancreatitis and intraductal papillary mucinous neoplasm. Hyperglycemia in itself is not a contraindication to pancreas procurement because its cause in brain-dead donors usually is severe insulin resistance, which is rarely observed in recipients.

In light of better anatomic understanding and improved surgical skills, all three abdominal organs that share a common blood supply (pancreas, liver, and intestine) can be procured at the same time and transplanted into three different recipients (Fig. 11-10). During pancreas procurement, a “no-touch” technique of the gland is preferred; dissection of the pancreas is carried out in a way that avoids direct manipulation of the organ such that simultaneous procurement of the spleen, duodenum, and surrounding connective tissues occurs.

In contrast to the liver and kidneys, the pancreas should not be extensively flushed at the end of the procurement. To minimize the amount of preservation fluid that reaches the pancreas, the splenic artery and SMA can be temporarily clamped...
at their origin from the aorta. Usually, the celiac axis with an aortic Carrel patch is retained with the liver. The splenic artery is divided close to its origin and is retained with the pancreas. The SMA is also procured with an aortic Carrel patch and is retained with the pancreas.

In case of a replaced or aberrant right hepatic artery, this first branch off of the SMA is carefully dissected out from the posterior surface of the pancreas. A replaced or aberrant right hepatic artery does not transverse the pancreas and is not a contraindication to combined pancreas and liver procurement. But with this anatomic variant, an aortic Carrel patch with the proximal SMA and replaced or aberrant right hepatic artery remains with the liver; the distal SMA with the inferior pancreaticoduodenal artery remains with the pancreas.

In the relatively rare event that the liver is not procured, then neither the splenic nor the gastroduodenal arteries need to be divided at their respective takeoff; the donor’s celiac axis and the SMA are included on a common Carrel patch. This technique allows a single arterial anastomosis to be performed in the recipient without reconstruction. At the end of the procurement, the pancreas is attached to the spleen, duodenum, and proximal jejunum, which is stapled at both ends.

**Back Table Preparation of the Pancreas Graft**

Back table preparation of the pancreas graft consists of four steps: (a) removal of the spleen; (b) shortening, restapling, and/or suture reinforcement of the mesenteric root; (c) trimming of any excess distal and proximal duodenum, along with reinforcement of the proximal staple line; and (d) arterial reconstruction.

Back table preparation is carried out in a basin filled with chilled preservation solution. The most common technique to create a single arterial inflow to the pancreas graft is the “Y-graft” reconstruction, using a resected segment of the donor iliac artery bifurcation. In this technique, the donor external iliac artery is anastomosed end-to-end to the donor SMA, and the donor internal iliac artery is anastomosed end-to-end to the splenic artery (Fig. 11-11). This procedure allows the donor common iliac artery to be anastomosed as a single vessel to the recipient’s common iliac artery. For venous outflow, the portal vein is kept relatively short, in order to avoid the risk of venous thrombosis by kinking or impingement.

**Recipient Operation**

Over the years, different surgical techniques have been described for (a) the management of exocrine pancreatic secretions and (b) the type of venous drainage. For the secretions, the two most common techniques are drainage of the duodenal segment to the bladder (bladder drainage) or to the small bowel (enteric drainage) (Figs. 11-12 and 11-13). For venous drainage, systemic venous drainage is preferred over portal venous drainage.

The pancreas graft is usually placed intra-abdominally and preferably on the right side because the iliac vessels are...
in a more shallow position on the right than on the left side; moreover, the vessels are already appropriately aligned for the vascular anastomoses (i.e., a lateral position for the common iliac vein, a medial position for the common iliac artery). Venous and arterial anastomoses are performed end-to-side. After restoration of blood flow to the graft, hemostasis must be meticulously maintained. Because the donor portal vein purposely is kept short, ligation and transection of all of the recipient’s internal iliac vein branches are frequently performed in order to prevent tension on the venous anastomosis. The pancreas usually is placed with the pancreatic head and duodenum pointing caudally.

Bladder drainage is performed using either a hand-sewn or a stapled anastomosis in which the antimesenteric side of the donor duodenum is sewn to the superior portion of the dome of the bladder. The stapled technique requires that a circular cutting stapler be inserted through the open distal end of the donor duodenum, which is subsequently closed. Bladder drainage has two main advantages. First, rejection of the exocrine pancreas precedes rejection of the endocrine pancreas by 5 to 7 days. Amylase levels are measured routinely in the recipient’s urine. With bladder drainage, antirejection treatment can successfully be implemented when the recipient is still normoglycemic and only hypoamylasuric. In the absence of hyperglycemia, more than 90% of pancreas rejection episodes are reversible. Second, bladder drainage avoids the bacterial contamination that occurs with enteric drainage. If an anastomotic leak occurs, it is easier to treat because the infection usually remains localized to the right lower quadrant.

Enteric drainage is more physiologic and has advantages as well. The antimesenteric side of the donor’s duodenum is anastomosed to the antimesenteric portion of the recipient’s jejunum in a side-to-side fashion. The enteric anastomosis can also involve a defunctionalized Roux-en-Y loop, which minimizes the potential complications if an enteric leak occurs. Currently, in the United States, more than 80% of all pancreas transplants are performed with enteric drainage for the exocrine pancreatic secretions, and more than 90% employ systemic venous drainage.
Complications

The technical complication rate for pancreas transplants is higher than for any other solid organ transplant. Four factors contribute to the high surgical complication rate: (a) the nature of the organ itself with inherent organ-specific surgical complications (e.g., peritonitis, abscesses, necrosis, fistulas, and pseudocysts) and its low blood flow (which significantly increases the risk of thrombosis, as compared with a kidney or liver transplant); (b) the risk of a leak or infection after connecting two hollow viscera (the duodenum and either the bladder or small intestine); (c) the increased incidence of rejection episodes because the pancreas is one of the most immunogenic solid organs; and (d) the underlying disease of diabetes mellitus, predisposing patients not only to infections but also to cardiovascular and other complications.

The most common surgical complications are thrombosis (an incidence of 5%–15%), intra-abdominal abscesses (5%–10%), and bleeding (6%–8%). Other pancreas-specific complications include graft pancreatitis (frequently due to procurement or reperfusion injury), pancreatic fistulas, and pancreatic pseudocysts. Anastomotic leaks do not always require a graft pancreatectomy, but arterial pseudoaneurysms, arteriovenous fistulas, and wound dehiscence may. Bleeding frequently requires relaparotomy.

Thrombosis usually occurs within the first week posttransplant. It manifests as a sudden increase in insulin requirements or as a sharp drop in urinary amylase levels. Venous thrombosis, which is more common than arterial thrombosis, is associated with distinct clinical symptoms, including a swollen and tender graft, hematuria, lower extremity edema, and deep vein thrombosis, the latter two occurring ipsilaterally. Arterial thrombosis is less symptomatic and may not initially cause pain; its diagnosis is usually confirmed by Doppler ultrasonography. Surgical exploration in recipients with thrombosis usually requires a graft pancreatectomy.

With the advent of advanced interventional radiologic procedures to drain intra-abdominal abscesses, the reoperation rate has markedly decreased. Pancreas transplant recipients are usually kept on broad-spectrum antimicrobial agents for the first 7 days posttransplant.

The most common nonsurgical complication posttransplant is rejection. The incidence of rejection is about 30% within the first year. The diagnosis is usually based on an increase in serum amylase and lipase levels and, in bladder-drained recipients, a decrease in urinary amylase levels. A sustained drop in urinary amylase levels greater than 25% from baseline should prompt a pancreas graft biopsy to rule out rejection. In enteric-drained recipients, one must rely on serum amylase and lipase levels only. Other signs and symptoms of rejection include tenderness over the graft, unexplained fever, and hyperglycemia, which usually is a late finding; fewer than 5% of all rejection episodes can be reversed in its presence. The diagnosis of rejection should be confirmed by a percutaneous pancreas graft biopsy.

Other nonsurgical complications include infections with CMV, HCV, or extra-abdominal bacteria or fungi; malignancies, such as PTLD; and, rarely, graft-versus-host disease. For such complications, the diagnosis and treatment are similar to what is recommended after other solid organ transplants.

Bladder-drained pancreas recipients may experience an array of unique urologic complications. Usually the result of the irritating nature of pancreatic enzymes on the urothelium in the bladder and urethra, these urologic complications can lead to cystitis, hematuria, and dysuria. With the loss of bicarbonate from pancreatic secretions, dehydration and metabolic acidosis are not uncommon. Many of these complications are chronic, such that approximately 20% to 30% of all bladder-drained recipients require conversion to enteric drainage within the first 5 years posttransplant.

Living Donor Pancreas Transplants

Pancreas transplants using living donors also can be performed safely and successfully in select donors and recipients. Since 1979, about 150 such transplants have been performed worldwide, with 1-year graft survival rates in excess of 85% over the last decade. A meticulous donor evaluation using standard criteria remains key to a low donor metabolic and surgical complication rate. The concept of procuring the distal pancreas from a living donor is based on the observation that patients with benign or malignant pancreatic disorders can undergo a distal hemipancreatectomy without any serious change in endocrine function.

Living donor pancreas transplants are ideal for patients with an identical twin, but other relatives can be suitable donors as well. In particular, patients with high PRA levels should be considered for a living donor transplant.

Living donor pancreas transplants decrease the number of deaths of diabetic patients on the waiting list, help overcome the organ shortage, reduce mortality and morbidity, and improve the quality of life for patients with debilitating side effects of diabetes. The use of living donors also reduces the risk of graft rejection, as compared with the use of deceased donors. Yet living donor pancreas transplants remain relatively rare, performed under very selective circumstances. In terms of surgical technique, the donor splenic artery and vein are anastomosed to the recipient’s external iliac artery and vein in an end-to-side fashion, and exocrine drainage can occur via an anastomosis.

new donor pancreases is an appealing option for patients with type 1 diabetes. An islet transplant involves the procurement of a solitary pancreas for one islet recipient. If the primary goal of current islet transplant trials is not insulin independence but rather a reduction in the incidence and severity of hypoglycemic events, a reduction in exogenous insulin requirements, and an amelioration of hemoglobin A1c levels. Islet transplants rarely maintain long-term insulin independence. A recent study showed a higher rate of insulin independence in PTA recipients than in recipients of an islet transplant alone, despite the use of up to three donor pancreases in each of the islet recipients. Until islet transplant results significantly improve and include long-term insulin independence, a pancreas transplant remains the treatment of choice for β-cell replacement therapy in patients with IDDM.

**Islet versus Pancreas Transplants**

Pancreas transplants are frequently compared with islet transplants (vide infra), which are less invasive and, therefore, more appealing. It is important to emphasize that these two types of transplants are not mutually exclusive but rather complementary. The results of islet transplants have improved over the past decade, but overall islet graft function, specifically long-term function, is still significantly trailing overall pancreas graft function.

Islet transplants involve pancreas procurement (as described earlier) and then separation of islets from the exocrine pancreatic tissues using proteolytic enzymes (as described later). The human pancreas contains about one million islets, of which half are lost during the isolation process. About 10,000 islets per kilogram of body weight are needed to achieve insulin independence when transplanted into the liver. Frequently, one donor pancreas does not suffice; in fact, up to four donor pancreases have been used for one islet recipient.

Because of the relatively disappointing long-term outcomes, insurance providers in the United States do not provide reimbursement for islet transplants. Transplant centers with both pancreas and islet transplant programs follow an algorithm that favors islet transplants in patients with a high surgical risk and pancreas transplants in patients with a low surgical risk. Although solitary donor pancreases are not in short supply, only one donor pancreas is required for a successful pancreas transplant; in contrast, two to four donor pancreases are commonly used for one islet recipient with less favorable long-term outcomes.

Of note, the primary goal of current islet transplant trials is not insulin independence but rather a reduction in the incidence and severity of hypoglycemic events, a reduction in exogenous insulin requirements, and an amelioration of hemoglobin A1c levels. Islet transplants rarely maintain long-term insulin independence. A recent study showed a higher rate of insulin independence in PTA recipients than in recipients of an islet transplant alone, despite the use of up to three donor pancreases in each of the islet recipients. Until islet transplant results significantly improve and include long-term insulin independence, a pancreas transplant remains the treatment of choice for β-cell replacement therapy in patients with IDDM.

**Islet Transplantation**

Transplanting islets of Langerhans isolated from deceased donor pancreases is an appealing option for patients with type 1 diabetes. An islet transplant involves the procurement of a simultaneous kidney transplant and excellent results. Transplant outcomes in SPK improved significantly because of a decrease in the rates of technical and immunologic graft loss. In 2010 to 2014 vs. 2005 to 2009, U.S. SPK transplant patient survival at 1 year posttransplant increased from 95.7% to 97.4%, pancreas graft function increased from 88.3% to 91.3%, and kidney function increased from 93.6% to 95.5%. A significant improvement was also noted in PAK transplants. One-year patient survival increased from 96.4% to 97.9%, and pancreas graft function increased from 81.0% to 86.0%. PTA 1-year patient survival remained constant at 97%, and pancreas 1-year graft survival improved from 81.0% to 85.7%. IPTR data show significant improvements in patient survival and pancreas graft function rates since the inception of UNOS, over a course of 24 years. Clearly, pancreas transplants now offer excellent outcomes for patients with IDDM.

**Results**

As of December 2010, more than 35,000 pancreas transplants had been reported to the IPTR: more than 25,000 transplants in the United States and more than 10,000 in other countries. According to IPTR data, recipient age at the time of the transplant has increased significantly, and so has the number of transplants for patients with type 2 diabetes. The trend over time has been toward stricter donor criteria, with a concentration on younger donors, preferably trauma victims, and on short pancreas graft preservation time.

Drainage techniques have changed over time, too: enteric drainage of exocrine pancreatic secretions is now predominant, in combination with systemic drainage of the venous effluent of the pancreas graft. Immunosuppressive protocols have developed toward antibody induction therapy, followed by administration of tacrolimus and MMF for maintenance. Steroid avoidance has increased over time in all three recipient categories.

Between 2005 and 2009 and 2010 and 2014, the number of U.S. pancreas transplants declined by over 20%, while the overall number of pancreas transplants performed outside the United States has increased. The decline in U.S. numbers is predominantly due to the decline in primary and secondary pancreas after kidney transplants (PAK). During the time period studied, the number of PAK transplants dropped by 50%. In contrast, the number of simultaneous pancreas/kidney transplants (SPK) declined by only 10%, and the number of pancreas transplants alone (PTA) by 20%. Over 90% of pancreas transplants worldwide were performed, with a simultaneous
donor pancreas and its transportation to a specialized islet isolation facility, where the pancreas is enzymatically digested; then, the islets are purified from the rest of the digested pancreas using density gradients. The purified islets are then cultured and evaluated for their identity, viability, and potency, before being infused into the portal vein of a diabetic recipient. When the procedure is successful, these islet cells engraft into the recipient and secrete insulin, providing excellent moment-to-moment control of blood glucose, as is seen with a whole-pancreas transplant.

A successful islet transplant offers advantages over exogenous insulin injections—advantages that are similar to those of a whole-pancreas transplant. These advantages include restoring β-cell secretory capacity, improving glucose counterregulation, restoring hypoglycemia awareness, providing perfect or near-perfect glucose homeostasis, and, potentially, preventing secondary diabetic complications.

Unlike a whole-pancreas transplant, an islet transplant does not involve a major surgical procedure with its associated mortality and morbidity. Instead, it can generally be performed as an outpatient procedure using percutaneous catheter-based therapy to cannulate a branch of the portal vein, with minimal recovery time for the recipient. Potential complications associated with islet injection include portal hypertension, portal vein thrombosis, hepatic abscesses, and bacteremia. Theoretically, islet transplants could have wider application (as compared with current practice and with whole-pancreas transplants), given the significantly lower surgical risk, the relatively small tissue volume transplanted, and the potential for islet immunomodulation or immunoisolation, which could minimize or eliminate the need for immunosuppression.

The first reported attempt at an islet transplant was in 1893 by Watson-Williams and Harsant: they transplanted a sheep’s minced pancreas into the subcutaneous tissue of a young boy with ketoacidosis. The discovery of insulin may have reduced interest in islet transplants as a treatment for diabetes, at least until the realization that insulin could not provide perfect glycemic control and that, therefore, patients ultimately suffered devastating secondary complications. Several milestones ensued: the first whole-pancreas transplants, early success with rodent islet transplants, and then, in the 1970s, human islet autotransplants after pancreatectomy, in order to address the intractable pain associated with chronic pancreatitis, by Sutherland, Najarian, and colleagues in Minnesota.108

Until recently, attempts to extend these trailblazing findings of clinical islet autotransplants to clinical islet allografts in patients with type 1 diabetes met with generally very poor success. For example, in 1995, a report of the International Islet Transplant Registry indicated that of 270 recipients, only 5% were insulin-independent at 1 year posttransplant.

In 2000, Shapiro and colleagues reported the results of the Edmonton protocol, which enabled consistent diabetes reversal and short-term (<1 year) insulin independence. The Edmonton protocol prescribed transplanting a large number of freshly isolated islets (>10,000 islet equivalents per kilogram body weight, typically requiring the use of two to four pancreases) with a specialized “islet-sparing,” steroid-free immunosuppressive protocol consisting of low-dose tacrolimus, sirolimus, and IL-2 receptor antibody induction. Those results were replicated at other experienced transplant centers, but the rates of long-term (>5 year) insulin independence remained poor, well below those of whole-pancreas transplants.114 Still, despite the low rates of long-term insulin independence, most islet recipients were C-peptide positive and retained hypoglycemia awareness, indicating residual islet function and benefit. In fact, at 9 years posttransplant, 15% remained insulin-independent, and 73% had hypoglycemia awareness and corrected hemoglobin A1c levels.

In the mid-2000s, new trials began with the goal of establishing protocols that enable insulin independence, using islets from a single donor pancreas; the results were good, especially with strict donor and recipient selection. In the most experienced centers, long-term rates of diabetes reversal are now about 50% at 5 years posttransplant. The reasons include refinements in pancreas preservation, islet isolation, and culture protocols, as well as the use of newer induction immunosuppressive agent combinations, such as a T-cell-depleting antibody (anti-CD3 antibody, alemtuzumab, or antithymocyte globulin) and a tumor necrosis factor-alpha (TNF-α) inhibitor (etanercept or infliximab). Presumably, viable β-cell mass is now preserved, both pre- and posttransplant. Thus, islet transplant results are approaching those of whole-pancreas transplants; however, because islets from more than one pancreas are typically needed, those results cannot be directly compared with the results of whole-pancreas transplants.

In the United States, an islet transplant is still officially deemed an experimental procedure. In contrast, since 2001, it has been considered a standard of care and is fully reimbursed in Canada and, more recently, in the United Kingdom, Sweden, Switzerland, France, and Italy as well. The full potential of islet transplants remains to be realized, but the future is exciting. As the latest improvements in pancreas preservation, islet isolation and purification, islet culture, and islet immunosolation are implemented clinically, the hope is that sustained insulin independence may become consistently possible with a single pancreas donor and without the need for systemic immunosuppression.

**LIVER TRANSPLANTATION**

The first attempts at liver transplants in the late 1960s through the 1980s were largely experimental endeavors, with a 1-year survival rate of only 30%. But breakthroughs in immunosuppression, surgical technique, organ preservation, anesthesia, and critical care have improved that rate to approximately 85% today. Liver transplants remain daunting, especially in the face of an organ shortage that results in sicker potential candidates. Unfortunately, the perioperative mortality rate and the 1-year mortality rate are among the highest of any surgical operation currently performed.

**History**

The first experimental liver transplants in dogs are often attributed to C. Stuart Welch in 1955 and then Jack Cannon in 1956. However, current scholarship reveals that Vittorio Staudacher first described the technique in 1952. A series of canine experiments followed, which refined the surgical technique to ensure perioperative survival.

The next obstacle—immunologic rejection—was addressed by drug immunosuppression with AZA and prednisone. The first human liver transplant trials started in 1963 with Thomas Starzl, but a series of deaths led to a voluntary moratorium for 3.5 years. With the resumption of clinical transplants in 1967, Starzl performed the first successful liver transplant.
Still, for the next decade, survival rates were dismal: only 20% of the 170 liver transplant recipients in Starzl’s program at the University of Colorado survived more than 5 years.\(^{124}\)

Several innovations dramatically improved outcomes. The advent of better immunosuppressive drugs was instrumental. In 1978, cyclosporine was introduced clinically in England. It was soon combined with prednisone to great effect. The arrival of tacrolimus in the 1990s further improved graft survival.

Technical advances were also significant. Donor procurement techniques and cold organ preservation protocols were standardized, and the recipient operation was also refined. Choledochocystic and choledochojunostomy to a Roux-en-Y limb became standard and significantly decreased the frequency of biliary complications. Innovations, including living donor liver transplants and deceased donor split-liver transplants, enabled more pediatric recipients to be transplanted. Improvements in portosystemic shunting and perioperative critical care also were contributory.

**Indications**

In general, any form of irreversible liver disease is an indication for a liver transplant. Chronic alcoholic disease and HCV are the most common indications in the United States. An extensive list of acute and chronic diseases of the liver that are treatable by a liver transplant is provided in Table 11-6.

Offering transplants to alcoholic patients has always drawn some opposition because of the perception of it being a self-inflicted illness, as well as concerns about recidivism and the recipient’s possible inability to maintain postoperative immunosuppression and care. Yet studies have shown that such patients have excellent outcomes and that liver transplants for them are cost-effective.\(^{125-127}\) Because patients who drink 4 to 8 ounces of liquor daily for 10 to 15 years have an increased risk of developing cirrhosis, the general requirement for acceptance as a transplant candidate is 6 months of abstinence. Furthermore, most transplant centers recommend rehabilitation and Alcoholics Anonymous programs.

Transplants for HCV have yielded worse outcomes than transplants for other diseases.\(^{128}\) The reason is the universal recurrence of the virus posttransplant. Viral levels reach pretransplant levels as early as 72 hours posttransplant.\(^{129}\) The course of the viral infection is often accelerated posttransplant: 10% to 20% of recipients develop cirrhosis after just 5 years.\(^{130}\) Studies have suggested that use of older donors may increase the chance of aggressive recurrence.\(^{131}\) The best method to prevent recurrence would be to eradicate the infection pretransplant, but doing so is not always possible because patients with decompensated cirrhosis often cannot tolerate treatment. Once recurrence occurs, treatment methods are limited. One study found that pegylated interferon and ribavirin therapy achieved a sustained viral response in 44% of patients.\(^{132}\)

A substantial number of patients undergo liver transplants for cholestatic disorders. Primary biliary cirrhosis, an autoimmune disease, is characterized by damage to the intralobular bile ducts that progresses to liver cirrhosis. Trends toward earlier treatment may explain the slight decrease in liver transplants for this disorder.\(^{133}\) Posttransplant outcomes in patients with this disorder have been excellent, with many centers achieving 1-year survival rates of 90% to 95%. Recurrence is relatively uncommon: a large series reported a 30% recurrence rate at 10 years posttransplant.\(^{134}\)

The second most common cholestatic disorder among liver transplant candidates is primary sclerosing cholangitis. It is characterized by inflammation and fibrosis of large intra- and extrahepatic biliary ducts; 70% of such patients also have inflammatory bowel disease. Recurrent cholangitis is common and increases mortality rates beyond what would be expected on the basis of laboratory values. On behalf of such patients, appeals can often be made for priority in allocation to the UNOS regional review boards. Posttransplant outcomes for such patients have been excellent. Primary sclerosing cholangitis is a significant risk factor for cholangiocarcinoma, so annual screenings (including imaging and measurement of serum CA 19-9 levels) should be carried out. Recurrence is fairly uncommon: studies have reported a recurrence rate of up to 20% at 10 years posttransplant.\(^{135}\)

Progressive metabolic disorders also are treatable with liver transplants. Hemochromatosis, an inherited disorder, results in excessive intestinal iron absorption. Iron deposition can cause cirrhosis and severe cardiomyopathy. Careful cardiac evaluation is necessary pretransplant.

Another metabolic disorder, \(\alpha_1\)-antitrypsin deficiency, is characterized by insufficient levels of a protease inhibitor, resulting in early-onset emphysema and cirrhosis. Careful pulmonary evaluation is necessary pretransplant.

Wilson’s disease, an autosomal recessive disorder characterized by impaired cellular copper transport, leads to copper accumulation in the liver, brain, and cornea. Patients can develop significant neurologic complications and cirrhosis. Several reports suggest improvement of neurologic deficiencies posttransplant.\(^{136,137}\)

Transplants can also be performed in patients with hepatic malignancies, but only in accordance with strict criteria.

Hepatocellular carcinoma (HCC), a complication of cirrhosis, is the most common type of hepatic malignancy. Resection is the first line of treatment if possible, but often, cirrhosis is too advanced. If the tumor meets the Milan criteria, a liver transplant can be performed. These criteria were established by a landmark paper in 1996 showing that patients with a single tumor under 5 cm in diameter, or with three tumors under 3 cm in diameter, in the absence of vascular invasion, had a 4-year survival rate of 85%. Patients with such tumors receive exception points, based on their UNOS region, allowing for a timely transplant before their tumors spread.

Transplants for cholangiocarcinoma remains controversial but may be performed if the center has an experimental protocol in place that entails strict recipient selection. The use of a multimodality oncologic approach including neoadjuvant chemo radiotherapy with subsequent OLT achieves excellent results for patients with localized, regional lymph node-negative pCCA. Patient survival after OLT is comparable to the results of OLT for other causes.

Acute fulminant hepatic failure also is an indication for a liver transplant; in fact, such patients are the highest priority for the next available liver in their UNOS region. This devastating illness is defined by acute and severe liver injury with impaired synthetic function and encephalopathy in a person who had normal liver function. It is often caused by acetaminophen overdose; acute fulminant viral hepatitis A, B, and E; other viral infections; drug toxicity; ingestion of Amanita mushrooms; acute fatty liver of pregnancy; or Wilson’s disease. A significant number of patients will recover with supportive care. The difficulty lies in predicting who will not recover and therefore would benefit from a liver transplant. The King’s College criteria were developed for this purpose: patients with acetaminophen-induced disease, a pH <7.3 or grade III/IV encephalopathy, a prothrombin time >100 seconds, and serum creatinine >3.4 mg/dL meet those criteria. Management of acute liver failure is very intensive. Such patients suffer from severe coagulopathy, hypoglycemia, lactic acidosis, and renal dysfunction. They are susceptible to infections, which are frequently overwhelming. Cerebral edema, a serious complication of acute liver failure, is a leading cause of death from brain herniation. Intracranial pressure monitoring and serial imaging are often necessary; if a patient develops irreversible brain damage, a transplant is not performed.

**Recipient Selection**

The diagnosis of cirrhosis itself is not an indication for a transplant. Patients may have compensated cirrhosis for years such that the traditional indication for a transplant is decompensated cirrhosis, manifested by hepatic encephalopathy, ascites, spontaneous bacterial peritonitis, portal hypertensive bleeding, and hepatorenal syndrome (each described below).

Hepatic encephalopathy is an altered neuropsychiatric state caused by metabolic abnormalities resulting from liver failure. The early stages result in sleep disturbances and depression. As the liver disease progresses, patients can become somnolent and confused and, in the end stages, comatose. Ammonia is produced by enterocytes from glutamine and from colonic bacterial catabolism, and the use of serum ammonia levels as a marker of encephalopathy is controversial because a variety of factors can influence levels. Hyperammonemia suggests worsening liver function and bypass of portal blood flow around the liver. GI bleeding and infection can exacerbate hepatic encephalopathy.

Ascites (the accumulation of fluid in the abdominal cavity) that is caused by cirrhosis is a transudate with a high serum-ascites gradient (>1.1 g/dL). Associated with portal hypertension, it is treated initially with sodium restriction and diuretics. Refractory ascites necessitates large-volume paracentesis and eventually a transjugular intrahepatic portosystemic shunt (TIPS). Contraindications to TIPS placement include significant hepatic encephalopathy, advanced liver disease, congestive heart failure, renal insufficiency, and severe pulmonary hypertension.

Spontaneous bacterial peritonitis, an infection of the ascitic fluid without an evident intra-abdominal source, is characterized by fever, abdominal pain, and an ascitic fluid polymorphonuclear count ≥250 cell/mm³ on paracentesis. The first line of empiric treatment is with a third-generation cephalosporin because the majority of cases are caused by aerobic gram-negative microbes such as *E. coli*, although Gram stain and culture results should be used to guide therapy.

Portal hypertensive bleeding can be a devastating event for patients with cirrhosis. Each bleeding event carries a 30% mortality rate and accounts for a third of all deaths related to cirrhosis. Only 50% of bleeding events cease spontaneously, so treatment must be expedient. The initial medical treatment is with vasopressin and octreotide. The initial intervention is endoscopy with sclerotherapy and band ligation of bleeding varices. If these initial attempts fail, more aggressive treatment is necessary with a balloon tamponade (using a Sengstaken-Blakemore tube) and with emergent TIPS placement. The last line of treatment is emergency surgery to place a portosystemic shunt, transect the esophagus, or devascularize the gastroesophageal junction (Sugiura procedure). Preventing variceal bleeding is essential and can be achieved, with some success, using β-blockers.

Hepatorenal syndrome is a form of acute renal failure that develops as liver disease worsens. The etiology is unclear, but splanchnic vasodilation from portal hypertension and increased production of circulating vasodilators result in a decline in renal perfusion. Characterized by oliguria (<500 mL of urine/day) and low urine sodium levels (<10 mEq/L), hepatorenal syndrome is often reversed by a liver transplant, even after dialysis dependence. Pretransplant, other causes of renal failure need to be excluded, including ATN, drug nephrotoxicity, and chronic renal disease. The initial medical therapy includes octreotide, midodrine, and vasopressin analogs, but the syndrome often progresses to dialysis dependence.

The Model for End-Stage Liver Disease (MELD) was originally developed to assess risk for TIPS placement. Later analysis revealed it to be an excellent model to predict survival among patients with cirrhosis, especially those on the waiting list for a liver transplant. In 2002, liver graft allocation was restructured to be based on the MELD score.

Although the historic indication for a liver transplant is decompensated cirrhosis, a landmark analysis comparing waiting list mortality with posttransplant mortality established that a minimum MELD score of 18 is necessary to have a survival benefit posttransplant. A MELD score between 15 and 18 does not confer a survival advantage, but a transplant may be justified if the patient has significant morbidity from cirrhosis.

Acute liver failure itself is an indication for a liver transplant. To qualify for Status 1 (first priority for a donor liver within the UNOS region), the transplant candidate must meet the following criteria: (a) onset of hepatic encephalopathy within 8 weeks after the first symptoms of liver disease;
(b) absence of preexisting liver disease; and (c) ventilator dependence, dialysis, or an international normalized ratio (INR) >2.0.

**Contraindications**

In general terms, contraindications to a liver transplant include insufficient cardiopulmonary reserve, uncontrolled malignancy or infection, and refractory noncompliance. Older age is only a relative contraindication: carefully selected recipients over the age of 70 years can achieve satisfactory outcomes.  

Patients with reduced cardiopulmonary reserve are unlikely to survive a liver transplant. Candidates should have a normal ejection fraction. If coronary arterial disease is present, they should undergo revascularization pretransplant. Severe chronic obstructive pulmonary disease (COPD) with oxygen dependence is a contraindication. Severe pulmonary hypertension with a mean pulmonary artery pressure greater than 35 mmHg that is refractory to medical therapy is also a contraindication. Candidates with pulmonary hypertension should be evaluated with a right heart catheterization.

For candidates with alcoholic liver disease, few reliable predictors of posttransplant relapse exist. Most centers require 6 months of abstinence from drugs and alcohol. Insurance companies often make more stringent demands, including random drug screening and 1 year of abstinence.

Uncontrolled infections pretransplant are a substantial risk posttransplant when the patient becomes significantly immunosuppressed. Fungal and multidrug-resistant bacterial infections are relative contraindications. Some centers require an extended period of treatment and documented eradication pretransplant. HIV infection is a relative contraindication; some centers have strict protocols that exclude patients with a history of acquired immunodeficiency syndrome (AIDS)-related illnesses as well as those who are coinfected with HCV.

Ideally, patients with a history of malignancy (with the exception of HCC) should be cured of the cancer pretransplant. In most cases, this means eradication, completion of curative therapy, and absence of recurrence over a certain period of time, which varies by the tumor type, but can be up to 5 years or longer for aggressive tumors (see “Malignancies”).

**Surgical Procedure**

A liver transplant is among the most extensive operations performed, and it can be associated with considerable blood loss. A bilateral subcostal incision with midline extension is used. Mechanical retraction spreads the rib cage to allow access. The ligamentous attachments of the liver are dissected free. The vascular structures are isolated, including the supracheliac and infrahepatic vena cava, the portal vein, and hepatic artery (Fig. 11-15). The bile duct, portal structures, and vena cava are divided, completing the hepatectomy (Fig. 11-16)—often the bloodiest and most difficult part of the operation, particularly in the presence of extensive varices and severe coagulopathy.

After the liver is removed, the anhepatic phase begins. This phase is characterized by the absence of inferior vena cava return to the heart and by portal congestion due to clamping of the portal vein. Significant hemodynamic instability and increased variceal bleeding can occur. Patients who are unable to tolerate this phase can be placed on venovenous bypass, with cannulas drawing blood from the IVC via the femoral vein and via the portal vein, returning it to the systemic circulation via the subclavian vein. Venovenous bypass itself can cause complications, including air embolism, thromboembolism, and trauma to the cannulated vessels.

The donor liver is placed in the orthotopic position. The supracheliac vena caval anastomosis is performed first in an end-to-end fashion, followed by the infrahepatic vena caval and portal anastomosis, both also end-to-end. The liver is then reperfused, often leading to a period of hemodynamic instability and cardiac arrhythmias due to the release of byproducts of ischemia from the donor liver. Coagulopathy also can worsen because of these byproducts as well as fibrinolysis.

The arterial anastomosis between the donor common hepatic or celiac trunk is most often performed with the recipient CHA in an end-to-end fashion. Of course, many variations are possible. After arterial reperfusion, the bile duct anastomosis is performed between the donor and recipient common ducts, also in an end-to-end fashion. If necessary for technical reasons, the recipient common duct can be joined to a Roux-en-Y limb. Some surgeons choose to insert a T-tube or place internal stents in the common bile duct to protect the anastomosis.

The piggyback technique is a common variation of the standard technique. The recipient’s IVC is preserved by carefully dissecting off the posterior aspect of the liver. This added dissection is a disadvantage of this variation, often increasing hepatectomy time and blood loss. The recipient’s liver is
removed by dividing it at the confluence of the hepatic veins. The preserved IVC is an advantage of this variation, allowing venous return from the lower body to the heart during the anhepatic phase and improving renal perfusion. No randomized studies, however, have demonstrated the superiority of the piggyback technique over the standard technique.

**Pediatric Transplants**

Outcomes after pediatric liver transplants are among the best after any type of transplant, with a 1-year survival rate of 90%. The most common indication is biliary atresia. After diagnosis is confirmed, a Kasai procedure is promptly carried out: a Roux-en-Y loop of bowel is directly anastomosed to the hilum of the liver. The Kasai procedure often allows time for the children to grow in size, reducing the risk of a transplant when it is required, as it eventually is in 75% of such children.

The other common indication for a pediatric liver transplant is a metabolic disorder, such as α₁-antitrypsin deficiency, tyrosine metabolism deficiencies, and primary oxalosis. Since the MELD score was developed for adults, pediatric liver allocation is based on an analogous model, the Pediatric End-Stage Liver Disease (PELD) score, which incorporates bilirubin levels, INR, albumin levels, age, and growth failure.

The surgical procedure is similar to the adult procedure. Graft implantation is more challenging, given the pediatric recipient’s smaller vascular structures. As a result, surgical complications are much more common in pediatric recipients. Hepatic artery thrombosis is about three times more common. Donor size matching is very important in the pediatric population and often limits the donor pool for pediatric recipients. To address this issue, deceased donor split-liver transplants and living donor transplants (both described in the following sections) have been developed.

**Deceased Donor Split-Liver Transplants**

A deceased donor allograft can be split into two grafts, most frequently into a left lateral segment for a child and an extended right segment for an adult (Fig. 11-17). It can be done in vivo (during the donor operation) or ex vivo (on the back table after the donor liver is removed). Both techniques have similar outcomes. Increased morbidity is associated with splitting allografts, whether for adult or pediatric recipients; however, the technique is justified given the donor shortage and has been important for improving access to transplants for pediatric recipients.¹⁴⁷

**Living Donor Transplants**

Donation by an adult living donor to an adult recipient requires either the right or left lobe of the liver (Fig. 11-18). Donation by an adult living donor to a pediatric recipient requires the left lateral lobe (Fig. 11-19). Donor safety is paramount. The overall donor mortality rate after donation was 0.4%, and the overall complication rate was 40%, with multiple complications occurring in 19% of the patients. The rate of serious complications resulting in lasting disability was 1.1%, with liver failure or death in 0.4%.¹⁴⁸ Careful donor selection is vital. Potential donors should be medically and psychologically healthy, their hepatic anatomy should be amenable to donation, and absolutely no coercion can occur. A separate donor team should serve as the donor advocate and thoroughly explain all risks.

Careful recipient selection is essential. Transplant candidates also must qualify for a deceased donor liver transplant because a significant number of living donor transplant recipients will eventually require a retransplant. Transplant candidates should be medically fit enough to withstand the rigors of the operation and of the postoperative course with a partial graft. An absolute contraindication is a critical illness: the limited success of such transplants does not justify the risks to the living donor. The obvious advantages of a living donor transplant are that it can be done expeditiously (avoiding the waiting list mortality associated with candidates for a deceased donor transplant) and that it can be planned.

**Postoperative Care**

A liver transplant imposes significant trauma on the major organ systems. Immediately posttransplant, the first goal is to stabilize those systems. Acid-base equilibrium and hemodynamic stability are often difficult to maintain but are essential. Periods of hypotension can increase the risk of hepatic artery thrombosis. Careful attention needs to be paid to ongoing bleeding. Appropriate hemoglobin levels should be maintained. Ongoing bleeding mandates a return trip to the operating room; the rate of reoperation can be as high as 25% among high-risk patients. Transfusion of platelets and fresh frozen plasma must be done prudently because theoretically their administration can increase the risk of hepatic artery thrombosis. Graft function should be evaluated frequently; if it is impaired, an ultrasound is urgently required to assess for the presence of vascular complications.
Evaluation of Graft Function

Evaluation of the graft begins in the operating room. Its appearance overall, any swelling, and the quantity and quality of bile production after reperfusion can help assess function. In the intensive care unit, hemodynamic stability, correction of coagulopathy, euglycemia, successful temperature regulation, clearance of lactic acid, and restoration of neurologic status are all signs of a functioning graft, even before the first set of liver function test results are obtained. Transaminases usually peak by postoperative day 2. An aspartate transaminase (AST) level greater than 2500 IU/L is suggestive of significant injury. Cholestasis usually peaks from

New York, NY: McGraw-Hill Education; 2008.)
postoperative day 7 to 12. The INR should improve shortly after reperfusion.

In 3% to 4% of patients undergoing a liver transplant, the graft does not function for any identifiable reason, a condition termed primary nonfunction; in such cases, a retransplant is the only option. Some studies suggest that a peak AST level of 5000 IU/L may be predictive of primary nonfunction. Factors associated with primary nonfunction include donor macrosteatosis, prolonged cold and warm ischemic times, and prolonged donor hospital stay.

Complications

Vascular complications occur in about 8% to 12% of recipients and include thrombosis, stenosis, and pseudoaneurysm formation.

The most common vascular complication is hepatic artery thrombosis. Initial reviews suggest that its incidence is between 1.6% and 4%;152 the mortality rate is 50%, even after definitive therapy.153 Early presentation can be quite dramatic, with fulminant hepatic necrosis, primary nonfunction, transaminisis, or fever. Late presentation, however, can be asymptomatic or subtle, with cholangitis, bile leak, mild transaminisis, hepatic abscesses, or failure to thrive. Diagnostic imaging with ultrasound has more than 90% sensitivity and specificity. If hepatic artery thrombosis is identified, urgent reexploration is needed. A thrombectomy or revision of an anastomosis may be successful, but with significant hepatic necrosis, a retransplant is necessary.

Thrombosis of the portal vein is very uncommon. Signs of early thrombosis include liver dysfunction, ascites, and variceal bleeding. Upon diagnosis, an operative thrombectomy should be attempted.

Biliary complications remain the “Achilles’ heel” of liver transplantation, affecting 10% to 35% of these organ recipients. Signs include fever and abdominal pain, with bilious drainage from surgical drains. Diagnosis is made with cholangiography.

Complications manifest themselves as leaks or strictures. Leaks require a reoperation and surgical correction, whereas strictures can most often be managed with radiologic or endoscopic interventions. Two common reconstructions are choledochostomy and choledochojejunostomy. Some centers also routinely use T-tube stents or internal stents. Consensus has not been reached as to which reconstruction technique is superior. Early infectious complications are often associated with initial graft function and pretransplant risk factors. Intra-abdominal infections should raise concerns of a possible bile leak. Fungal infections are often associated with poor graft function. Given the immunosuppressed and compromised state of liver recipients, early infectious complications can be devastating.

The types of opportunistic infections that occur in liver transplant recipients are similar to those that occur in other types of solid organ transplant recipients and are due to suppression of cell-mediated immunity by chronic immunosuppressive drug administration.

Acute rejection occurs in approximately 20% of liver recipients. The first line of treatment is with a high dose of a corticosteroid, which is usually effective; if not, antilymphocyte therapy is initiated. Rejection of the liver (unlike other transplanted organs) does not adversely affect patient or graft survival rates. Maintenance immunosuppression consists of a corticosteroid, tacrolimus, and mycophenolate.

INTESTINE AND MULTIVISCERAL TRANSPLANTATION

After the introduction of long-term total parenteral nutrition (TPN) in the late 1970s and the early success of liver, kidney, and heart transplants, the first attempts at intestine transplants were made. Over the first two decades, the results were dismal. But the introduction of the immunosuppressive drug tacrolimus in the late 1980s led to significant improvement in graft and patient survival rates. Nonetheless, intestine transplants remain the least frequently performed of all transplants, with the lowest graft survival rates.

The main obstacle is the high immunogenicity of the intestine, caused by its abundant lymphoid tissue. High levels of immunosuppression are needed, yet the rejection rate is still high. The microbial colonization of the intestine confers the risk of translocation of pathogenic microorganisms into the recipient’s circulation, causing severe systemic infections. Through the first decade of the 21st century, the survival of patients on long-term TPN was superior to the survival of intestine transplant recipients, so a transplant was considered only as rescue therapy for patients with life-threatening TPN-related complications.
Over the last several years, improvements in surgical techniques, in perioperative and postoperative care, and particularly in immunosuppressive protocols have led to significantly better patient and graft survival rates posttransplant. Recent data indicate that survival rates after an intestine transplant often are better than, or at least similar to, survival rates among patients receiving chronic TPN in the home setting with improved quality of life in selected patients. Today, an intestine or multivisceral transplant is recognized as a feasible treatment.

**Indications and Recipient Selection**

An intestine transplant is indicated for patients with irreversible intestine failure in combination with TPN failure. The definition of intestine failure does not specify the exact length of the remaining intestine. Intestine failure is typically multifactorial. Variables include what part of the small intestine is absent, whether or not the ileocecal valve is present, whether or not the patient underwent an ostomy, and how long the remaining colon is. TPN failure is defined as significant biochemical or pathologic evidence of liver injury, loss of central vein access with thrombosis of at least two central veins, frequent indwelling catheter infection or a single episode of fungal infection, and recurrent episodes of severe dehydration despite IV fluid supplementation.

Indications for a transplant differ between the adult and pediatric population. The leading causes of intestine failure are summarized in Table 11-7. The disease involvement of organs other than the intestine dictates the extent of the operation required. Liver failure is often seen in patients on long-term TPN. If pathologic or biochemical evidence of severe liver damage is combined with signs of portal hypertension, then a combined liver-intestine transplant is the treatment of choice. However, a multivisceral transplant (liver, pancreas, stomach, duodenum, and/or small intestine) might be necessary among children who suffer diffuse intestinal dysmotility syndromes and adults who develop diffuse portomesenteric thrombosis, extensive intra-abdominal desmoid disease encasing the main visceral vascular structures with concurrent short gut syndrome, or massive abdominal trauma.

**Surgical Procedure**

For both the donor and recipient surgery, the key decision is which organs will be transplanted. For an isolated intestine transplant, the blood supply is based on the arterial inflow from the SMA and the venous outflow from the superior mesenteric vein (SMV). Both vessels are isolated at the root of the mesentery.

For a combined liver-intestine transplant, the blood supply is based on the arterial inflow from the celiac axis and SMA, which are procured en bloc with an aortic patch. The liver, duodenum, pancreas, and small intestine—because of their close anatomic relationship—are procured en bloc. If the hepatoduodenal ligament is left intact, no biliary reconstruction is necessary, which virtually eliminates the risk of postoperative biliary complications. Because the entire splanchnic system drains into the liver, venous drainage is achieved by Anastomosis of the hepatic veins to the recipient’s vena cava.

For both an isolated intestine transplant and a combined liver-intestine transplant, the proximal transection of the GI tract occurs at the first portion of the duodenum. For a multivisceral transplant, the stomach is part of the graft; hence, the transection of the GI tract occurs at the distal esophagus. Figures 11-20 to 11-22 show these three main types of transplants.

The vast majority of intestine transplants use a deceased donor organ. However, advances in surgical techniques have made the use of living donors a feasible alternative for either an isolated intestine transplant or a combined liver-intestine transplant. With a living donor, the donor operation is slightly different: for an isolated intestine transplant, 150 to 200 cm of the donor’s ileum, on a vascular pedicle comprising the ileocolic artery and vein, are used (Fig. 11-23); for a combined liver-intestine transplant, performed almost exclusively for pediatric recipients, segments II and III of the donor’s liver are used, in addition to the intestine (Fig. 11-24).

BASIC CONSIDERATIONS

HEART AND LUNG TRANSPLANTATION

History

The first successful heterotopic heart transplant, in an animal model, was performed by Carrel and Guthrie in 1905. Subsequent progress with cardiopulmonary bypass and immunologic modulation facilitated the first successful adult human heart transplant, performed by Christiaan Barnard in 1967 in Cape Town, South Africa. However, it was Norman Shumway at Stanford who persisted with heart transplants, in the face of disappointing patient outcomes at a number of early centers.

Postoperative Care

Initial postoperative care for intestine transplant recipients does not significantly differ from that for other organ transplant recipients. In the intensive care unit, each recipient’s cardiovascular, pulmonary, and renal function is closely monitored; aggressive resuscitation with fluid, electrolytes, and blood products is performed. Broad-spectrum antibiotics are an integral component of care.

Of all solid organ transplants, intestine transplants have the highest rate of rejection. With intestine transplants, no serologic marker of rejection is available, so frequent biopsies and histologic evaluation of the intestinal mucosa are of utmost importance. Rejection leads to structural damage of the intestinal mucosa. Translocation of endoluminal pathogens into the circulation can cause systemic infections.

Thanks to the introduction of new immunosuppressive protocols, the rejection rates and the overall patient and graft survival rates have improved significantly. Variations between the protocols exist, but the general concept is to induce immunosuppression with polyclonal T-cell antibody and high doses of a corticosteroid, followed by maintenance doses of corticosteroids and the calcineurin inhibitor tacrolimus.

Immediately, posttransplant, recipients are maintained on TPN. Enteral nutrition is initiated as early as possible, but it is advanced very cautiously. It can take several weeks for the transplanted intestine to achieve structural integrity and functionality and for the recipient to tolerate the full strength of tube feeds.

Despite all the recent advances, the complication rate posttransplant remains high. The most common complications include intra-abdominal abscesses, enteric leaks, intra-abdominal sepsis, the need for a reoperation, graft thrombosis, life-threatening bleeding, and central line problems. Immunosuppression-specific complications include rejection, PTLD, graft-versus-host disease (GVHD), infections, and malignancies. Tailoring the recipient’s immunosuppression plays a critical role in preventing these complications; a low level of immunosuppression leads to graft rejection, but too much confers a high risk of infectious complications, PTLD, and, less commonly, GVHD—all of which are associated with a significantly increased risk of graft failure and mortality.

The long-term results of intestine transplants have improved significantly, even though they still remain inferior to the results of other abdominal organ transplants.159,160

Figure 11-24. Recipient operation. For a combined living donor liver-intestine transplant in a pediatric recipient, liver segments 2 and 3 are implanted in standard fashion (the donor’s left hepatic vein to the recipient’s vena cava, the donor’s left hepatic artery to the recipient’s proper or common hepatic artery, the donor’s left portal vein branch to the recipient’s portal vein trunk). The donor’s ileocolic artery and vein are anastomosed to the recipient’s infra-renal aorta and cava. In the recipient, a duodenum-to-donor ileum anastomosis and a distal Bishop-Coop ileostomy are constructed to reestablish bowel continuity. A very short Roux-en-Y loop (10 to 20 cm) is anastomosed to the donor’s bile duct(s). (Reproduced with permission from Gruessner RWG, Benedetti E: Living Donor Organ Transplantation. New York, NY: McGraw-Hill Education; 2008.)

Similarly, the recipient operation also varies by the organs transplanted. Generally, the recipient’s infrarenal aorta is used to achieve the arterial inflow to the graft. For an isolated intestine transplant, venous drainage is achieved via systemic or portomesenteric drainage; for a combined liver-intestine transplant or a multivisceral transplant, venous drainage is achieved via the hepatic veins. Systemic venous drainage, given its lesser technical difficulty, is preferred over portomesenteric drainage. The diversion of splanchnic flow into the systemic venous circulation can cause several metabolic abnormalities, but no hard evidence shows any negative impact clinically on the recipient.

After the organs are perfused, the continuity of the recipient’s GI tract is restored, which includes the placement of a gastrostomy or jejunostomy feeding tube and an ileostomy. In the early postoperative period, the ileostomy enables regular endoscopic surveillance and biopsy of the intestinal mucosa. Once the recipient recovers, the ileostomy can be taken down.

The last, but often the most difficult, part of the recipient operation is abdominal wall closure. It is especially challenging in intestine transplant recipients because they have usually undergone multiple previous procedures, resulting in many scars, ostomies, feeding tubes, and the loss of abdominal domain. To provide sufficient coverage of the transplanted organs, the use of prosthetic mesh often is necessary.
Thanks to the diligence of Shumway and colleagues in perfecting heart transplant techniques, along with the development, by Caves, of endomyocardial biopsy as a method of allograft rejection surveillance, human heart transplants began to reappear in the 1980s as a viable solution to end-stage heart failure. By 1981, the introduction of cyclosporin A finally created the necessary clinical immunologic modulation necessary to make long-term survival of heart recipients a reality.

Lung transplants have a similar history. In the 1950s, Metras in France and Hardin and Kittle in the United States performed canine lung transplants, demonstrating that meticulous anastomotic technique could produce normal pulmonary pressures. Hardy performed the first human lung transplant in 1963, although the patient lived only 18 days. The first successful long-term lung transplant was performed in 1983 in Toronto. These early lung recipients, however, were plagued by infection, rejection, and, most significantly, bronchial anastomotic dehiscence. Cooper and colleagues soon determined that the high-dose corticosteroids used for immunosuppression were responsible for the frequent occurrence of dehiscence. The combination of high-dose corticosteroids and ischemic donor bronchi was deadly to lung recipients. Cooper, Morgan, and colleagues showed that the bronchial anastomosis could be protected by wrapping it with a vascular omental pedicle, which not only provided neovascularity but also offered a buttress against any partial dehiscence.

Once cyclosporine became available for lung recipients, corticosteroid doses could be quickly tapered and stopped; cyclosporine poses no danger to the integrity of the bronchial anastomosis. In fact, the introduction of cyclosporine allowed the success of the first combined heart-lung transplant at Stanford in 1981 (after unsuccessful attempts by Cooley in 1969, Lillehei in 1970, and Barnard in 1981, all of whom used only high-dose corticosteroids for immunosuppression). The 1980s marked the start of the modern age of thoracic transplants.

Heart Transplants

Indications. The most common diagnosis leading to a heart transplant is ischemic dilated cardiomyopathy, which stems from coronary artery disease, followed by idiopathic dilated myopathy and congenital heart disease. About 3000 patients are added to the waiting list each year.

Evaluation. Pretransplant, both candidates and potential donors are evaluated to ensure their suitability for the procedure. Transplant candidates undergo echocardiography, right and left heart catheterization, evaluation for any undiagnosed malignancies, laboratory testing to assess the function of other organs (such as the liver, kidneys, and endocrine system), a dental examination, psychosocial evaluation, and appropriate screening (such as mammography, colonoscopy, and prostate-specific antigen testing). Once the evaluation is complete, the selection committee determines, at a multidisciplinary conference, whether or not a heart transplant is needed and is likely to be successful. Transplant candidates who meet all of the center’s criteria are added to the waiting list, according to the UNOS criteria, which are based on health status.

Once a potential deceased donor is identified, the surgeon reviews the status report and screening examination results. The donor is initially matched to the recipient per the recipient’s status on the UNOS waiting list, the size match, and the blood type. Results of the donor’s serologic testing, echocardiography, chest X-ray, hemodynamic testing, and possibly coronary artery evaluation are assessed, in order to determine whether or not the donor’s heart can withstand up to 4 hours of cold ischemic time during procurement, transport, and surgery.

Procedure. Heart transplants are most often performed orthotopically (Fig. 11-25). The recipient’s native heart is removed, leaving the superior vena cava, the IVC, the left atrial cuff, the aorta, and the pulmonary artery in situ, in order to allow for anastomosis of the donor’s heart. Usually the left atrial cuff is anastomosed first, providing left heart inflow. Right heart inflow is achieved using a bicaval technique, by directly sewing the donor’s superior vena cava and IVC to the recipient’s venae cavae or by creating an anastomosis of the right atrium to a right atrial cuff. The donor’s main pulmonary artery is connected to the recipient’s pulmonary artery, and finally, the aortic anastomosis is completed (Fig. 11-26).

Once the cross-clamp is removed, the heart is allowed to receive circulation from the recipient and begins to function normally. Inotropic support with isoproterenol, dobutamine, or epinephrine is often required for 3 to 5 days, in order to support recovery from the cold ischemia.

On rare occasions, a heterotopic or “piggyback” heart can be transplanted, leaving the native heart in place. But this scenario is becoming very uncommon with the increasing use of mechanical circulatory support for single-ventricle failure.

Posttransplant Care. Patient survival rates for heart recipients differ slightly after primary transplants vs. retransplants. In 2016, 3209 heart transplants were performed in the United States. New, active listings increased 57% since 2005. Overall 1-year survival for patients who underwent heart transplant in 2009 to 2011 was 90.1%, 3-year survival was 83.5%, and 5-year survival was 76.2%.
survival was 78.3%, and the most common cause of death within the first year after transplant was infection. An increasing number of heart recipients have now survived more than 15 to 20 years with their first graft, especially those with no significant history of either cellular or antibody-mediated rejection.

Heart recipients must be monitored for both early and late complications. Early complications include primary graft dysfunction, acute cellular or antibody-mediated rejection, right heart failure secondary to pulmonary hypertension, and infection. Hemodynamic values are monitored to assess early graft function; pharmacologic and sometimes mechanical support is instituted if needed.

The goal of immunosuppression is to prevent rejection, which is assessed by immunosuppressive levels and, early on, by endomyocardial biopsy. Both T-cell–mediated (cellular) and B-cell–mediated (antibody-mediated) rejection are monitored. Most of the immunosuppression used is aimed at T cells; however, if the recipient has many preformed antibodies or develops donor-specific antibodies, other strategies (such as plasmapheresis or rituximab) are used to reduce the antibody load. Immunosuppressive regimens can vary by center, but most often consist of three categories of medications: a calcineurin inhibitor (usually tacrolimus or cyclosporine), an antiproliferative agent (MMF or AZA), and a corticosteroid (prednisone). Other immunosuppressive agents can be used, depending on the needs of individual recipients.

Recipients are also assessed for any infections, with visual inspection of wound healing and with monitoring of the complete blood count and cultures as needed. Other common early sequelae include drug-induced nephrotoxicity, glucose intolerance, hypertension, hyperlipidemia, osteoporosis, malignancies, and biliary disease.

Late complications include acquired transplant vasculopathy, progressive renal failure, and, most commonly, malignancies, especially skin cancer and PTLD. Accelerated coronary artery disease is the third most common cause of death posttransplant (after infections and acute rejection) and the most common cause after the first year. Coronary artery disease can begin to develop as early as 1 year posttransplant. Its pathogenesis is unknown, but it is believed to be immunologic. Because of these late complications, most transplant centers continue to perform screening tests and recipient examinations at least annually after the first year.

### Lung Transplants

**Indications.** The indications for a lung transplant include congenital disease, emphysema, COPD, cystic fibrosis, idiopathic pulmonary fibrosis, primary pulmonary hypertension, α1-antitrypsin deficiency, and the need for a retransplant after primary graft failure. Each year in the United States, about 1600 patients are added to the waiting list; nearly a third of them have COPD and/or emphysema. The next most common diagnosis among patients on the waiting list is cystic fibrosis. A lung allocation score (LAS) was instituted in 2005. The average lung transplant candidate requires oxygen (often 4 L/min or more at rest) and has an extensively compromised quality of life, as documented by the results of pulmonary function and 6-minute walk tests.

**Evaluation.** Evaluation for a lung transplant is very similar to evaluation for a heart transplant, except that lung transplant candidates undergo more extensive pulmonary function testing, a 6-minute walk test, chest computed tomography, ventilation-perfusion (V-Q) scanning, and arterial blood gas assessment. In addition, all lung transplant candidates must have adequate cardiac function and must meet psychosocial requirements.

Potential lung donors are also screened for blood type and size match. Larger lungs are accepted for COPD patients; smaller lungs are chosen for the restricted chest cavity of fibrotic patients. Donors should have a partial pressure of oxygen in arterial blood (Pao2) value >300 mmHg on a fraction of inspired oxygen (FiO2) of 100% and a positive end-expiratory pressure (PEEP) value of 5. Ideally, donors will have normal chest X-ray results, but exceptions for isolated abnormalities that will not affect subsequent graft function can be made. Living donors can donate a single lobe to a smaller recipient, such as a child. Single-lung transplants are common in many centers and can serve to increase the availability of lungs for multiple recipients. Newer concepts, such as “lung in the box” extracorporeal lung perfusion and stem cell technologies, may further improve the availability of donor lungs by optimizing the use of otherwise marginal grafts.

**Procedure.** Lung transplants can be done either as (a) single-lung transplants (to either side via thoracotomy) or as (b) sequential bilateral-lung transplants (via bilateral thoracotomies or via a single clamshell incision that divides the sternum; Fig. 11-27). They can be done absent extracorporeal mechanical cardiopulmonary perfusion (bypass), with the lung with the worst function (as predicted by preoperative ventilation and perfusion scanning) transplanted first. Despite careful surgical technique and excellent anesthesia, the poor pulmonary reserve of some lung recipients may require the institution of cardiopulmonary bypass to complete the transplant. Bypass is initiated through the chest by direct cardiac cannulation or peripherally via the femoral vessels.

Once the thoracotomy is made, a recipient pneumonectomy is performed with care, in order to avoid injury to the phrenic or recurrent laryngeal nerves. The pulmonary veins and main pulmonary artery are encircled outside the pericardium. At this point, once the main pulmonary vessels are occluded, the need for cardiopulmonary bypass can be assessed.
Posttransplant Care. Patient survival rates for lung recipients vary significantly after primary vs. redo transplants. After primary transplants, the patient survival rates at 1, 3, and 5 years are 83%, 62%, and 46%, respectively; after retransplants, the rates are 64%, 38%, and 28%.

Postoperative care of lung recipients can be very labor-intensive. These patients require meticulous ventilator management, in order to maintain Fio₂ at a minimum and to keep Pao₂ at 70 mmHg. Most patients are extubated within the first 24 to 48 hours. Recipients can require multiple bronchoscopies for both airway management and surveillance biopsies. Diuretics are used generously to counteract any positive fluid balance from the operation and to help with pulmonary recovery.

Early complications include technical complications, graft dysfunction, infections, and rejection. Technical complications often involve stenosis of one or more anastomoses leading to graft dysfunction. Bronchoscopy, V-Q scanning, echocardiography, and radiologic imaging are useful in identifying the causes of graft dysfunction. In up to 20% of recipients, primary early graft dysfunction can occur with no obvious cause. Such dysfunction may be due to some pathology from the donor, perhaps an unknown aspiration, infection, or contusion; or it could result from poor graft preservation at the time of organ procurement. In the intensive care unit, aggressive ventilator and pharmacologic management can help, but recipients can nonetheless progress to the need for mechanical support in the form of ECMO. Infections are treated with appropriate antibiotics, which can be challenging in patients with cystic fibrosis and a history of multidrug-resistant organisms. Rejection is monitored by biopsies and treated as needed.

Late complications include airway complications, such as strictures and, rarely, dehiscence, bronchiolitis obliterans, and malignancies. Strictures are treated with bronchosopic dilation and intervention. Bronchiolitis obliterans often is a sequel of chronic rejection, but can be due to aspiration, chronic infections, or various other causes. In recipients with a progressive fall in their forced expiratory volume in 1 second (FEV₁), bronchiolitis obliterans is suspected. All recipients should be taught to perform microspirometry at home as a screening tool posttransplant. Biopsies are performed to confirm the diagnosis of any complication and, if possible, the cause. Despite aggressive screening and treatment, more than 50% of recipients will develop graft dysfunction. Most if not all of the sequelae of chronic immunosuppression that occur in lung transplant recipients are similar to those occurring in other groups of solid organ transplants.

Heart-Lung Transplants

Every year in the United States, 30 to 50 patients are added to the list of patients waiting to receive a simultaneous heart-lung transplant. The most common diagnosis is idiopathic pulmonary fibrosis, followed by primary pulmonary hypertension. Heart-lung candidates are often younger than their single-organ counterparts. The patient survival rates at 1, 3, and 5 years are 66%, 48%, and 39%, respectively. Often, lung complications ultimately lead to graft failure. The immunosuppression is the same as that for single thoracic organ recipients, with emphasis on weaning the patient off corticosteroids as early as possible.

XENOTRANSPLANTS

Xenotransplants (i.e., cross-species transplants of organs, tissues, or cells) have immense, yet untapped, potential to solve the critical shortage of available grafts. A primary hurdle is the formidable immunologic barrier between species, especially
with vascularized whole organs. Other problems include the potential risk of transmitting infections (known as zoonoses or xenoses) and the ethical problems of using animals for widespread human transplants, even though great progress has been made in the past few years in efforts to overcome these problems.

Pigs are generally accepted as the most likely donor species for xenotransplants into human beings. Pigs would also be easier to raise on a large-scale basis. Guidelines for raising pigs in specialized facilities designated as pathogen-free have been established; in anticipation of clinical trials, such facilities have already been created and populated.

The immunologic barrier in pig-to-human xenotransplants is highly complex, but generally involves four subtypes of rejection. The first is hyperacute rejection (HAR), which is mediated by the presence of natural (preformed) xenoblood factors in humans. These antibodies bind to antigens found mainly on the vascular endothelial cells of porcine donor organs, leading to complement activation, intravascular coagulation, and rapid graft ischemia soon after the transplant. The second subtype is acute humoral xenograft rejection (AHXR), a delayed form of antibody-mediated rejection seen in pig-to-nonhuman-primate transplants after steps to prevent HAR—steps such as depletion of antipig antibodies or complement from nonhuman primates’ serum. Alternative names for AHXR include acute vascular rejection or delayed xenograft rejection. The third subtype is an acute cellular rejection process (similar to the classic T-cell–mediated acute rejection seen in allograft recipients). The fourth subtype is chronic rejection in grafts that survive for more than a few weeks (similar to the chronic rejection seen in long-surviving allograft recipients, with features of chronic vasculopathy).

Many different options are being tested to overcome this immunologic barrier, including the genetic engineering of pigs, the use of agents to inhibit platelet aggregation and complement activation, and the administration of powerful immunosuppressive drugs.

During the first decade of the 21st century, the field of whole-organ xenotransplantation progressed significantly, thanks to the increasing availability of genetically engineered pigs and new immunosuppressive protocols. At a recent symposium organized by the International Xenotransplantation Association, data presented demonstrated extended survival time of porcine solid organs in nonhuman primates: from about 30 days to an average of 60 days and even up to 250 days (depending on the model). However, clinical application is still limited by thrombotic microangiopathy and consumptive coagulopathy; novel methods to prevent those complications will be required for further progress.

Cellular xenotransplants have made great strides and are currently in the early stages of clinical trials. Porcine islet xenotransplants are the most advanced form; five independent groups have now demonstrated survival and function of porcine islets in nonhuman primates for more than 100 days. For the clinical trials, cost-benefit models have been developed, and the regulatory framework has been established. One trial of particular interest involves transplanting encapsulated porcine islets without immunosuppression. Early results are encouraging. But the efficacy of that approach may be limited until further genetic engineering enables proper oxygenation and nourishment of islet grafts, thereby supporting their viability and function.

The future of xenotransplantation is exciting. Continued active research will focus on further genetic engineering of pigs, newer immunosuppressive drugs, and tissue engineering approaches that will minimize or eliminate the need for immunosuppression. Given recent progress, routine clinical application of cellular xenotransplants is likely within the next decade.

BACKGROUND

Patient harm due to medical mistakes can be catastrophic, resulting in high-profile consequences for the patient, surgeon, and institution. A single error can even destroy a surgeon’s career. While mistakes are inherent to human nature, it is becoming more recognized that many mistakes are preventable.

Patient safety is a science that promotes the use of evidence-based medicine and local wisdom to minimize the impact of human error on quality patient care. Wrong-site/wrong-procedure surgeries, retained sponges, unchecked blood transfusions, mismatched organ transplants, and overlooked allergies are all examples of potentially catastrophic events that can be prevented by implementing safer hospital systems. This chapter provides an overview of the modern-day field of patient safety by reviewing key measures of safety and quality, components of culture, interventions and tools, assessment methods, risk management strategies, and a selected review of common complications in surgery.

Medical Care Gone Wrong

Today, there are more medications, diagnoses, procedures, and handoffs performed than ever in the history of medicine. Moreover, overtreatment is now an endemic problem in some areas of healthcare. With more medical care being delivered, there are naturally more opportunities for things to go wrong. In fact, harm may be associated with complexity. The Commonwealth Fund reported that the United States leads the world in medical errors, observing that 34% of patients with health problems in the United States report experiencing medical, medication, or test errors—the highest rate of any nation, and an analysis suggests that the problem of medical care gone wrong, i.e., medical errors including systems errors, may rank as the third leading cause of death in the United States.¹

Medical error is defined as an unintended act (either omission or commission) or one that does not achieve its intended outcome, the failure of a planned action to be completed as intended (an error of execution) or the use of a wrong plan to achieve an aim (an error of planning), and a deviation from the process of care, which may or may not cause harm to the patient. Medical error can occur at the individual provider level or at the system level. An expanding taxonomy is maturing to better categorize the types of factors and events that are avoidable. The role of error may be complex; error can sometimes tragically end the life of a thriving person with a long life expectancy, or it can also accelerate an imminent death.

The most commonly cited report on the incidence of deaths due to medical error, the 1999 Institute of Medicine (IOM) report, describes an incidence of 44,000 to 98,000 deaths annually.² However, this estimate by the IOM was not based on primary research conducted by the IOM; rather, it was based on two older studies conducted in 1984 and 1992. Both studies were small and limited. In 2013, after compiling more recent evidence from multiple sources, James estimated an incidence range of 210,000 to 400,000 deaths a year associated with
Key Points

1. Medical error ranks as the third leading cause of death in the United States when defined to include system errors.
2. One form of medical error is unnecessary or excessive medical care, which represents 21% of medical care administered in the United States.
3. New peer-comparison metrics evaluate appropriateness of surgical care by measuring a physician’s practice pattern among all the physician’s patients benchmarked to the physician’s peers.
4. Judicious opioid prescribing upon discharge after surgery is critical given the magnitude of the opioid crisis.
5. The structure-process-outcome framework within the context of an organization’s culture helps to clarify how risks and hazards embedded within the organization’s structure may potentially lead to error and injure or harm patients.
6. Poor communication contributes to approximately 60% of the sentinel events reported to The Joint Commission.
7. Operating room briefings are team discussions of critical issues and potential hazards that can improve the safety of the operation and have been shown to improve operating room culture and decrease operating room delays.
9. The most important determinant of malpractice claims against a surgeon is patient rapport, not undertesting.

Unnecessary Medical Care

Increasingly preventable complications and complications from unnecessary procedures are considered to be forms of medical error. Unnecessary medical care accounts for an estimated $210 billion in excess spending each year, according to the National Academy of Medicine. The issue represents a significant opportunity to make improve patient safety and lower healthcare costs.

Based on our estimate, medical error is the 3rd most common cause of death in the US

Figure 12-1. Causes of death in the United States 2013. (Reproduced with permission from Makary MA, Daniel M. Medical error—the third leading cause of death in the US, BMJ. 2016 May 3;353:i2139.)
costs. In a Johns Hopkins study, surveying over 2000 physicians in the United States, unnecessary medical care was reported to be common. On average, these authors reported that 21% of medical care is unnecessary. Breaking the problem down by type of medical care, the doctors reported that 22% of prescription medications, 25% of medical tests, and 11% of procedures are unnecessary. These perceptions by U.S. physicians validate previous estimates of the National Academy of Medicine that suggest that one-third of healthcare spending is wasteful and does not result in better health. Addressing avoidable medical and surgical care is a topic gaining increasing recognition in healthcare.

One example of overtreatment in surgical care is opioid over-prescribing. In the United States in 2015 alone, clinicians handed out 249 million opioid prescriptions, almost one for every American adult. And in 2016, the United States produced 14 billion opioid pills (40 for every American citizen). With the exception of pain specialists treating patients with pain syndromes, surgeons are the most common prescribers of opioids. Judicious opioid prescribing is important because of the addictive potential of these medications. Moreover, many patients can recover comfortably after hospital discharge with nonopioid or nonaddictive pain regimens.

**THE SCIENCE OF PATIENT SAFETY**

Medicine is considered a high-risk system with a high error rate, but these two characteristics are not always correlated. Other high-risk industries have managed to maintain an impeccably low error rate. For example, one of the highest risk systems in existence today, the U.S. Navy’s nuclear submarine program, has an unmatched safety record.

Much of the credit for their safety record is due to the culture of the nuclear submarine program, with its insistence on individual ownership, responsibility, attention to detail, professionalism, moral integrity, and mutual respect. These characteristics have created the cultural context necessary for high-quality communications under high-risk, high-stress conditions. Each reactor operator is aware of what is going on at all times and is responsible for understanding the implications and possible consequences of any action. Communication flows freely between crewmen and officers, and information about any mistakes that occur are dispersed rapidly through the entire system so that other workers can learn how to prevent similar mistakes in the future.

**High Reliability Organizations**

The nuclear submarine program is an example of an organization that has achieved the distinction of being considered a “high reliability organization.” High reliability organization theory recognizes that there are certain high-risk industries and organizations that have achieved very low accident and error rates compared to what would be expected given the inherent risks involved in their daily operations. Other high reliability industries and organizations include aircraft carrier flight decks, nuclear power plants, and the Federal Aviation Administration’s air traffic control system. In fact, one reason why nuclear power plants have such an excellent reliability record may be that their operators are often former naval submarine officers whose previous experience and training within one highly reliable organization are easily transferable to other organizations.

One of the assumptions underlying the science of high reliability organizations is that humans who operate and manage complex systems are themselves not sufficiently complex to sense and anticipate the problems generated by the system. This introduces another important idea undergirding the science of patient safety: the concept of normal accident theory. Instead of attributing accidents to individual error, this theory states that accidents are intrinsic to high-volume activities and even inevitable in some settings. Accidents should not be used merely to identify and punish the person at fault, but should be seen as a systems problem and addressed at a broader level. As Ruchlin states, even the “best people can make the worst errors as a result of latent conditions.”

High-risk systems, as defined by Perrow in 1984:

- Have the potential to create a catastrophe, loosely defined as an event leading to loss of human or animal life, despoiling of the environment, or some other situation that gives rise to the sense of “dread.”
- Are complex, in that they have large numbers of highly interdependent subsystems with many possible combinations that are nonlinear and poorly understood.
- Are tightly coupled, so that any perturbation in the system is transmitted rapidly between subsystems with little attenuation.

However, high reliability organization theory suggests that proper oversight of people, processes, and technology can handle complex and hazardous activities and keep error rates acceptably low. Studies of multiple high reliability organizations show that they share the following common characteristics:

- People are supportive of one another.
- People trust one another.
- People have friendly, open relationships emphasizing credibility and attentiveness.
- The work environment is resilient and emphasizes creativity and goal achievement, providing strong feelings of credibility and personal trust.

Developing these characteristics is an important step toward achieving a low error rate in any organization. For this reason, safety culture is a measure used by hospitals nationwide to improve outcomes and is increasingly recognized as a metric of hospital quality.

**The Conceptual Model**

The Donabedian model of measuring quality identifies three main types of improvements: changes to organizational structure, changes in organizational processes, and changes in outcomes. Structure refers to the physical and organizational tools, equipment, and policies that improve safety. Structural measures ask, “Do the right tools, equipment, and policies exist?” Process is the application of these tools, equipment, and policies/procedures to patients (good practices and evidence-based medicine). Process measures ask, “Are the right tools, policies, and equipment being used?” Outcome is the result on patients. Outcome measures ask, “How often are patients harmed?” In this model, structure (how care is organized) plus process (what we do) influences patient outcomes (the results achieved).

The structure, process, and outcome components of quality measurement all occur within the context of an organization’s overall culture. The local culture impacts all aspects of the delivery of care because it affects how front-line personnel
understand and deliver safe patient care. In fact, culture (collective attitudes and beliefs of caregivers) is increasingly being recognized to be the fourth measurable component to the structure-process-outcome model. This recognition is based on growing evidence that local culture is linked to a variety of important clinical outcomes. For any new patient safety initiative to be deemed successful, any change in structure or process must lead to a corresponding positive change in patient outcomes.

### CREATING A CULTURE OF SAFETY

Culture is to an organization what personality is to the individual—a hidden, yet unifying theme that provides meaning, direction, and mobilization. Organizations with effective safety cultures share a constant commitment to safety as a top-level priority that permeates the entire organization. These organizations frequently share the following characteristics:

- An acknowledgment of the high-risk, error-prone nature of an organization’s activities
- A nonpunitive environment where individuals are able to report errors or close calls without fear of punishment or retaliation
- An expectation of collaboration across ranks to seek solutions to vulnerabilities
- A willingness on the part of the organization to direct resources to address safety concerns

Traditional surgical culture stands almost in direct opposition to the values upheld by organizations with effective safety cultures for several reasons. Surgeons are less likely to acknowledge their propensity to make mistakes or to admit these mistakes to others. Surgeons tend to minimize the effect of stress on their ability to make decisions. The surgical culture, especially in the operating room (OR), is traditionally rife with hierarchy. Intimidation of other OR personnel by surgeons was historically accepted as the norm. This can prevent nurses and other OR staff from pointing out potential errors or

Case 12-2  High-profile sentinel event

On December 3, 1994, Betsy Lehman, a *Boston Globe* health columnist, died as a result of receiving four times the intended dose of chemotherapy for breast cancer. Remarkably, 2 days later, Maureen Bateman, a teacher being treated for cancer, also received a chemotherapy overdose and suffered irreversible heart damage. After investigating the medication errors, the prescribing doctor, three druggists, and 15 nurses were disciplined by state regulators. The hospital was sued by the two women’s families and by one of the doctors disciplined.

As a result of this widely publicized event, the Dana-Farber Cancer Institute invested more than $11 million to overhaul their safety programs, including providing new training for their employees and giving doctors more time to meet with patients. The hospital adopted a full disclosure policy so that patients would be informed anytime a mistake had affected their care. Dana-Farber also started a patient committee providing advice and feedback on ways to improve care at the hospital.

Although perceptions of teamwork climate can differ as a function of one’s role in the OR, perceptions of safety climate are relatively consistent across OR providers in a given hospital. Validated in over 300 hospitals, the SAQ is used to establish benchmark safety culture scores by healthcare worker type, department, and hospital. Using this survey, hospitals can compare culture between different types of healthcare workers within a department as well as culture between departments throughout the institution. Scores can be compared to those of other participating institutions to compare safety climates. This allows hospitals to participate with one another to implement programs to improve safety culture. In addition, scores are used to evaluate the effectiveness of safety interventions by comparing the SAQ safety climate scores after implementation to baseline scores.

Strong teamwork is at the core of any effective organization and is a key element to ensuring patient safety in the OR. Teamwork is dependent on the underlying culture and patterns of communication. The ability for all team members, to “speak up” about patient safety concerns is one of the most important elements of creating a culture of patient safety.

### TEAMWORK AND COMMUNICATION

According to The Joint Commission, communication breakdown is one of the top three root causes of sentinel events such as wrong-site surgery (Fig. 12-2). Poor communication contributed to over 60% of sentinel events reported to The Joint Commission in 2011. Good communication is an essential component of teamwork and is especially important in the OR, one of the most complex work environments in healthcare.

Within the realm of patient care, there are enormous amounts of information being exchanged between healthcare providers on a daily basis. Much of this information, if prioritized correctly, has the potential to prevent unintended medical errors and serious harm to patients. The importance of good communication in preventing medical errors is undeniable; however, it is difficult to achieve. The traditional surgical hierarchy can prevent OR personnel from sharing important patient data and expressing safety concerns. One perioperative field study showed a 30% rate of communication failure in the OR, with 36% of these breakdowns having a substantial impact on patient safety.

In addition to overcoming the cultural barrier to better teamwork and communication, the prospective study by Christian and associates of patient safety in the OR demonstrated that the standard workflow of the OR itself presents many opportunities for the loss or degradation of critical information. Hand-offs of patient care from the OR to other locations or providers are particularly prone to information loss, which has been demonstrated in other clinical settings. Hand-offs and auxiliary tasks, such as surgical sponge and instrument counts, frequently take place during critical portions of the case and place competing demands on provider attention from primary patient-centered activities. Communication between the surgeon and pathologist also is vulnerable because the communication often occurs through secondary messengers such as nurses or technicians. This information loss can lead to delays, overuse of
staff and resources, uncertainty in clinical decision making and planning, and oversights in patient preparation.

**Measuring Teamwork**

Research in commercial aviation has demonstrated a strong correlation between better teamwork and improved safety performance. Cockpit crew members’ reluctance to question a captain’s judgment has been identified as a root cause of aviation accidents. Good attitudes about teamwork are associated with error-reduction behaviors in aviation, improved patient outcomes in ICUs, and decreased nurse turnover in the OR. It is also associated with higher job satisfaction ratings and less sick time taken from work.

The SAQ can be used to measure teamwork and provide benchmarks for departments or hospitals seeking to measure and improve their teamwork climate. The SAQ teamwork scores are responsive to interventions that aim to improve teamwork among operating teams, such as the implementation of ICU checklists, executive walk rounds, and preoperative briefing team discussions. The communication and collaboration sections of the SAQ reflect OR caregiver views on teamwork and can be used to distinguish meaningful interventions from impractical and ineffective programs.

In a survey of OR personnel across 60 hospitals, the SAQ identified substantial differences in the perception of teamwork in the OR depending on one’s role. Physicians frequently rated the teamwork of others as good, while nurses at the same institutions perceived teamwork as poor (Fig. 12-3). Similiar

**COMMUNICATION TOOLS**

High reliability organizations such as aviation frequently use tools such as prompts, checks, standard operating protocols, and communication interventions such as team briefings and debriefings. These tools identify and mitigate hazards and allow an organization to complete tasks more efficiently. They also foster a culture of open communication and speaking up if a team member senses a safety concern. Safety checks and standardized team discussions serve as prompts to help “engineer out” human error, providing quality assurance and improving information flow. They also can prevent errors related to omissions, which are more likely to occur when there is information overload, multiple steps in a process, repetitions in steps, and planned departures from routine processes, and when there are other interruptions and distractions present while the process is being executed. These same interventions have been shown to improve patient safety in ORs and ICUs.

**Operating Room Briefings (A Surgical Checklist)**

Preoperative briefings and checklists, when used appropriately, help to facilitate transfer of information between team members (Table 12-3). A briefing, or checklist, is any preprocedure discussion of requirements, needs, and special issues of the procedure. Briefings often are locally adapted to the specific needs of the specialty. They have been associated with an improved safety culture, including increased awareness of wrong-site/wrong-procedure errors, early reporting of equipment problems, reduced operational costs and fewer unexpected delays.

In one study, 30.9% of OR personnel reported a delay before the
institution of OR briefings, and only 23.3% reported delays after briefings were instituted. OR briefings are increasingly being used to ensure evidence-based measures are used, such as the appropriate administration of preoperative antibiotics and deep vein thrombosis (DVT) prophylaxis. Briefings allow personnel to discuss potential problems, before they become a “near miss” or cause actual harm.

Operating Room Debriefings

Postprocedural debriefings improve patient safety by allowing for discussion and reflection on causes for errors and critical incidents that occurred during the case. Errors or critical incidents are regarded as learning opportunities rather than cause for punishment. During the debriefing, the team also can discuss what went well during the case and designate a point person to follow up on any proposed actions that result from the discussion. In addition, most debriefings include a verification of the sponge, needle, and instrument counts and confirmation of the correct labeling of the surgical specimen.

Errors in surgical specimen labeling have not received as much attention as incorrect sponge or instrument counts as an indicator of the quality of communication in the OR. However, an error in communication or during the hand-off process increases the risk of mislabeling a surgical specimen before its arrival in a pathology laboratory. In one study, this type of identification error occurred in 4.3 per 1000 surgical specimens, which implies an annualized rate of occurrence of 182 mislabeled specimens per year (Fig. 12-5). Errors involving specimen identification can result in delays in care, the need for an additional biopsy or therapy, failure to use appropriate therapy, or therapy administered to the wrong body site, side, or patient. These errors can lead to significant harm to the patient, costs to the institution, and distrust by a community. Given the frequency of occurrence and the feasibility and validity of measuring them, mislabeled surgical specimens may serve as a useful indicator of patient safety and should be included in any postprocedural debriefing checklist.

Sign Outs

In healthcare, information frequently passes to covering providers without prioritizing potential concerns. This makes sign outs a very vulnerable process of care, which can lead to catastrophic events.

The term sign out can refer to either the verbal or written communication of patient information to familiarize oncoming physicians about patients who will be under their care. Sign outs should occur whenever a patient’s care setting or provider is changing. When performed well, sign outs help to ensure the transfer of pertinent information. However, previous studies have shown the hand-off process to be variable, unstructured, and prone to error. Common categories of communication failure during sign outs include content omissions, such as failure to mention active medical problems, and failures in the actual communication process, such as leaving illegible or unclear notes (Case 12-3). These failures lead to confusion and uncertainty by the covering physician during patient care decisions, resulting in the delivery of inefficient and suboptimal care.

The use of more structured verbal communication such as the Situational Debriefing Model, otherwise known as SBAR (situation, background, assessment, and recommendation), used by the U.S. Navy, can be applied to healthcare to improve the communication of critical information in a timely and orderly fashion. In addition, all sign outs should begin with the statement, “In this patient, I am most concerned about . . .” to signal to the healthcare provider on the receiving end the most important safety concerns regarding that specific patient.

Implementation

Tools such as checklists, sign outs, briefings, and debriefings improve communication between healthcare providers and create a safer patient environment (Fig. 12-6). Although their use in healthcare is still highly variable, specialties that

have incorporated them, such as intensive care and anesthesia, have made impressive strides in patient safety. Currently, communication breakdowns, information loss, hand off, multiple competing tasks, and high workload are considered “annoying but accepted features” of the perioperative environment.20 As physician attitudes toward errors, stress, and teamwork in medicine become more favorable toward the common goals of reducing error and improving teamwork and communication, medicine will likely achieve many of the milestones in safety that high-reliability industries such as aviation have already accomplished.

### COMPREHENSIVE UNIT-BASED SAFETY PROGRAM

As medical care and hospitals continue to expand, the care that is provided to patients is becoming more fragmented. This fragmentation makes communication more difficult and opportunities for medical errors more common. These problems require common sense solutions, often necessitating a change in the way that care is delivered on the local level. Unit-based meetings to discuss processes that are potentially dangerous for patients can quickly bring danger areas out into the open. These meetings

Case 12-3 Inadequate sign out leading to medical error

Josie King was an 18-month-old child who was admitted to Johns Hopkins Hospital in January of 2001 for first- and second-degree burns. She spent 10 days in the pediatric intensive care unit and was well on her way to recovery. She was transferred to an intermediate care floor with the expectation that she would be sent home in a few days.

The following week, her central line was removed, but nurses would not allow Josie to drink anything by mouth. Around 1 pm the next day, a nurse came to Josie’s bedside with a syringe of methadone. Although Josie’s mother told the nurse that there was no order for narcotics, the nurse insisted that the orders had been changed and administered the drug. Josie’s heart stopped, and her eyes became fixed. She was moved to the pediatric intensive care unit and placed on life support. Two days later, on February 22, 2001, she died from severe dehydration.

After her death, Josie’s parents, Sorrel and Jay King, were motivated to work with leaders at Johns Hopkins to ensure that no other family would have to endure the death of a child due to medical error. They later funded the Josie King Patient Safety Program and an academic scholarship in the field of safety.

Implementing CUSP

The implementation of the Comprehensive Unit-based Safety Program (CUSP) involves measurement of a unit’s safety culture prior to starting the program and inclusion of hospital management from the start. Having management involved allows for more efficient allocation of resources and allows them to better understand the problems faced by front-line providers. Once CUSP is in place, changes can be made using local wisdom to advance patient care. The impact of changes made using CUSP can be measured using both patient outcomes and safety culture data.

Implementation of CUSP has been associated with improved patient outcomes, including decreased surgical site infections. In a 2-year study of colorectal patients, where the first year was pre-CUSP implementation and the second year was post-CUSP implementation, there was a 33% decrease in the surgical site infection rate after CUSP. In this study, the CUSP group met monthly and came up with a list of interventions based on their experience with these cases, including standardization of skin preparation and warming of patients in the preanesthesia area. This study showed that CUSP can be highly effective in ameliorating patient harm and improving patient care.

MEASURING QUALITY IN SURGERY

Despite the newfound focus on patient safety in surgery and the number of initiatives being undertaken by many organizations to improve their safety culture, there are few tools to actually measure whether these efforts are effective in reducing the number of errors. Several agencies and private groups have developed criteria to evaluate quality and safety within hospitals.

Practice Pattern Measures

New quality measures in healthcare focus on the appropriateness of medical care. These appropriateness indicators are doctor-defined and specialty-specific so they are smart and fair. One of the first of these new appropriateness metrics is the average number of tissue blocks a skin cancer (Mohs) surgeon will use to surgically remove a skin cancer. The American College of Mohs Surgeons formalized and endorsed the surgeon metric: average number of blocks a surgeon requires to remove a standardized skin cancer. In a report describing the national distribution of surgeons by their mean number of blocks per case, the national average was found to be 1.7 blocks per surgeon. Statistical outlier surgeons had an average four or more blocks per patient. Boundaries of normal variation was determined by expert physician leaders to define an acceptable range and an

![Figure 12-6](image-url)
unacceptable range (greater than two standard deviations from the national norm). The American College of Mohs Surgeons sent letters to outliers, letting them know where they stand, and offered coaching and retraining help. The new Mohs surgery metric demonstrates the opportunity to reduce unwarranted clinical variation and lower healthcare costs by simply using clinical wisdom and the power of peer-comparison.

Appropriateness measures approach quality differently than traditional quality measures and rely on expert physicians to define the metric and set boundaries of reasonable versus unsafe variation in an individual physician’s practice pattern relative to his or her peers nationally. This concept is being applied to utilization rates of minimally invasive surgery in candidate patients as well as rates of physical therapy utilization before elective spine surgery for chronic pain.

Agency for Healthcare Research and Quality Patient Safety Indicators
The Agency for Healthcare Research and Quality (AHRQ) was created in 1989 as a Public Health Service agency in the Department of Health and Human Services. Its mission is to improve the quality, safety, efficiency, and effectiveness of healthcare for all Americans. Nearly 80% of the AHRQ’s budget is awarded as grants and contracts to researchers at universities and other research institutions across the country. The AHRQ sponsors and conducts research that provides evidence-based information on healthcare outcomes, quality, cost, use, and access. It has advocated the use of readily available hospital inpatient administrative data to measure healthcare quality. The information helps healthcare decision makers make more informed decisions and improve the quality of healthcare services.29

One of the major contributions of the AHRQ is a set of Patient Safety Indicators (PSIs), initially released in 2003 and revised in 2010. PSIs are a tool to help health system leaders identify potential adverse events occurring during hospitalization. Developed after a comprehensive literature review, analysis of International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) codes, review by a clinician panel, implementation of risk adjustment, and empirical analyses, these 27 indicators provide information on potential in-hospital complications and adverse events following surgeries, procedures, and childbirth (Table 12-4).

Provider-level indicators provide a measure of the potentially preventable complications for patients who received their initial care and the complication of care within the same hospitalization. They include only those cases where a secondary diagnosis code flags a potentially preventable complication. Area-level indicators capture all cases of the potentially preventable complications that occur in a given area (e.g., metropolitan area or county), either during their initial hospitalization or resulting in subsequent hospitalization.30

Currently, PSIs are considered indicators, not definitive measures, of patient safety concerns. They can identify potential safety problems that merit further investigation. They also can be used to better prioritize and evaluate local and national initiatives, and even as benchmarks for tracking progress in patient safety. In the future, further growth in electronic health data will make administrative data-based tools like the PSIs more useful.31

The Surgical Care Improvement Project Measures
The Surgical Care Improvement Project (SCIP) was established in 2003 by a national partnership of organizations committed to improving surgical care by reducing surgical complications. The steering committee is comprised of groups such as the Centers for Medicare & Medicaid Services, the American Hospital Association, Centers for Disease Control and Prevention (CDC), Institute for Healthcare Improvement, The Joint Commission, and others.

The incidence of postoperative complications ranges from 6% for patients undergoing noncardiac surgery to more than 30% for patients undergoing high-risk surgery. Common postoperative complications include surgical site infections (SSIs), myocardial infarction, postoperative pneumonia, and thromboembolic complications. Patients who experience postoperative complications have increased hospital length of stay (3 to 11 days longer than those without complications), increased hospital costs (ranging from $1398 for an infectious complication to $18,310 for a thromboembolic event), and increased mortality (median patient survival decreases by up to 69%).32

Despite well-established evidence that many of these adverse events are preventable, failure to comply with standards

CHAPTER 12
QUALITY, PATIENT SAFETY, ASSESSMENTS OF CARE, AND COMPLICATIONS

The Surgical Care Improvement Project measures

<table>
<thead>
<tr>
<th>Process of care performance measures</th>
<th>Infection</th>
</tr>
</thead>
<tbody>
<tr>
<td>• Prophylactic antibiotic received within 1 h before surgical incision</td>
<td></td>
</tr>
<tr>
<td>• Prophylactic antibiotic selection for surgical patients</td>
<td></td>
</tr>
<tr>
<td>• Prophylactic antibiotics discontinued within 24 h after surgery end time (48 h for cardiac patients)</td>
<td></td>
</tr>
<tr>
<td>• Cardiac surgery patients with controlled 6 A.M. postoperative serum glucose</td>
<td></td>
</tr>
<tr>
<td>• Surgery patients with appropriate hair removal</td>
<td></td>
</tr>
<tr>
<td>• Colorectal surgery patients with immediate postoperative normothermia</td>
<td></td>
</tr>
</tbody>
</table>

Venous thromboembolism

• Surgery patients with recommended venous thromboembolism prophylaxis ordered
• Surgery patients who received appropriate venous thromboembolism prophylaxis within 24 h before surgery to 24 h after surgery

Cardiac events

• Surgery patients on a β-blocker prior to arrival who received a β-blocker during the perioperative period

Proposed outcome measures

Infection
• Postoperative wound infection diagnosed during index hospitalization

Venous thromboembolism
• Intra- or postoperative pulmonary embolism diagnosed during index hospitalization and within 30 d of surgery
• Intra- or postoperative deep vein thrombosis diagnosed during index hospitalization and within 30 d of surgery

Cardiac events
• Intra- or postoperative acute myocardial infarction diagnosed during index hospitalization and within 30 d of surgery

Global measures
• Mortality within 30 d of surgery
• Readmission within 30 d of surgery

Data from The Joint Commission, 2012.

The SCIP effort provides an infrastructure and guidelines for data collection and quality improvement on a national scale. By achieving high levels of compliance with evidence-based practices to reduce SSIs, venous thromboembolism events, and perioperative cardiac complications, the potential number of lives saved in the Medicare patient population alone exceeds 13,000 annually.

National Surgical Quality Improvement Program

The National Surgical Quality Improvement Program (NSQIP) is a measurement program that allows hospitals to sample their rates of postoperative events and compare them to similar hospitals. Created by the Veterans Health Administration (VA) in 1991, NSQIP has been credited with measuring and improving morbidity and mortality outcomes at the VA, reducing 30-day mortality rate after major surgery by 31%, and 30-day postoperative morbidity by 45% in its first decade. Beta testing at 18 non-VA sites from 2001 to 2004 demonstrated the feasibility and utility of the program in the private sector. The program was subsequently expanded to the private sector in 2004 when the American College of Surgeons endorsed the program and encouraged hospital participation to measure and evaluate outcomes on a large scale. A study of 118 hospitals participating in NSQIP between 2005 to 2007 showed that 82% of hospitals decreased their complication rates and there was a decrease in morbidity of 11% and mortality of 7% annually per hospital. Currently, over 400 private-sector U.S. hospitals participate in the program.

NSQIP uses a risk-adjusted ratio of the observed to expected outcome (focusing primarily on 30-day morbidity and mortality) to compare the performance of participating hospitals with their peers. The data the program has compiled also can be used to conduct observational studies using prospectively collected information on more than 1.5 million patients and operations. The expansion of NSQIP to the private sector has helped shift the focus from merely preventing the provider errors and sentinel events highlighted by the IOM publication “To Err Is Human” to the larger goal of preventing all adverse postoperative outcomes.

Several insights about patient safety have arisen as a result of NSQIP. First, safety is indistinguishable from overall quality of surgical care and should not be addressed separately. Defining quality in terms of keeping a patient safe from adverse outcomes allows the NSQIP data to be used to assess and improve quality of care by making improvements in patient safety. In other words, prevention of errors is synonymous with the reduction of adverse outcomes and can be used as a reliable quality measure. Second, during an episode of surgical care, adverse
outcomes, and hence, patient safety, are primarily determined by the quality of the systems of care. Errors in hospitals with higher than expected observed to expected outcomes ratios are more likely to be from system errors than from provider incompetence. This underscores the importance of adequate communication, coordination, and teamwork in achieving quality surgical care. Finally, reliable comparative outcomes data are imperative for the identification of system problems. Risk-adjusted rates of adverse outcomes must be compared with those at peer institutions to appreciate more subtle system errors that lead to adverse outcomes to prompt changes in the quality of an institution’s processes and structures.

The Leapfrog Group

One of the largest efforts to standardize evidence-based medicine in the United States is led by The Leapfrog Group, an alliance of large public and private healthcare purchasers representing more than 37 million individuals across the United States. This healthcare consortium was founded in 2000 with the aim to exert their combined leverage toward improving nationwide standards of healthcare quality, optimizing patient outcomes, and ultimately lowering healthcare costs. The Leapfrog Group’s strategy to achieve these goals is through providing patient referral, financial incentives, and public recognition for hospitals that practice or implement evidence-based healthcare standards.

The healthcare quality and safety practices (leaps) that Leapfrog initially identified to measure healthcare standards were hospital use of computerized physician order entry systems, 24-hour ICU physician staffing, and evidence-based hospital referral (EBHR) standards for five high-risk operations. In 2010, after the National Quality Forum (NQF) released its updated Safe Practices for Better Healthcare, Leapfrog added a safe practices leap, which includes eight practices from the NQF report.

Leapfrog collects data on these practices through administration of an ongoing, voluntary, web-based hospital quality and safety survey. This survey is conducted in 41 regions that cover over half of the U.S. population and 62% of all hospital beds in the country. In 2011, more than 1200 urban, suburban, and rural hospitals participated in the survey. Leapfrog asks for information on eight high-risk conditions or procedures, including coronary artery bypass graft, percutaneous coronary intervention, abdominal aortic aneurysm (AAA) repair, pancreatic resection, and esophagectomy. These procedures were chosen because evidence exists that adherence to certain process measures can dramatically improve the outcomes of these procedures. In addition, more than 100 studies also have demonstrated that better results are obtained at high-volume hospitals when undergoing cardiovascular surgery, major cancer resections, and other high-risk procedures. Hospitals fulfilling the EBHR Safety Standard are expected to meet the hospital and surgeon volume criteria shown in Table 12-6. Hospitals that do not meet these criteria but adhere to the Leapfrog-endorsed process measures for coronary artery bypass graft surgery, percutaneous coronary intervention, AAA repair, and care for high-risk neonates, receive partial credit toward fulfilling the EBHR Safety Standard. Leapfrog purchasers work to recognize and reward hospitals that provide care for their enrollees who meet EBHR standards.

In a recent study, Brooke and associates analyzed whether achieving Leapfrog’s established evidence-based standards for AAA repair, including meeting targets for case volume and perioperative β-blocker usage, correlated with improved patient outcomes over time. After controlling for differences in hospital and patient characteristics, hospitals that implemented a policy for perioperative β-blocker usage had an estimated 51% reduction in mortality following open AAA repair cases. Among 111 California hospitals in which endovascular AAA repair was performed, in-hospital mortality was reduced by an estimated 61% over time among hospitals meeting Leapfrog case volume standards, although this result was not statistically significant. These results suggest that hospital compliance with Leapfrog standards for elective AAA repair is an effective means to help improve in-hospital mortality outcomes over time and support further efforts aimed at standardizing patient referral to hospitals that comply with evidence-based medicine standards for other surgical procedures.

The newest effort of the Leapfrog group is to promote transparency of hospital outcomes using a safety scorecard. This information can be viewed at www.hospitalsafetygrade.org.

World Health Organization “Safe Surgery Saves Lives” Initiative

In October 2004, the WHO launched a global initiative to strengthen healthcare safety and monitoring systems by creating the World Alliance for Patient Safety. As part of the group’s efforts to improve patient safety, the alliance implemented a series of safety campaigns that brought together experts in specific problem areas through individual Global Patient Safety Challenges. The second Global Patient Safety Challenge focuses on improving the safety of surgical care. The main goal of the campaign, called Safe Surgery Saves Lives, is to reduce surgical deaths and complications through the universal adaptation of a comprehensive perioperative surgical safety checklist in ORs worldwide (Fig. 12-4). In addition to the checklist, the WHO defined a set of uniform measures for national and international surveillance of surgical care to better assess the quantity and quality of surgical care being delivered worldwide. At the population level, metrics include the number of surgeon, anesthesia, and nurse providers per capita, the number of ORs per capita, and overall surgical case volumes and mortality rates. At the hospital level, metrics include safety improvement structures and a surgical “Apgar score,” a validated method of prognosticating patient outcomes based on intraoperative events (i.e., hypotension, tachycardia, blood loss).

National Quality Forum

The National Quality Forum (NQF) is a coalition of healthcare organizations that has worked to develop and implement a national strategy for healthcare quality measurement and
reporting. Their mission is to improve the quality of American healthcare by setting national priorities and goals for performance improvement, endorsing national consensus standards for measuring and publicly reporting on performance, and promoting the attainment of national goals through education and outreach programs.

One of the major contributions of the NQF is the development of a list of Serious Reportable Events, which are frequently referred to as “never events.” According to the NQF, “never events” are errors in medical care that are clearly identifiable, preventable, and serious in their consequences for patients and that indicate a real problem in the safety and credibility of a healthcare facility. Examples of never events include surgery performed on the wrong body part; a foreign body left in a healthcare facility. Despite widespread agreement that never events are preventable and many never events to help elucidate the root cause.

"NEVER EVENTS" IN SURGERY

Never events are errors in medical care that are clearly identifiable, preventable, and serious in their consequences for patients and that indicate a real problem in the safety and credibility of a healthcare facility. Despite widespread agreement that surgical never events are preventable and despite several national and local programs being launched to decrease them, never events are still a significant problem. A study from Mehtsun and colleagues showed that from October 1990 to October 2010, nationwide there were 9744 paid malpractice claims for never events. Of these, mortality was reported in 6.6%, permanent injury in 33.8%, and temporary injury in 49.7%. The cost of the never events totaled $1.3 billion. Also, of physicians who were named in a surgical never event claim, 12.4% were named in a future never events claim. Another study in 2010 by The Joint Commission found that wrong-site surgery occurs 40 times per week nationwide. Future directions for decreasing these problems include public reporting of never events by hospitals to increase hospital accountability, more formal training in teamwork, and CUSP programs in hospitals that have higher rates of never events to help elucidate the root cause.

Retained Surgical Items

A retained surgical item refers to any surgical item found to be inside a patient after he or she has left the OR, thus requiring a second operation to remove the item. Estimates of retained foreign bodies in surgical procedures range from one case per 8000 to 18,000 operations, corresponding to one case or more each year for a typical large hospital or approximately 1500 cases per year in the United States. This estimate is based on an analysis of malpractice claims and is likely to underestimate the true incidence. The risk of having a retained surgical item increases during emergency surgery, when there are unplanned changes in
sensation of a mass of fullness after a surgical procedure that leads to the discovery of a metallic object on a radiographic study. Commonly retained instruments include the malleable and "FISH" instrument that are used to protect the viscera when closing abdominal surgery.

A retained surgical foreign body should be included in the differential diagnosis of any postoperative patient who presents with pain, infection, a palpable mass, or a radiopaque structure on imaging. The diagnosis can usually be made using a computed tomographic (CT) scan, and this is often the only test needed. If a retained surgical item is identified in the setting of an acute clinical presentation, the treatment usually is removal of the item. However, if the attempt to remove the retained surgical item can potentially cause more harm than the item itself, as in the case of a needle or a small part of a surgical item, then removal is occasionally not recommended. Retained surgical sponges should always be removed.

The American College of Surgeons and the Association of Perioperative Registered Nurses, in addition to The Joint Commission, have issued guidelines to try to prevent the occurrence of retained surgical items. Current recommendations include the use of standard counting procedures, performing a thorough wound exploration before closing a surgical site, and using only X-ray–detectable items in the surgical wound. These organizations also strongly endorse the completion of a postoperative debriefing after every operation. An X-ray at the completion of an operation is encouraged if there is any concern for a foreign body based on confusion regarding the counts by even a single member of the OR team or in the presence of a risk factor.

### Surgical Counts

The benefit of performing surgical counts to prevent the occurrence of retained surgical items is controversial. The increased risk of a retained surgical item during emergency surgery in the study by Gawande and colleagues appeared to be related to bypassing the surgical count in many of these cases. However, in another study, the “falsely correct count,” in which a count is performed and declared correct when it is actually incorrect, occurred in 21% to 100% of cases in which a retained surgical item was found. This type of count was the most common circumstance encountered in all retained surgical item cases, which suggests that performing a surgical count in and of itself does not prevent this error from taking place. The counting protocol also imposes significant demands on the nursing staff and

</tbody>
</table>
distracts them from focusing on other primarily patient-centered tasks, often during critical portions of the case.19

A retained surgical item can occur even in the presence of a known incorrect count. This event is usually a result of poor communication in which a surgeon will dismiss the incorrect count and/or fail to obtain a radiograph before the patient leaves the OR. Having stronger institutional policies in place in case of an incorrect count (such as requiring a mandatory radiograph while the patient is still in the OR) can avoid conflict among caregivers and mitigate the likelihood of a retained surgical item occurring as a result of a known incorrect count.

Although there is no single tool to prevent all errors, the development of multiple lines of defense to prevent retained surgical items and universally standardizing and adhering to OR safety protocols by all members of the surgical team will help reduce the incidence of this never event.46 Surgeons should take the lead in the prevention of retained surgical items by avoiding the use of small or nonradiologically detectable sponges in large cavities, performing a thorough wound inspection before closing any surgical incision, and having a vested interest in the counting procedure performed by nursing staff. The value of routine radiography to prevent a retained surgical item in emergency cases or when major procedures involving multiple surgical teams are being performed is becoming more apparent.

The widely accepted legal doctrine when a foreign body is erroneously left in a patient is that the mere presence of the item in the plaintiff’s body indicates that the patient did not receive proper surgical care. The characteristics of the surgeon and their style, bedside manner, honesty, and confidence demonstrated in the management of the case can go a long way in averting a lawsuit or mitigating damages.

Wrong-Site Surgery
Wrong-site surgery is any surgical procedure performed on the wrong patient, wrong body part, wrong side of the body, or wrong level of a correctly identified anatomic site. It is difficult to determine the true incidence of wrong-site surgery for several reasons. First, there is no standard definition for what constitutes wrong-site surgery among various healthcare organizations. Another factor is that wrong-site surgery is underreported by healthcare providers. Finally, the total number of potential opportunities for each type of wrong-site error is unknown. However, various studies show incidences ranging from 1 in 112,994 cases to 1 in 15,500 cases.46 The Washington University School of Medicine suggests a rate of 1 in 17,000 operations, which adds up to approximately 4000 wrong-site surgeries in the United States each year. If these numbers are correct, wrong-site surgery is the third most frequent life-threatening medical error in the United States.47

Several states now require mandatory reporting of all wrong-site surgery events, including near misses. These data provide some insight into the number of actual errors compared to the number of potential opportunities to perform wrong-site surgery. Of the 427 reports of wrong-site surgery submitted from June 2004 through December 2006 to the Pennsylvania Patient Safety Reporting System, more than 40% of the errors actually reached the patient, and nearly 20% involved completion of a wrong-site procedure.46

The risk of performing wrong-site surgery increases when there are multiple surgeons involved in the same operation or multiple procedures are performed on the same patient, especially if the procedures are scheduled or performed on different areas of the body.47 Time pressure, emergency surgery, abnormal patient anatomy, and morbid obesity are also thought to be risk factors. Communication errors are the root cause in more than 70% of the wrong-site surgeries reported to The Joint Commission.46 Other risk factors include receiving an incomplete preoperative assessment; having inadequate procedures in place to verify the correct surgical site; or having an organizational culture that lacks teamwork or reveres the surgeon as someone whose judgment should never be questioned.

There is a one in four chance that surgeons who work on symmetric anatomic structures will be involved in a wrong-site error sometime during their careers.47 The specialties most commonly involved in reporting wrong-site surgeries according to The Joint Commission are orthopedic/pediatric surgery (41%); general surgery (20%); neurosurgery (14%); urology (11%); and maxillofacial, cardiovascular, otolaryngology, and ophthalmology (14%).46 Most errors involved symmetric anatomic structures: lower extremities (30%), head/neck (24%), and genital/urinary/pelvic/groin (21%).42 Although orthopedic surgery is the most frequently involved, this may be due to the higher volume of cases performed as well as the increased opportunity for lateralization errors inherent in the specialty. In addition, because the American Academy of Orthopaedic Surgeons has historically tried as a professional organization to reduce wrong-site operations, orthopedic surgeons may be more likely to report these events when they do occur.47

The Joint Commission Universal Protocol to Ensure Correct Surgery
The movement to eliminate wrong-site surgery began among professional orthopedic societies in the mid-1990s, when both the Canadian Orthopaedic Association and the American Academy of Orthopaedic Surgeons issued position statements and embarked on educational campaigns to prevent the occurrence of wrong-site surgery within their specialty.47 Other organizations that issued position statements advocating for the elimination of wrong-site surgery include the North American Spine Society, the American Academy of Ophthalmology, the Association of Perioperative Registered Nurses, and the American College of Surgeons. After issuing a review of wrong-site surgery in their Sentinel Event Alert in 1998, The Joint Commission made the elimination of wrong-site surgery one of their first National Patient Safety Goals in 2003 and adopted a universal protocol for preventing wrong-site, wrong-procedure, and wrong-person surgery in 2004. The protocol has been endorsed by more than 50 professional associations and organizations.

A preoperative “time-out” or “pause for the cause” to confirm the patient, procedure, and site to be operated on before incision was recommended by The Joint Commission and is now mandatory for all ORs in the United States. Elements of the protocol include the following:

- Verifying the patient’s identity
- Marking the surgical site
- Using a preoperative site verification process such as a checklist
- Confirming the availability of appropriate documents and studies before the start of a procedure
- Taking a brief time-out immediately before skin incision, in which all members of the surgical team actively communicate and provide oral verification of the patient’s identity, surgical site, surgical procedure, administration of preoperative
medications, and presence of appropriate medical records, imaging studies, and equipment
• Monitoring compliance with protocol recommendations

Focusing on individual process components of the universal protocol, such as surgical site marking or the time-out, is not enough to prevent wrong-site surgery. Over a 30-month period in Pennsylvania, 21 wrong-site errors occurred despite the proper use of time-out procedures, with 12 of these errors resulting in complete wrong-site procedures. During the same period, correct site markings failed to prevent another 16 wrong-site surgeries, of which six were not recognized until after the procedure had been completed.47

Site verification begins with the initial patient encounter by the surgeon, continues throughout the preoperative verification process and during multiple critical points in the OR, and requires the active participation of the entire operating team, especially the surgeon and anesthesia provider. Based on a recent review of malpractice claims, two-thirds of wrong-site operations could have been prevented by a site-verification protocol.48

Despite the proliferation of wrong-site protocols in the last decade, their effectiveness is difficult to measure as the incidence of wrong-site surgery is too rare to measure as a rate. Interestingly, the number of sentinel events reported to The Joint Commission has not changed significantly since the widespread implementation of the Universal Protocol in 2004.47 This could be due to an increase in reporting rather than an actual increase in the incidence of wrong-site surgery.

The legal treatment of wrong-site surgery is similar to that of surgical items erroneously left in a patient: the mere fact that it occurred indicates that the patient did not receive proper surgical care. A malpractice claim may lead to a settlement or award on verdict in the six- or seven-figure range in 2011 U.S. dollars.41

Ultimately, the occurrence of retained surgical items or wrong-site surgery is a reflection of the quality of professional communication between caregivers and the degree of teamwork among the members of the operating team. In addition to standardizing procedures like the surgical count, instituting mandatory postoperative radiographs in the presence of a known miscount, and reforming the processes of patient identification and site verification, organizations should also strive to create a culture of safety, create independent and redundant checks for key processes, and create a system in which caregivers can learn from their mistakes (Table 12-10).49

TRANSPARENCY IN HEALTHCARE

Despite a large increase in data being collected about patient safety and harm, much of it is not available to the public or other hospitals. This lack of transparency allows some hospitals to continue to practice outdated medicine and, in some cases, puts patients at a higher risk of serious complications. In a study by Mark Chassin, the health commissioner of New York State, having hospitals publicly disclose their mortality rates for coronary artery bypass graft (CABG) procedures resulted in a 41% decline in mortality from CABGs statewide.50 In this study, when CABG mortality data were initially made public, there was a wide range in cardiac surgery-related mortality from 1% to 18%, depending on the hospital; the standard of care is 2%. The reasons for higher mortality in the poorly performing hospitals ranged from poor communication between care teams to one rogue surgeon operating when the surgeon should not have been. The consequence of making this data transparent was that the hospitals held multidisciplinary, CUSP-like meetings, where as a team they decided on the measures to implement for improvement. Through this, over the next year, most hospitals decreased their mortality rate to below 2%. Even the hospital that had an 18% mortality rate decreased it to 7% within 3 years and 1.7% over the next several years.

Transparency in healthcare is becoming central to the healthcare quality discussion. A new SCIP core measure is publishing practitioner performance, and all Leapfrog survey results are published online where other hospitals and the public can see them. Additionally, different large medical societies, including the Society for Thoracic Surgery (STS), are encouraging and rewarding practitioners and hospitals that are transparent with their outcomes. Making hospital outcomes transparent makes hospitals accountable to the public for their outcomes and, in the case of New York, caused a radical improvement in the quality of care provided to patients. It also empowers patients by making them better informed about which hospital they choose for their care, which will further incentivize hospitals to improve.

Public Reporting and Patient Assessment of Care
The epiphany moment in contemporary healthcare created by the Institute of Medicine report2 generated far-reaching effects. One important aspect has been development of a variety of initiatives focused on the generation, endorsement, and reporting of numerous measures related to the safety and quality of healthcare—primarily process and outcomes measures. However, the science of measure development is slow paced and, unfortunately, has difficulty evolving at the same pace of change as clinical medicine or healthcare delivery systems.

Given the strong interest for improved knowledge and information by consumers of healthcare, the trend toward public reporting has rapidly gained momentum and outpaced reporting from the measurement science community. This has subsequently created occasional confusion and uncertainty in the marketplace—simply because the generation of public reports are not necessarily always based upon solid scientific data or evidence. The resulting net effect can be creation of a premature focus by organizations and providers on achieving success within influential public reporting venues (e.g., U.S. News Best Hospitals) and uncertainty by patients on what are optimal healthcare information resources.
Ideally centered on the public good, federal government sponsored healthcare payment plans are also focused upon measurement and reporting within the industry. One such initiative funded and overseen by the Agency for Healthcare Research and Quality (AHRQ) is the Hospital Consumer Assessment of Healthcare Providers and Systems (HCAHPS) program. AHRQ works closely with a consortium of public and private research organizations to develop and maintain the HCAHPS surveys, but they do not administer any of the surveys to patients or require use of the surveys. The intent of the HCAHPS initiative is to provide a standardized survey instrument and data collection methodology for measuring patients’ perspectives on hospital care (Fig. 12-7).

While many hospitals have collected information on patient satisfaction, prior to HCAHPS there was no national standard for collecting or publicly reporting patients’ perspectives of care information that would enable valid comparisons to be made across all hospitals. Three broad goals have shaped the HCAHPS Survey. First, the survey is designed to produce comparable data on the patient’s perspective on care that allows objective and meaningful comparisons between hospitals on domains that are important to consumers. Second, public reporting of the survey results is designed to create incentives for hospitals to improve their quality of care. Hospitals frequently distribute the results of HCAHPS surveys of individual services or physicians to incentivize corrective steps and improve patients’ perceptions of their care. Third, public reporting will serve to enhance public accountability in healthcare by increasing the transparency of the quality of hospital care provided in return for the public investment (www.hcahpsonline.org).

HCAHPS scores are now directly tied to a hospital’s CMS reimbursement by federal law, and survey results account for 25% of the value-based purchasing score—directly impacting a hospital’s Medicare payments. In May 2005, the National Quality Forum (NQF), an organization established to standardize healthcare quality measurement and reporting, formally endorsed the HCAHPS Hospital Survey. The NQF endorsement represents the consensus of many healthcare providers, consumer groups, professional associations, purchasers, federal agencies, and research and quality organizations (www.qualityforum.org).

While the American College of Surgeons and other professional societies continue to develop and implement scientifically based healthcare measures, the escalating prevalence of less robust measures developed outside of scientific communities will also continue to expand. The patient population, provider organizations, payer organization, and the surgical community will necessarily need to find the balance of developing and utilizing valid patient-based information for decision-making.

RISK MANAGEMENT

Between one-half to two-thirds of hospital-wide adverse events are attributable to surgical care. Most surgical errors occur in the OR and are technical in nature. Surgical complications and adverse outcomes have previously been linked to lack of surgeon specialization, low hospital volume, communication breakdowns, fatigue, surgical residents and trainees, and numerous other factors.

However, poor surgical outcomes are not necessarily correlated with a surgeon’s level of experience in performing a certain procedure. In one study, three-fourths of the technical errors that occurred in a review of malpractice claims data involved fully trained and experienced surgeons operating within their area of expertise, and 84% occurred in routine operations that do not require advanced training. Rather than surgeon expertise, these errors likely occurred due to situations complicated by patient comorbidity, complex anatomy, repeat surgery, or equipment problems (Table 12-11). Because these errors occurred during routine operations, previous suggestions to limit the performance of high-complexity operations using selective referral, regionalization, or limitation of privileging may not actually be effective in reducing the incidence of technical error among surgical patients.

In any event, although there has been much emphasis on reducing the prevalence of surgical technical errors as a way of improving surgical care, a technical error in the OR may not be the most important indicator of whether a surgeon will be sued by a patient. Recent studies point to the importance of a surgeon’s communication skills in averting malpractice litigation. In the American College of Surgeons’ Closed Claims Study, although intraoperative organ injuries occurred in 40% of patients, a surgical technical misadventure was the most deficient component of care in only 12% of patients. In fact, communication and practice pattern violations were the most common deficiency in care for one third of patients in the Closed Claims Study who received the expected standard of surgical care.

The Importance of Communication in Managing Risk

The manner and tone in which a physician communicates is potentially more important to avoiding a malpractice claim than the actual content of the dialogue. For example, a physician relating to a patient in a “negative” manner may trigger litigious feelings when there is a bad result, whereas a physician relating in a “positive” manner may not. Expressions of dominance, in which the voice tone is deep, loud, moderately fast, unaccented, and clearly articulated, may communicate a lack of empathy and understanding for the patient, whereas concern or anxiety in the surgeon’s voice is often positively related to expressing concern and empathy. General and orthopedic surgeons whose tone of voice was judged to be more dominant were more likely to have been sued than those who sounded less dominant.

When significant medical errors do occur, physicians have an ethical and professional responsibility to immediately disclose them to patients. Failure to disclose errors to patients undermines public confidence in medicine and can create legal liability related to fraud. Physicians’ fear of litigation represents a major barrier to error disclosure. However, when handled appropriately, immediate disclosure of errors frequently leads to improved patient rapport, improved satisfaction, and fewer malpractice claims. In fact, rapport is the most important factor in determining whether a lawsuit is filed against a physician.

In 1987, the Department of Veterans Affairs Hospital in Lexington, Kentucky, implemented the nation’s first formal apology and medical error full disclosure program, which called for the hospital and its doctors to work with patients and their families to settle a case. As a result, the hospital improved from having one of the highest malpractice claims totals in the VA system to being ranked among the lowest quartile of a comparative group of similar hospitals for settlement and litigation costs over a 7-year period. Its average payout in 2005 was $16,000 per settlement vs the national VA average of $98,000 per settlement, and only two lawsuits went to trial during a

Table 12-11

Common causes of lawsuits in surgery

- Positional nerve injury
- Common bile duct injury
- Failure to diagnose or delayed diagnosis
- Failure to treat, delayed treatment, or wrong treatment
- Inadequate documentation
- Inappropriate surgical indication
- Failure to call a specialist
- Cases resulting in amputation/limb loss

10-year period. As a result of the success of this program, the Department of Veteran Affairs expanded the program to all VA hospitals nationwide in October 2005. This model also was replicated at the University of Michigan Health System with similar results. Its full-disclosure program cut the number of pending lawsuits by one half and reduced litigation costs per case from $65,000 to $35,000, saving the hospital approximately $2 million in defense litigation bills each year. In addition, University of Michigan’s doctors, patients, and lawyers are happier with this system. The cultural shift toward honesty and openness also has led to the improvement of systems and processes to reduce medical errors, especially repeat medical errors.
With regard to risk management, the importance of good communication by surgeons and other care providers cannot be overemphasized. Whether alerting other members of the care team about a patient’s needs, openly discussing concerns the patient and/or family might have, or disclosing the cause of a medical error, open communication with all parties involved can reduce anger and mistrust of the medical system; the frequency, morbidity, and mortality of preventable adverse events; and the likelihood of litigation.

**COMPLICATIONS**

Despite the increased focus on improving patient safety and minimizing medical errors, it is impossible to eliminate human error entirely. Individual errors in judgment or technique can cause minor or major complications during or after a surgical procedure. Although these types of errors may not be quantified as easily as wrong-site surgery or a retained surgical item, they can still lead to surgical complications that prolong the course of illness, lengthen hospital stay, and increase morbidity and mortality rates. In addition to technical and management errors, patient comorbidities also increase the risk of complications. The recognition and management of complications is a critical component of surgical care.

**Robotic Surgery**

Surgical advancements would not exist without intellectual curiosity, innovation, and technical developments; robotic surgery is a prime example of such an advance. With these advancements, however, errors and complications appear to be an inevitable and recognized risk by institutions and stakeholders due to unforeseen risks inherent in the new technology and the failure or delay of achieving expertise with a new device or technology. Although the reward for adopting new advances may be notoriety, increased patient referrals, improved patient satisfaction, decreased pain, and possibly decreased length of stay, the risks of adopting new technologies and methods become apparent only after widespread use.

Multiple surgical specialties have begun or continue to develop their experiences using robotic surgery from general surgery procedures such as inguinal hernia repairs to pancreatecduodenectomies to complex thoracic, urologic and ear, nose, and throat procedures. When robotic surgery goes awry, however, the complications can be serious. The MAUDE (Manufacturer and User Facility Device Experience) is an open access database where mandatory and voluntary adverse events are collected. As it relates to robotic surgery, some important information has been elucidated. Device failures (electrocautery, instrument malfunctions), make up roughly half of the complications. A retrospective study over the past 14 years in the United States documented over 10,000 robotic device-related complications that have occurred, of which 98% were reported by the manufacturers and distributors, and 2% were voluntary reports by hospitals and physicians. The data revealed that 1535 adverse events (14.4%) led to significant negative patient experiences (1391 injuries and 144 deaths). Additionally, the absolute number of reports increased 32 times since 2006, while in the same time period, the number of cases performed has only increased tenfold. Despite the large number of reports contained within this database, the extent to which it is a true representation of the complications associated with robotic surgery is uncertain due to the lack of comprehensive and mandatory reporting.

Despite the numbers and trends reported from this database, few prospective, controlled trials exist that examine the risks and benefits of robotic surgery with those of open and laparoscopic surgery. The data from 5 to 10 years ago may also be misleading as the approved use of robotic surgery continues to expand to additional specialties. The more recent adoption of robotic surgery by specialties such as gynecologic surgery, for example, appears to be accompanied by a disproportionately high rate of morbidity and mortality in robotically assisted procedures. Teaching institutions are producing a newer generation of robotic surgeons who will continue important advances in surgery and identify those patients who would benefit most from this type of approach. The challenge for the surgical community is to develop robust and effective training programs to allow trainees and practicing surgeons to acquire the skills necessary to perform robotic procedures with the highest degree of safety. This need replicates the development of skill acquisition processes that reversed the high number of bile duct injuries after the introduction of laparoscopic cholecystectomy and suggests that validated curricula and the use of robotic simulation applications will be crucial to achieve these goals (see Chapter 53, Skills and Simulation).

**Complications in Minor Procedures**

When performing procedures such as central line insertion or arterial line insertion, one should consider the necessity of the access, the use of less invasive or lower risk alternatives such as PICC line insertion instead of central line insertion, and non-invasive cardiac monitoring instead of arterial line insertion. While these alternatives may not be reliable substitutes in all patients, considering less invasive procedures can reduce the problem of avoidable harm.

**Central Venous Access Catheters.** Complications of central venous access catheters are common. Improvements in ultrasound technology and mass education surrounding the use and techniques in ultrasonography have led to increased employment and enthusiasm for its use in central venous catheter placement. Numerous institutions have mandated the use of ultrasound for placement of all central venous lines. In addition, many subclavian catheters have been alternatively placed at the internal jugular position due to a perceived benefit of decreasing the complication of pneumothorax. This theoretical benefit may be offset by an increase in line infections as the neck is a difficult site to keep clean and the dressing intact. Steps to decrease complications include:

- Ensure that central venous access is indicated.
- Experienced personnel should insert the catheter or should supervise the insertion.
- Use proper positioning and sterile technique.
- Ultrasound is recommended for internal jugular vein insertion.
- All central venous catheters should be assessed on a daily basis and should be exchanged only for specific indications (not as a matter of routine).
- All central catheters should be removed as soon as possible.

Common complications of central venous access include the following.

**Pneumothorax** Occurrence rates from both subclavian and internal jugular vein approaches are 1% to 6%. Prevention requires proper positioning of the patient and correct insertion technique. A postprocedure chest X-ray is recommended to confirm the presence or absence of a pneumothorax, regardless
of whether a pneumothorax is suspected. Recent reports have questioned whether a chest X-ray is required when the line is placed and confirmed under ultrasound guidance. Pneumothorax rates are higher among inexperienced providers and under-weight patients but occur with experienced operators as well. If the patient is stable, and the pneumothorax is small (<15%), close expectant observation may be adequate. If the patient is symptomatic, a thoracostomy tube should be placed. Occasionally, pneumothorax will occur as late as 48 to 72 hours after central venous access attempts. This usually creates sufficient compromise that a tube thoracostomy is required.

**Arrhythmias** Arrhythmias can result from myocardial irritability secondary to guidewire placement and usually resolve when the catheter or guidewire is withdrawn from the right heart. Prevention requires electrocardiogram (ECG) monitoring whenever possible during catheter insertion and rapid recognition when a new arrhythmia occurs.

**Arterial Puncture** Inadvertent puncture or laceration of an adjacent artery with bleeding can occur, but the majority will resolve with direct pressure on or near the arterial injury site. Rarely will angiography, stent placement, or surgery be required to repair the puncture site, but close observation and a chest X-ray are indicated. Ultrasound-guided insertion has not mitigated this complication, but it may decrease the incidence of arterial puncture. Ultrasound use has also been shown to decrease the number of attempts and the time it takes to complete insertion.

**Lost Guidewire** A guidewire or catheter that inadvertently migrates further into the vascular space away from the insertion site can be readily retrieved with interventional angiography techniques. A prompt chest X-ray and close monitoring of the patient until retrieval are indicated.

**Air Embolus** Although estimated to occur in only 0.2% to 1% of patients, an air embolism can be dramatic and fatal. If an embolus is suspected, the patient should immediately be placed into a left lateral decubitus Trendelenburg position so the entrapped air can be stabilized within the right ventricle. Auscultation over the precordium may reveal a “crunching” sound, but a portable chest X-ray will help confirm the diagnosis. Aspiration via a central venous line accessing the heart may decrease the volume of gas in the right side of the heart and minimize the amount traversing into the pulmonary circulation. Subsequent recovery of intracardiac and intrapulmonary air may require open surgical or angiographic techniques. Treatment may prove futile if the air bolus is larger than 50 mL, however.

**Pulmonary Artery Rupture** Flow-directed, pulmonary artery (Swan-Ganz) catheters can cause pulmonary artery rupture due to excessive advancement of the catheter into the pulmonary circulation. There usually is a sentinel bleed with coughing noted when a pulmonary artery catheter balloon is inflated, followed by uncontrolled hemoptysis. Reinflation of the catheter balloon is the initial step in management, followed by immediate airway intubation with mechanical ventilation, an urgent portable chest X-ray, and notification of the OR that an emergent thoracotomy may be required. If there is no further bleeding after the balloon is reinflated, the X-ray shows no significant consolidation of lung fields from ongoing bleeding, and the patient is easily ventilated, then a conservative nonoperative approach may be considered. However, more typically a pulmonary angiogram with angiembolization or vascular stenting is required. Hemodynamically unstable patients rarely survive because of the time needed to initiate and perform interventional procedures or a thoracotomy and to identify the ruptured branch of the pulmonary artery.

**Central Venous Line Infection** The CDC reports mortality rates of 12% to 25% when a central venous line infection becomes systemic, with a cost of approximately $25,000 per episode.60-62 The CDC does not recommend routine central line changes, but when the clinical suspicion of infection is high, the site of venous access must be changed. Nearly 15% of hospitalized patients will acquire central venous line sepsis. In many instances, once an infection is recognized as central line sepsis, removing the line is adequate. *Staphylococcus aureus* infections, however, present a unique problem because of the potential for metastatic seeding of bacterial emboli. The required treatment is 4 to 6 weeks of tailored antibiotic therapy. Using a checklist when inserting central venous catheters has been shown to significantly decrease rates of line infections.63-65 Following a checklist strategy and close monitoring of catheters has resulted in significant reductions in infection rates for numerous institutions, and many are now reporting zero annual infection rates.

**Arterial Lines.** Arterial lines are placed to facilitate arterial blood gas sampling and hemodynamic monitoring. The use of ultrasound to assist in placement of these catheters has become commonplace and markedly reduces the number of attempts and time for insertion completion.

Arterial access requires a sterile Seldinger technique, and a variety of arteries are used, including the radial, femoral, brachial, axillary, dorsalis pedis, or superficial temporal arteries. Although complications occur less than 1% of the time, they can be catastrophic. Complications include thrombosis, bleeding, hematoma, arterial spasm (nonthrombotic pulselessness), and infection. Thrombosis or embolization of an extremity arterial catheter can result in the loss of a digit, hand, or foot, and the risk is nearly the same for both femoral and radial cannulation. Thrombosis with distal tissue ischemia is treated with anticoagulation, but occasionally surgical intervention is required. Pseudoaneurysms and arteriovenous fistulae can also occur.

**Endoscopy and Bronchoscopy.** The principal risk of gastrointestinal (GI) endoscopy is perforation. Perforations occur in 1 in 10,000 patients with endoscopy alone but have a higher incidence rate when biopsies are performed (up to 10%). This increased risk is due to complications of intubating a GI diverticulum (either esophageal or colonic) or from the presence of weakened or inflamed tissue in the intestinal wall (e.g., diverticulitis, glucocorticoid use, or inflammatory bowel disease).

Patients will usually complain of diffuse abdominal pain shortly after the procedure and then progress with worsening abdominal discomfort and peritonitis on examination. In obtunded or elderly patients, a change in clinical status may be delayed for 24 to 48 hours. Radiologic studies to look for free intraperitoneal air, retroperitoneal air, or a pneumothorax are diagnostic. Open or laparoscopic exploration locates the perforation and allows repair and local decontamination of the surrounding tissues.

The occasional patient who may be a candidate for nonoperative management is one in whom perforation arises during an elective, bowel-prepped endoscopy and who does not have significant pain or clinical signs of infection. These patients must be closely observed in a monitored setting and must be on strict dietary restriction and broad-spectrum antibiotics.

Complications of bronchoscopy include bronchial plugging, hypoxemia, pneumothorax, lobar collapse, and bleeding.
When diagnosed in a timely fashion, they are rarely life-threatening. Bleeding usually resolves spontaneously and rarely requires surgery but may require repeat endoscopy for thermocoagulation or fibrin glue application. The presence of a pneumothorax necessitates placement of a thoracostomy tube when significant deoxygenation occurs or the pulmonary mechanics are compromised. Lobar collapse or mucous plugging usually responds to aggressive pulmonary toilet but occasionally requires repeat bronchoscopy. If biopsies have been performed, the risk for these complications increases.

**Tracheostomy.** Tracheostomy facilitates weaning from a ventilator, may decrease length of ICU or hospital stay, and improves pulmonary toilet. Tracheostomies are performed open, percutaneously, with or without bronchoscopy, and with or without Doppler guidance. The advantages of percutaneous tracheostomy include efficiency and cost containment over open tracheostomy. A recent literature review examining early (<3–7 days) vs late (>14 days) tracheostomy after endotracheal intubation demonstrates little difference in outcomes but does demonstrate greater patient comfort in those patients with tracheostomy than those with an endotracheal tube. Complications and outcomes between the two different methods remain largely equivalent.

Recent studies do not support obtaining a routine chest X-ray after percutaneous or open tracheostomy. However, significant lobar collapse can occur from copious tracheal secretions or mechanical obstruction. The most dramatic complication of tracheostomy is tracheoinnominate artery fistula (TIAF) (Fig. 12-8). This occurs rarely (<0.3%) but carries a 50% to 80% mortality rate. TIAF can occur as early as 2 days or as late as 2 months after tracheostomy. A sentinel bleed occurs in 50% of TIAF cases, followed by a large-volume bleed. Should a TIAF be suspected, the patient should be transported immediately to the OR for fiberoptic evaluation. If needed, remove the tracheostomy and place a finger through the tracheostomy site to apply direct pressure anteriorly for compression of the innominate artery while preparation for a more definitive approach is organized.

**Percutaneous Endogastronomy.** A misplaced percutaneous endogastronomy (PEG) tube may lead to intra-abdominal sepsis with peritonitis and/or an abdominal wall abscess with necrotizing fasciitis. As in other minor procedures, the initial placement technique must be fastidious to avoid complications.

Endoscopic transillumination of the abdomen from within the stomach has been proposed to decrease the risk for error, but this is without supporting evidence. Inadvertent colotomies, intraperitoneal placement of the tube and subsequent leakage of tube feeds with peritonitis, and abdominal wall abscesses require surgery to correct the complications and to replace the PEG with an alternate feeding tube, usually a jejunostomy.

A dislodged or prematurely removed PEG tube should be replaced as early as possible after dislodgment because the gastrostomy site closes rapidly. A contrast X-ray (sinogram) should be performed to confirm the tube’s intragastric position before feeding. If there is uncertainty of the tube location, conversion to an open tube placement procedure is required.

**Tube Thoracostomy.** Chest tube insertion is performed for pneumothorax, hemothorax, pleural effusions, or empyema. In most patients, a chest tube can be easily placed with a combination of local analgesia and light conscious sedation. Common complications include inadequate analgesia or sedation, incomplete penetration of the pleura with formation of a subcutaneous tube track, lacerations to the lung or diaphragm, intraperitoneal placement of the tube through the diaphragm, and bleeding. Additional problems include slippage of the tube out of position or mechanical problems related to the drainage system. In patients with bullous disease, there can be significant intrapleural scarring, and it can be easy to mistakenly place the chest tube into bullae. All of these complications can be avoided with proper initial insertion techniques, plus a daily review of the drainage system and follow-up radiographs. Tube removal can create a residual pneumothorax if the patient does not maintain positive intrapleural pressure by Valsalva maneuver during tube removal and dressing application.

**Complications of Angiography.** Intramural dissection of a cannulated artery can lead to complications such as ischemic stroke from a carotid artery dissection or occlusion, mesenteric ischemia from dissection of the superior mesenteric artery, or a more innocuous finding of “blue toe syndrome” from a dissected artery in a peripheral limb. Invasive or noninvasive imaging studies confirm the suspected problem. The severity of ischemia, extent of dissection determine if anticoagulation therapy or urgent surgical exploration is indicated.

Bleeding from a vascular access site usually is obvious, but may not be visible when the blood loss is tracking into the retroperitoneal tissue planes after femoral artery cannulation. These patients can present with hemorrhagic shock, an abdominopelvic CT scan delineates the extent of bleeding along the retroperitoneum. Initial management is direct compression at the access site and resuscitation as indicated. Urgent surgical exploration may be required to control the bleeding site and evacuate larger hematomas.

Renal complications of angiography occur in 1% to 2% of patients. Contrast nephropathy is a temporary and preventable complication of radiologic studies such as CT, angiography, and/or venography. Intravenous (IV) hydration before and after the procedure is the most efficient method for preventing contrast nephropathy. Nonionic contrast also may be of benefit in higher-risk patients. Close communication between providers is often required to resolve the priorities in care as well as to balance the risks versus benefits of renal protection when managing patients in need of angiographic procedures.

**Complications of Biopsies.** Lymph node biopsies have direct and indirect complications that include bleeding, infection,
lymph leakage, and seromas. Measures to prevent direct complications include proper surgical hemostasis, proper skin preparation, and a single preoperative dose of antibiotic to cover skin flora 30 to 60 minutes before incision. Bleeding at a biopsy site usually can be controlled with direct pressure. Infection at a biopsy site will appear 5 to 10 days postoperatively and may require opening of the wound to drain the infection. Seromas or lymphatic leaks resolve with aspiration of seromas and the application of pressure dressings but may require repeated treatments or even placement of a vacuum drain.

**Organ System Complications**

**Neurologic System.** Neurologic complications that occur after surgery include motor or sensory deficits and mental status changes. Peripheral motor and sensory deficits are often due to neurapraxia secondary to improper positioning and/or padding during operations. Treatment is largely clinical observation, and the majority of deficits resolve spontaneously within 1 to 3 months.

Direct injury to nerves during a surgical intervention is a well-known complication of several specific operations, including superficial parotidectomy (facial nerve), carotid endarterectomy (hypoglossal nerve), thyroidectomy (recurrent laryngeal nerve), prostatectomy (nervi erigentes), inguinal herniorrhaphy (ilioinguinal nerve), and mastectomy (long thoracic and thoracodorsal nerves). The nerve injury may be a stretch injury or an unintentionally severed nerve. In addition to loss of function, severed nerves can result in a painful neuroma that may require subsequent surgery.

Mental status changes in the postoperative patient can have numerous causes (Table 12-12). Mental status changes must be continually assessed. A noncontrast CT scan should be used early to detect new or evolving intracranial causes.

Atherosclerotic disease increases the risk for intraoperative and postoperative stroke (cerebrovascular accident). Postoperatively, hypotension and hypoxemia are the most likely causes of a cerebrovascular accident. Neurologic consultation should be obtained immediately to confirm the diagnosis. Management is largely supportive and includes adequate intravascular volume replacement plus optimal oxygen delivery. Advents in interventional radiology by radiologists and vascular and neurologic surgeons have proven successful alternatives in patients requiring diagnostic and therapeutic care in the immediate and acute postoperative period. Catheter-directed therapy with anticoagulants such as the kinases and tissue plasminogen activator (tPA) has potential benefit in postoperative thrombosis where reoperation carries significant risk. In addition, endoluminal stents with drug-eluting stents (DESs) or non-DESs have been used with some degree of success. DESs do require systemic antplatelet therapy due to the alternative coagulation pathway. Duration of antiplatelet therapy of 1 year is routine.

**Eyes, Ears, and Nose.** Corneal abrasions are unusual, but are due to inadequate protection of the eyes during anesthesia. Overlooked contact lenses in patients occasionally cause conjunctivitis.

Persistent epistaxis can occur after nasogastric tube placement or removal, and nasal packing is the best treatment option if prolonged persistent direct pressure on the external nares fails. Anterior and posterior nasal gauze packing with balloon tamponade, angioembolization, and fibrin glue placement may be required in refractory cases. The use of antibiotics for posterior packing is controversial.

External otitis and otitis media occasionally occur postoperatively. Patients complain of ear pain or decreased hearing, and treatment includes topical antibiotics and nasal decongestion for symptomatic improvement.

Otoxicity due to aminoglycoside administration occurs in up to 10% of patients and is often irreversible. Vancomycin-related otoxicity occurs about 3% of the time when used alone, and as often as 6% when used with other ototoxic agents.68

**Vascular Problems of the Neck.** Complications of carotid endarterectomy include central or regional neurologic deficits or bleeding with an expanding neck hematoma. An acute change in mental status or the presence of localized neurologic deficit requires an immediate return to the OR. An expanding hematoma may warrant emergent airway intubation and subsequent transfer to the OR for control of hemorrhage. Intraoperative anticoagulation with heparin during carotid surgery makes bleeding a postoperative risk. Other complications include arteriovenous fistulae, pseudoaneurysms, and infection, all of which are treated surgically.

AIDS = acquired immunodeficiency syndrome; ICU = intensive care unit; MAOI = monoamine oxidase inhibitor; TCA = tricyclic antidepressant.
Intraoperative hypotension during manipulation of the carotid bifurcation can occur and is related to increased tone from baroreceptors that reflexively cause bradycardia. Should hypotension occur when manipulating the carotid bifurcation, an injection of 1% lidocaine solution around this structure should attenuate this reflexive response.

The most common delayed complication following carotid endarterectomy remains myocardial infarction. The possibility of a postoperative myocardial infarction should be considered as a cause of labile blood pressure and arrhythmias in high-risk patients.

**Thyroid and Parathyroid Glands.** Surgery of the thyroid and parathyroid glands can result in hypocalcemia in the immediate postoperative period. Manifestations include ECG changes (shortened P-R interval), muscle spasm (tetany, Chvostek’s sign, and Trouseau’s sign), paresthesias, and laryngospasm. Treatment includes calcium gluconate infusion and, if tetany ensues, chemical paralysis with intubation. Maintenance treatment is thyroid hormone replacement (after thyroidectomy) in addition to calcium carbonate and vitamin D.

Recurrent laryngeal nerve (RLN) injury occurs in less than 5% of patients. Of those with injury, approximately 10% are permanent. Dissection near the inferior thyroid artery is a common area for RLN injury. At the conclusion of the operation, if there is suspicion of an RLN injury, direct laryngoscopy is diagnostic. The cord on the affected side will be in the paramedian position. With bilateral RLN injury, the chance of a successful extubation is poor. If paralysis of the cords is not permanent, function may return 1 to 2 months after injury. Permanent RLN injury can be treated by various techniques to stent the cords in a position of function.

Superior laryngeal nerve injury is less debilitating, as the common symptom is loss of projection of the voice. The glottic aperture is asymmetrical on direct laryngoscopy, and management is limited to clinical observation.

**Respiratory System.** Surgical complications that put the respiratory system in jeopardy are not confined to technical errors. Malnutrition, inadequate pain control, inadequate mechanical ventilation, inadequate pulmonary toilet, and aspiration can cause serious pulmonary problems.

Pneumothorax can occur from central line insertion during anesthesia or from a diaphragmatic injury during an abdominal procedure. Hypotension, hypoxemia, and tracheal deviation away from the affected side may be present. A tension pneumothorax can cause complete cardiovascular collapse. Treatment is by needle thoracostomy, followed by tube thoracostomy. The chest tube is inserted at the fifth intercostal space in the anterior axillary line. The anterior chest wall is up to 1 cm thicker than the lateral chest wall, so needle decompression is more effective in the lateral position. Attempted prehospital needle decompression in the traditional anterior position results in only 50% needle entry into the thoracic cavity.

Hemothoraces should be evacuated completely. Delay in evacuation of a hemothorax leaves the patient at risk for empyema and entrapped lung. If evacuation is incomplete with tube thoracostomy, video-assisted thoracoscopic or open evacuation and pleurodysis may be required.

Pulmonary atelectasis results in a loss of functional residual capacity (FRC) of the lung and can predispose to pneumonia. Poor pain control in the postoperative period contributes to poor inspiratory effort and collapse of the lower lobes in particular. The prevention of atelectasis is facilitated by sitting the patient up as much as possible, early ambulation, and adequate pain control. An increase in FRC by 700 mL or more can be accomplished by sitting patients up to greater than 45°. For mechanically ventilated patients, simply placing the head of the bed at 30° to 45° elevation and delivering adequate tidal volumes (8–10 mL/kg) improves pulmonary outcomes.

Patients with inadequate pulmonary toilet are at increased risk for bronchial plugging and lobar collapse. Patients with copious and tenacious secretions develop these plugs most often, but foreign bodies in the bronchus can be the cause of lobar collapse as well. The diagnosis of bronchial plugging is based on chest X-ray and clinical suspicion with acute pulmonary decompensation with increased work of breathing and hypoxemia. Fiberoptic bronchoscopy can be useful to clear mucous plugs and secretions.

Aspiration complications include pneumonitis and pneumonia. The treatment of pneumonitis is similar to that for acute respiratory distress syndrome (see later in this section) and includes oxygenation with general supportive care. Antibiotics are not indicated. Hospitalized patients who develop aspiration pneumonitis have a mortality rate as high as 70% to 80%. Early, aggressive, and repeated bronchoscopy for suctioning of aspirated material from the tracheobronchial tree will help minimize the inflammatory reaction of pneumonitis and facilitate improved pulmonary toilet. Forced diuresis to overcome anasarca and over-resuscitation remains controversial and unsubstantiated. Complications of forced diuresis include electrolyte disturbances, replacement of those electrolytes, metabolic alkalosis, hypotension, and acute kidney injury.

Pneumonia is the second most common nosocomial infection and is the most common infection in ventilated patients. Ventilator-associated pneumonia (VAP) occurs in 15% to 40% of ventilated ICU patients, with a probability rate of 5% per day, up to 70% at 30 days. The 30-day mortality rate of nosocomial pneumonia can be as high as 40% and depends on the microorganisms involved and the timeliness of initiating appropriate antimicrobials. Protocol-driven approaches for prevention and treatment of VAP are recognized as beneficial in managing these difficult infectious complications.

Once the diagnosis of pneumonia is suspected (an abnormal chest X-ray, fever, productive cough with purulent sputum, and no other obvious fever sources), it is invariably necessary to initially begin treatment with broad-spectrum antibiotics until proper identification, colony count (≥100,000 colony-forming units [CFU]), and sensitivity of the microorganisms are determined. The spectrum of antibiotic coverage should be narrowed as soon as the culture sensitivities are determined. Double-coverage antibiotic strategy for the two pathogens, *Pseudomonas* and *Acinetobacter* spp., may be appropriate if the local prevalence of these particularly virulent organisms is high. One of the most helpful tools in treating pneumonia and other infections is the tracking of a medical center’s antibiogram every 6 to 12 months.

Epidural analgesia decreases the risk of perioperative pneumonia. This method of pain control improves pulmonary toilet and the early return of bowel function; both have a significant impact on the potential for aspiration and for acquiring pneumonia. The routine use of epidural analgesia results in a lower incidence of pneumonia than patient-controlled analgesia.

Acute lung injury (ALI) was a diagnosis applied to patients with similar findings to those with acute respiratory distress...
syndrome (ARDS). The Berlin definition of ARDS developed by the American-European Consensus Conference of 2012 not only simplifies the definition of ARDS but also eliminates the term ALI from critical care vernacular. ARDS is now classified by partial pressure of oxygen in arterial blood (Pao₂)/fraction of inspired oxygen (Fio₂) ratios as mild (300–201 mmHg), moderate (200–101 mmHg), and severe (<100 mmHg). Elements of modification of the definition include the following: <7 days of onset; removal of pulmonary artery occlusion pressure; and clinical judgment for characterizing hydrostatic pulmonary edema is acceptable, unless risk factors for ARDS have been eliminated, in which case objective analysis is necessary.72-75

The definition of ARDS traditionally included five criteria (Table 12-13). The multicenter ARDS Research Network (ARDSnet) research trial demonstrated improved clinical outcomes for ARDS patients ventilated at tidal volumes of only 5 to 7 mL/kg.76 This strategy is no longer prescribed solely for patients with ARDS but is also recommended for patients with normal pulmonary physiology who are intubated for reasons other than acute respiratory failure. The beneficial effects of positive end-expiratory pressure (PEEP) for ARDS were confirmed in this study as well. The maintenance of PEEP during ventilatory support is determined based on blood gas analysis, pulmonary mechanics, and requirements for supplemental oxygen. As gas exchange improves with resolving ARDS, the initial step in decreasing ventilatory support should be to decrease the levels of supplemental oxygen first, and then to slowly bring the PEEP levels back down to minimal levels.77 This is done to minimize the potential for recurrent alveolar collapse and a worsening gas exchange.

Not all patients can be weaned easily from mechanical ventilation. When the respiratory muscle energy demands are not balanced or there is an ongoing active disease state external to the lungs, patients may require prolonged ventilatory support. Protocol-driven ventilator weaning strategies are successful and have become part of the standard of care. The use of a weaning protocol for patients on mechanical ventilation greater than 48 hours reduces the incidence of VAP and the overall length of ventilator time, and the number of ICU patient days.

The occurrence of PE is probably underdiagnosed. Its etiology is thought to stem from DVT. This concept, however, has recently been questioned by Spaniolas et al.81 The diagnosis of PE is made when a high degree of clinical suspicion for PE leads to imaging techniques such as ventilation–perfusion nuclear scans or CT pulmonary angiogram. Clinical findings include elevated central venous pressure, hypoxemia, shortness of breath, hypocarbia secondary to tachypnea, and right heart strain on ECG. Ventilation–perfusion nuclear scans are often indeterminate in patients who have an abnormal chest X-ray and are less sensitive than a CT angiogram or pulmonary angiogram for diagnosing PE. The pulmonary angiogram remains the gold standard for diagnosing PE, but spiral CT angiogram has become an alternative method because of its relative ease of use and reasonable rates of diagnostic accuracy. For cases without clinical contraindications to therapeutic anticoagulation, patients should be empirically started on heparin infusion until the imaging studies are completed if the suspicion of a PE is high.

Sequential compression devices on the lower extremities and low-dose subcutaneous heparin or low molecular weight heparinoid administration are routinely used to prevent DVT and, by inference, the risk of PE. Neurosurgical and orthopedic patients have higher rates of PE, as do obese patients and those at prolonged bed rest.

When anticoagulation is contraindicated, or when a known clot exists in the inferior vena cava (IVC), decreasing the risk for PE includes insertion of an IVC filter. The Greenfield filter has been most widely studied, and it has a failure rate of less than 4%. Newer devices include those with nitinol wire that expands with body temperature and retrievable filters. Retrievable filters, however, must be considered as permanent. In most studies, the actual retrievable rate only reached about 20%. Some studies recognize the benefit of automated reminders and diligence of outlying patient follow-up, where higher retrieval rates have been achieved.82 Patients with spinal cord injury and multiple long-bone or pelvic fractures frequently receive IVC filters, and

| Table 12-13 |
| Inclusion criteria for the acute respiratory distress syndrome |
| Acute onset |
| Predisposing condition |
| Pao₂:Fio₂ <200 (regardless of positive end-expiratory pressure) |
| Bilateral infiltrates |
| Pulmonary artery occlusion pressure <18 mmHg |
| No clinical evidence of right heart failure |

Fio₂ = fraction of inspired oxygen; Pao₂ = partial pressure of arterial oxygen.
Cardiac System. Arrhythmias are often seen preoperatively in elderly patients but may occur postoperatively in any age group. Atrial fibrillation is the most common arrhythmia and occurs between postoperative days 3 to 5 in high-risk patients. This is typically when patients begin to mobilize their intrastitial fluid into the vascular fluid space. Contemporary evidence suggests that rate control is more important than rhythm control for atrial fibrillation. The first-line treatment includes β-blockade and/or calcium channel blockade. β-Blockade must be used judiciously because hypotension, as well as withdrawal from β-blockade with rebound hypertension, is possible. Calcium channel blockers are an option if β-blockers are not tolerated by the patient, but caution must be exercised in those with a history of congestive heart failure. Although digoxin is still a standby medication, it has limitations due to the need for optimal dosing levels. Cardioversion may be required if patients become hemodynamically unstable and the rhythm cannot be controlled.

Ventricular arrhythmias and other tachyarrhythmias may occur in surgical patients as well. Similar to atrial rhythm problems, these are best controlled with β-blockade, but the use of other antiarrhythmics or cardioversion may be required if patients become hemodynamically unstable.

Cardiac ischemia is a cause of postoperative mortality. Acute myocardial infarction (AMI) can present insidiously, or it can be more dramatic with the classic presentation of shortness of breath, severe angina, and sudden cardiogenic shock. The workup to rule out an AMI includes an ECG and cardiac enzyme measurements. The patient should be transferred to a monitored (telemetry) floor. Morphine, supplemental oxygen, nitroglycerine, and aspirin (MONA) are the initial therapeutic maneuvers for those being investigated for AMI.

Gastrointestinal System. Surgery of the esophagus is potentially complicated because of its anatomic location and blood supply. Nutritional support strategies should be considered for esophageal resection patients to maximize the potential for survival. The two primary types of esophageal resection performed are the transthiatal resection and the transthoracic (Ivor-Lewis) resection. The transthiatal resection has the advantage that a formal thoracotomy incision is avoided. However, dissection of the esophagus is blind, and anastomotic leaks occur more than with other resections. However, when a leak does occur, simple opening of the cervical incision and draining the leak is all that is usually required.

The transthoracic Ivor-Lewis resection includes an esophageal anastomosis performed in the chest near the level of the azygos vein. These have lower leak rates, but the leaks that do occur result in mediastinitis and can be difficult to control. The reported mortality is about 50% with an anastomotic leak, and the overall mortality of the procedure is about 5%, which is similar to transthiatal resection.

Postoperative ileus is related to dysfunction of the neural reflex axis of the intestine. Excessive narcotic use may delay return of bowel function. Epidural anesthesia results in better pain control, and there is an earlier return of bowel function and a shorter length of hospital stay. The limited use of nasogastric tubes and the initiation of early postoperative feeding are associated with an earlier return of bowel function. The use of chewing gum and other oral stimulants to minimize ileus remains controversial.

Pharmacologic agents commonly used to stimulate bowel function include metoclopramide and erythromycin. Metoclopramide’s action is limited to the stomach and duodenum, and it may help primarily with gastroparesis. Erythromycin is a motilin agonist that works throughout the stomach and bowel. Several studies demonstrate significant benefit from the administration of erythromycin in those suffering from an ileus. Alvimopan, a newer agent and a µ-opioid receptor antagonist, has shown some promise in many studies for earlier return of gut function and subsequent reduction in length of stay. Neostigmine has been used in refractory pan-ileus patients (Ogilvie’s syndrome) with some degree of success. It is recommended for patients receiving this type of therapy to be in a monitored unit.

Small bowel obstruction occurs in less than 1% of early postoperative patients. When it does occur, adhesions are usually the cause. Internal and external hernias, technical errors, and infections or abscesses are also causative. Hyaluronidase is a mucolytic enzyme that degrades connective tissue, and the use of a methylcellulose form of hyaluronidase, Seprafilm®, has been shown to result in a 50% decrease in adhesion formation in some patients. This may translate into a lower occurrence of postoperative bowel obstruction, but has yet to be proven.

Fistulae are the abnormal communication of one structure to an adjacent structure or compartment and are associated with extensive morbidity and mortality. Common causes for fistula formation are summarized in the mnemonic FRIENDS (Foreign body, Radiation, Ischemia/Inflammation/Infection, Epithelialization of a tract, Neoplasia, Distal obstruction, and Steroid use). Postoperatively, they are most often caused by infection or obstruction leading to an anastomotic leak. The cause of the fistula must be recognized early, and treatment may include nonoperative management with observation and nutritional support, or a delayed operative management strategy that also includes nutritional support and wound care.

Gastrointestinal (GI) bleeding can occur perioperatively (Table 12-14). Technical errors such as a poorly tied suture, a nonhemostatic staple line, or a missed injury can all lead to

### Table 12-14

| Common causes of upper and lower gastrointestinal (GI) hemorrhage |
|---------------------------------|----------------|
| UPPER GI BLEED                  | LOWER GI BLEED |
| Erosive esophagitis             | Angiodysplasia |
| Gastric varices                 | Radiation proctitis |
| Esophageal varices              | Hemangioma     |
| Dieulafoy’s lesion              | Diverticulosis |
| Aortoduodenal fistula           | Neoplastic diseases |
| Mallory-Weiss tear              | Trauma         |
| Peptic ulcer disease            | Vasculitis     |
| Trauma                          | Hemorrhoids    |
| Neoplastic disease              | Aortoenteric fistula |
|                                 | Intussusception |
|                                 | Ischemic colitis |
|                                 | Inflammatory bowel disease |
|                                 | Postprocedure bleeding |
postoperative intestinal bleeding.\textsuperscript{94,95} The source of bleeding is in the upper GI tract about 85% of the time and is usually detected and treated endoscopically. Surgical control of intestinal bleeding is required in up to 40% of patients.\textsuperscript{96}

When patients in the ICU have a major bleed from stress gastritis, the mortality risk is as high as 50%. It is important to keep the gastric pH greater than 4 to decrease the overall risk for stress gastritis in patients mechanically ventilated for 48 hours or greater and patients who are coagulopathic.\textsuperscript{97} Proton pump inhibitors, $\text{H}_2$-receptor antagonists, and intragastric antacid installation are all effective measures. However, patients who are not mechanically ventilated or who do not have a history of gastritis or peptic ulcer disease should not be placed on gastritis prophylaxis postoperatively because it carries a higher risk of causing pneumonia.

**Hepatobiliary-Pancreatic System.** Complications involving the hepatobiliary system are usually due to technical errors. Laparoscopic cholecystectomy has become the standard of care for cholecystectomy, but common bile duct injury remains a nemesis of this approach. Intraoperative cholangiography has not been shown to decrease the incidence of common bile duct injuries because the injury to the bile duct usually occurs before the cholangiogram.\textsuperscript{98,99} Early recognition and immediate repair of an injury are important because delayed bile duct leaks often require a more complex repair.

Ischemic injury due to devascularization of the common bile duct has a delayed presentation days to weeks after an operation. Endoscopic retrograde cholangiopancreatography (ERCP) demonstrates a stenotic, smooth common bile duct, and liver function studies are elevated. The recommended treatment is a Roux-en-Y hepaticojejunostomy.

A bile leak due to an unrecognized injury to the ducts may present after cholecystectomy as a biloma. These patients may present with abdominal pain and hyperbilirubinemia. The diagnosis of a biliary leak can be confirmed by CT scan, ERCP, or radionuclide scan. Once a leak is confirmed, a retrograde biliary stent and external drainage are the treatment of choice.

Hyperbilirubinemia in the surgical patient can be a complex problem. Cholestasis makes up the majority of causes for hyperbilirubinemia, but other mechanisms of hyperbilirubinemia include reabsorption of blood (e.g., hematoma from trauma), decreased bile excretion (e.g., sepsis), increased unconjugated bilirubin due to hemolysis, hyperthyroidism, and impaired excretion due to congenital abnormalities or acquired disease. Errors in surgery that cause hyperbilirubinemia largely involve missed or iatrogenic injuries.

The presence of cirrhosis predisposes to postoperative complications. Abdominal or hepatobiliary surgery is problematic in the cirrhotic patient. Ascites leak in the postoperative period can be an issue when any abdominal operation has been performed. Maintaining proper intravascular oncotic pressure in the immediate postoperative period can be difficult, and resuscitation should be maintained with crystalloid solutions. Prevention of renal failure and the management of the hepatorenal syndrome can be difficult, as the demands of fluid resuscitation and altered glomerular filtration become competitive. Spironolactone with other diuretic agents may be helpful in the postoperative care. These patients often have a labile course, and bleeding complications due to coagulopathy are common. The operative mortality in cirrhotic patients is 10% for Child class A, 30% for Child class B, and 82% for Child class C patients.\textsuperscript{100}

Pyogenic liver abscess occurs in less than 0.5% of adult admissions, due to retained necrotic liver tissue, occult intestinal perforations, benign or malignant hepatobiliary obstruction, sepsis, and hepatic arterial occlusion. The treatment is long-term antibiotics with percutaneous drainage of large abscesses.

Pancreatitis can occur following injection of contrast during cholangiography and after endoscopic cholangiopancreatography (ERCP). These episodes range from a mild elevation in amylase and lipase with abdominal pain, to a fulminant course of pancreatitis with necrosis requiring surgical debridement. The incidence of post-ERCP pancreatitis has been shown to be reduced by the administration of rectal indomethacin.\textsuperscript{101} Studies are underway to determine whether the prophylactic use of pancreatic duct stenting in patients at high risk for post-ERCP pancreatitis can be avoided with the use of rectal indomethacin.

Traumatic injuries to the pancreas can occur during surgical procedures on the kidneys, GI tract, and spleen most commonly. Treatment involves serial CT scans and percutaneous drainage to manage infected fluid and abscess collections; sterile collections should not be drained because drain placement can introduce infection. A pancreatic fistula may respond to antisecretory therapy with a somatostatin analogue. Management of these fistulae initially includes ERCP with or without pancreatic stenting, percutaneous drainage of any fistula fluid collections, total parenteral nutrition (TPN) with bowel rest, and repeated CT scans. The majority of pancreatic fistulae will eventually heal spontaneously.

**Renal System.** Renal failure can be classified as prerenal failure, intrinsic renal failure, and postrenal failure. Postrenal failure, or obstructive renal failure, should always be considered when low urine output (oliguria) or anuria occurs. The most common cause is a misplaced or clogged urinary catheter. Other, less common causes to consider are unintentional ligation or transection of ureters during a difficult surgical dissection (e.g., colon resection for diverticular disease) or a large retroperitoneal hematoma (e.g., ruptured aortic aneurysm).

Oliguria is initially evaluated by flushing the urinary catheter using sterile technique. Urine electrolytes should also be measured (Table 12-15). A hemoglobin and hematocrit level should be checked immediately. Patients in compensated shock from acute blood loss may manifest anemia and end-organ malperfusion as oliguria.

Acute tubular necrosis (ATN) carries a mortality risk of 25% to 50% due to the many complications that can cause, or result from, this insult. When ATN is due to poor inflow (prerenal failure), the remedy begins with IV administration of crystalloid or colloid fluids as needed. If cardiac insufficiency is the problem, the optimization of vascular volume is achieved first, followed by inotropic agents, as needed. Intrinsic renal failure

CHF = congestive heart failure; FE$_{\text{Na}}$ = fractional excretion of sodium; UR$_{\text{Na}}$ = urinary excretion of sodium.
and subsequent ATN are often the result of direct renal toxins. Aminoglycosides, vancomycin, and furosemide, among other commonly used agents, contribute directly to nephrotoxicity. Contrast-induced nephropathy usually leads to a subtle or transient rise in creatinine. In patients who are volume depleted or have poor cardiac function, contrast nephropathy may permanently impair renal function.102-105

The treatment of renal failure due to myoglobinuria has shifted away from the use of sodium bicarbonate for alkalinizing the urine, to merely maintaining brisk urine output of 100 mL per hour with crystalloid fluid infusion. Mannitol and furosemide are not recommended. Patients who do not respond to resuscitation are at risk for needing renal replacement therapy. Fortunately, most of these patients eventually recover from their renal dysfunction.

Musculoskeletal System. A compartment syndrome can develop in any compartment of the body. Compartment syndrome of the extremities generally occurs after a closed fracture. The injury alone may predispose the patient to compartment syndrome, but aggressive fluid resuscitation can exacerbate the problem. Pain with passive motion is the hallmark of compartment syndrome, and the anterior compartment of the leg is usually the first compartment to be involved. Confirmation of the diagnosis is obtained by direct pressure measurement of the individual compartments. If the pressures are greater than 20 to 25 mmHg in any of the compartments, then a four-compartment fasciotomy is considered. Compartment syndrome can be due to ischemia-reperfusion injury, after an ischemic time of 4 to 6 hours. Renal failure (due to myoglobinuria), tissue loss, and a permanent loss of function are possible results of untreated compartment syndrome.

Decubitus ulcers are preventable complications of prolonged bed rest due to traumatic paralysis, dementia, chemical paralysis, or coma. Unfortunately, they are still occurring despite extensive research and clinical initiatives that demonstrate successful prevention strategies. Ischemic changes in the microcirculation of the skin can be significant after 2 hours of sustained pressure. Routine skin care and turning of the patient help ensure a reduction in skin ulceration. This can be labor intensive, and special mattresses and beds are available to help. The treatment of a decubitus ulcer in the noncoagulopathic patient is surgical debridement. Once the wound bed has a viable granulation base without an excess of fibrinous debris, a vacuum-assisted closure dressing can be applied. Wet to moist dressings with frequent dressing changes is the alternative and is labor intensive. Expensive topical enzyme preparations are also available. If the wounds fail to respond to these measures, soft tissue coverage by flap is considered.

Contractures are the result of muscle disuse. Whether from trauma, amputation, or vascular insufficiency, contractures can be prevented by physical therapy and splinting. If not attended to early, contractures will prolong rehabilitation and may lead to further wounds and wound healing issues. Depending on the functional status of the patient, contracture releases may be required for long-term care.

Hematologic System. The traditional transfusion guideline of maintaining the hematocrit level in all patients at greater than 30% is no longer valid. Only patients with symptomatic anemia, who have significant cardiac disease, or who are critically ill and require increased oxygen-carrying capacity to adequately perfuse end organs require higher levels of hemoglobin. Other than these select patients, the decision to transfuse should generally not occur until the hemoglobin level falls to 7 mg/dL or the hematocrit reaches 21%.

Transfusion reactions are common complications of blood transfusion. These can be attenuated with a leukocyte filter, but not completely prevented. The manifestations of a transfusion reaction include simple fever, pruritus, chills, muscle rigidity, and renal failure due to myoglobinuria secondary to hemolysis. Discontinuing the transfusion and returning the blood products to the blood bank is an important first step, but administration of antihistamine and possibly steroids may be required to control the reaction symptoms. Severe transfusion reactions are rare but can be fatal.

Infectious complications in blood transfusion range from cytomegalovirus transmission, which is benign in the nontransplant patient, to human immunodeficiency virus (HIV) infection, to passage of the hepatitis viruses (Table 12-16).

Patients on warfarin (Coumadin) who require surgery can have anticoagulation reversal by administration of fresh frozen plasma. Each unit of fresh frozen plasma contains 200 to 250 mL of plasma and includes one unit of coagulation factor per milliliter of plasma.

Thrombocytopenia may require platelet transfusion for a platelet count less than 20,000/mL when invasive procedures are performed, or when platelet counts are low and ongoing bleeding from raw surface areas persists. One unit of platelets will increase the platelet count by 5000 to 7500 per mL in adults. It is important to delineate the cause of the low platelet count. Usually there is a self-limiting or reversible condition such as sepsis. Rarely, it is due to heparin-induced thrombocytopenia I and II. Complications of heparin-induced thrombocytopenia II can be serious because of the diffuse thrombogenic nature of the disorder. Simple precautions to limit this hypercoagulable state include saline solution flushes instead of heparin solutions and limiting the use of heparin-coated catheters. The treatment is anticoagulation with synthetic agents such as argatroban.

For patients with uncontrollable bleeding due to disseminated intravascular coagulopathy (DIC), a potentially useful drug is factor VIIa, but its use should be judicious.106-109 Originally used in hepatic trauma and obstetric emergencies, this agent was lifesaving in some circumstances. The CONTROL Trial,109 however, has largely decreased overuse of this agent because investigators demonstrated no benefit over simple factor replacement in severely coagulopathic patients. Factor VIIa use may also be limited due to its potential thrombotic complications. For some situations, the combination of ongoing.

*Post-nucleic acid amplification technology (1999). Earlier rates were erroneously reported higher due to lack of contemporary technology.

*HBV is reported with prenucleic acid amplification technology. Statistical information is unavailable with postnucleic acid amplification technology at this writing.

Note that bacterial transmission is 50 to 250 times higher than viral transmission per transfusion.

HBV = hepatitis B virus; HCV = hepatitis C virus.
nonsurgical bleeding and renal failure can occasionally be successfully treated with desmopressin.

In addition to classic hemophilia, other inherited coagulation factor deficiencies can be difficult to manage in surgery. When required, transfusion of appropriate replacement products is coordinated with the regional blood bank center before surgery. Other blood dyscrasias seen by surgeons include hypercoagulopathic patients. Those who carry congenital anomalies such as the most common factor V Leiden deficiency, as well as protein C and S deficiencies, are likely to form thromboses if inadequately anticoagulated, and these patients should be managed in consultation with a hematologist.

**Abdominal Compartment Syndrome.** Multisystem trauma, thermal burns, retroperitoneal injuries, and surgery related to the retroperitoneum are the major initial causative factors that may lead to abdominal compartment syndrome (ACS). Ruptured AAA, major pancreatic injury and resection, or multiple intestinal injuries are also examples of clinical situations in which a large volume of IV fluid resuscitation puts these patients at risk for intra-abdominal hypertension. Manifestations of ACS typically include progressive abdominal distention followed by increased peak airway ventilator pressures, oliguria followed by anuria, and an insidious development of intracranial hypertension. These findings are related to elevation of the diaphragm and inadequate venous return from the vena cava or renal veins secondary to the transmitted pressure on the venous system.

Measurement of abdominal pressures is easily accomplished by transducing bladder pressures from the urinary catheter after instilling 100 mL of sterile saline into the urinary bladder. A pressure greater than 20 mmHg constitutes intra-abdominal hypertension, but the diagnosis of ACS requires intra-abdominal pressure greater than 25 to 30 mmHg, with at least one of the following: compromised respiratory mechanics and ventilation, oliguria or anuria, or increasing intracranial pressures.

The treatment of ACS is to open any recent abdominal incision to release the abdominal fascia or to open the fascia directly if no abdominal incision is present. Immediate improvement in mechanical ventilation pressures, intracranial pressures, and urine output is usually noted. When expectant management for ACS is considered in the OR, the abdominal fascia should be left open and covered under sterile conditions (e.g., a vacuum-assisted open abdominal wound closure system) with plans made for a second-look operation and delayed fascial closure. Patients with intra-abdominal hypertension should be monitored closely with repeated examinations and measurements of bladder pressure, so that any further deterioration is detected and operative management can be initiated. Left untreated, ACS may lead to multiple system end-organ dysfunction or failure and has a high mortality.

Abdominal wall closure should be attempted every 48 to 72 hours until the fascia can be reapproximated. If the abdomen cannot be closed within 5 to 7 days following release of the abdominal fascia, a large incisional hernia is the net result. A variety of surgical options have evolved for prevention and closure of the resultant hernias, but no standard approach has yet evolved.

**Wounds, Drains, and Infection**

**Wound (Surgical Site) Infection.** No prospective, randomized, double-blind, controlled studies exist that demonstrate antibiotics used beyond 24 hours in the perioperative period prevent infections. Prophylactic use of antibiotics should simply not be continued beyond this time. Irrigation of the operative field and the surgical wound with saline solution has shown benefit in controlling wound inoculum. Irrigation with an antibiotic-based solution has not demonstrated significant benefit in controlling postoperative infection.

Antibacterial-impregnated polyvinyl placed over the operative wound area for the duration of the surgical procedure has not been shown to decrease the rate of wound infection.

Although skin preparation with 70% isopropyl alcohol has the best bactericidal effect, it is flammable and could be hazardous when electrocautery is used. The contemporary formulas of chlorhexidine gluconate with isopropyl alcohol remain more advantageous.

There is a difference between wound colonization and infection. Over-treating colonization is just as injurious as undertreating infection. The strict definition of wound infection is more than 10^5 CFU per gram of tissue. This warrants expeditious and proper antibiotic/antifungal treatment. Often, however, clinical signs raise enough suspicion that the patient is treated before a confirmatory culture is undertaken. The clinical signs of wound infection include rubor, tumor, calor, and dolor (redness, swelling, heat, and pain). Once the diagnosis of wound infection has been established, the most definitive treatment remains open drainage of the wound. The use of antibiotics for wound infection treatment should be limited.

One type of wound dressing/drainage system that has gained popularity is the vacuum-assisted closure dressing. The principle of the system is to decrease local wound edema and to promote healing through the application of a sterile dressing that is then covered and placed under controlled suction for a period of 2 to 4 days at a time. Although costly, the benefits are frequently dramatic and may offset the costs of nursing care, frequent dressing changes, and operative wound debridement.

**Drain Management.** The four indications for applying a surgical drain are:

- To collapse surgical dead space in areas of redundant tissue (e.g., neck and axilla)
- To provide focused drainage of an abscess or grossly infected surgical site
- To provide early warning notice of a surgical leak (either bowel contents, secretions, urine, air, or blood)—the so-called sentinel drain
- To control an established fistula leak

Open drains are often used for large contaminated wounds such as perirectal or perianal fistulas and subcutaneous abscess cavities. They prevent premature closure of an abscess cavity in a contaminated wound. More commonly, surgical sites are drained by closed suction drainage systems, but data do not support closed suction drainage to “protect an anastomosis” or to “control a leak” when placed at the time of surgery. Closed suction devices can exert a negative pressure of 70 to 170 mmHg at the level of the drain; therefore, the presence of this excess suction may call into question whether an anastomosis breaks down on its own or whether the drain creates a suction injury that promotes leakage (Fig. 12-9). On the other hand, CT- or ultrasound-guided placement of percutaneous drains is now the standard of care for abscesses, loculated infections, and other isolated fluid collections such as protein C and S deficiencies, are likely to form thromboses if inadequately anticoagulated, and these patients should be managed in consultation with a hematologist.

**Abdominal Compartment Syndrome.** Multisystem trauma, thermal burns, retroperitoneal injuries, and surgery related to the retroperitoneum are the major initial causative factors that may lead to abdominal compartment syndrome (ACS). Ruptured AAA, major pancreatic injury and resection, or multiple intestinal injuries are also examples of clinical situations in which a large volume of IV fluid resuscitation puts these patients at risk for intra-abdominal hypertension. Manifestations of ACS typically include progressive abdominal distention followed by increased peak airway ventilator pressures, oliguria followed by anuria, and an insidious development of intracranial hypertension. These findings are related to elevation of the diaphragm and inadequate venous return from the vena cava or renal veins secondary to the transmitted pressure on the venous system.

Measurement of abdominal pressures is easily accomplished by transducing bladder pressures from the urinary catheter after instilling 100 mL of sterile saline into the urinary bladder. A pressure greater than 20 mmHg constitutes intra-abdominal hypertension, but the diagnosis of ACS requires intra-abdominal pressure greater than 25 to 30 mmHg, with at least one of the following: compromised respiratory mechanics and ventilation, oliguria or anuria, or increasing intracranial pressures.

The treatment of ACS is to open any recent abdominal incision to release the abdominal fascia or to open the fascia directly if no abdominal incision is present. Immediate improvement in mechanical ventilation pressures, intracranial pressures, and urine output is usually noted. When expectant management for ACS is considered in the OR, the abdominal fascia should be left open and covered under sterile conditions (e.g., a vacuum-assisted open abdominal wound closure system) with plans made for a second-look operation and delayed fascial closure. Patients with intra-abdominal hypertension should be monitored closely with repeated examinations and measurements of bladder pressure, so that any further deterioration is detected and operative management can be initiated. Left untreated, ACS may lead to multiple system end-organ dysfunction or failure and has a high mortality.

Abdominal wall closure should be attempted every 48 to 72 hours until the fascia can be reapproximated. If the abdomen cannot be closed within 5 to 7 days following release of the abdominal fascia, a large incisional hernia is the net result. A variety of surgical options have evolved for prevention and closure of the resultant hernias, but no standard approach has yet evolved.

**Wounds, Drains, and Infection**

**Wound (Surgical Site) Infection.** No prospective, randomized, double-blind, controlled studies exist that demonstrate antibiotics used beyond 24 hours in the perioperative period prevent infections. Prophylactic use of antibiotics should simply not be continued beyond this time. Irrigation of the operative field and the surgical wound with saline solution has shown benefit in controlling wound inoculum. Irrigation with an antibiotic-based solution has not demonstrated significant benefit in controlling postoperative infection.

Antibacterial-impregnated polyvinyl placed over the operative wound area for the duration of the surgical procedure has not been shown to decrease the rate of wound infection.

Although skin preparation with 70% isopropyl alcohol has the best bactericidal effect, it is flammable and could be hazardous when electrocautery is used. The contemporary formulas of chlorhexidine gluconate with isopropyl alcohol remain more advantageous.

There is a difference between wound colonization and infection. Over-treating colonization is just as injurious as undertreating infection. The strict definition of wound infection is more than 10^5 CFU per gram of tissue. This warrants expeditious and proper antibiotic/antifungal treatment. Often, however, clinical signs raise enough suspicion that the patient is treated before a confirmatory culture is undertaken. The clinical signs of wound infection include rubor, tumor, calor, and dolor (redness, swelling, heat, and pain). Once the diagnosis of wound infection has been established, the most definitive treatment remains open drainage of the wound. The use of antibiotics for wound infection treatment should be limited.

One type of wound dressing/drainage system that has gained popularity is the vacuum-assisted closure dressing. The principle of the system is to decrease local wound edema and to promote healing through the application of a sterile dressing that is then covered and placed under controlled suction for a period of 2 to 4 days at a time. Although costly, the benefits are frequently dramatic and may offset the costs of nursing care, frequent dressing changes, and operative wound debridement.

**Drain Management.** The four indications for applying a surgical drain are:

- To collapse surgical dead space in areas of redundant tissue (e.g., neck and axilla)
- To provide focused drainage of an abscess or grossly infected surgical site
- To provide early warning notice of a surgical leak (either bowel contents, secretions, urine, air, or blood)—the so-called sentinel drain
- To control an established fistula leak

Open drains are often used for large contaminated wounds such as perirectal or perianal fistulas and subcutaneous abscess cavities. They prevent premature closure of an abscess cavity in a contaminated wound. More commonly, surgical sites are drained by closed suction drainage systems, but data do not support closed suction drainage to “protect an anastomosis” or to “control a leak” when placed at the time of surgery. Closed suction devices can exert a negative pressure of 70 to 170 mmHg at the level of the drain; therefore, the presence of this excess suction may call into question whether an anastomosis breaks down on its own or whether the drain creates a suction injury that promotes leakage (Fig. 12-9). On the other hand, CT- or ultrasound-guided placement of percutaneous drains is now the standard of care for abscesses, loculated infections, and other isolated fluid collections such as
QUALITY, PATIENT SAFETY, ASSESSMENTS OF CARE, AND COMPLICATIONS

CHAPTER 12

Figure 12-9 This illustration demonstrates typical intraoperative placement of closed suction devices in pancreatic or small bowel surgery, where there may be an anastomosis. At negative pressures of 70 to 170 mmHg, these devices may actually encourage anastomotic leaks and not prevent them or become clogged by them.

as pancreatic leaks. The risk of surgery is far greater than the placement of an image-guided drain.

The use of antibiotics when drains are in place is often unnecessary as the drain provides direct source control. Twenty-four to 48 hours of antibiotic use after drain placement is prophylactic, and after this period, only specific treatment of positive cultures should be performed to avoid increased drug resistance and superinfection.

**Urinary Catheters.** Several complications of urinary catheters can occur that lead to an increased length of hospital stay and morbidity. In general, use of urinary catheters should be minimized and every opportunity to expeditiously remove them should be encouraged. If needed, it is recommended that the catheter be inserted its full length up to the hub and that urine flow is established before the balloon is inflated because misplacement of the catheter in the urethra with premature inflation of the balloon can lead to tears and disruption of the urethra.

Enlarged prostatic tissue can make catheter insertion difficult, and a catheter could be required. If this attempt is also unsuccessful, then a urologic consultation for endoscopic placement of the catheter may be required to prevent harm to the urethra. For patients with urethral strictures, filiform-tipped catheters and followers may be used, but these can potentially cause bladder injury. If endoscopic attempts fail, the patient may require a percutaneously placed suprapubic catheter to obtain decompression of the bladder. Follow-up investigations of these patients are recommended so definitive care of the urethral abnormalities can be pursued.

The most frequent nosocomial infection is urinary tract infection (UTI). These infections are classified into complicated and uncomplicated forms. The uncomplicated type is a UTI that can be treated with outpatient antibiotic therapy. The complicated UTI usually involves a hospitalized patient with an indwelling catheter whose UTI is diagnosed as part of a fever workup. The interpretation of urine culture results of less than 100,000 CFU/mL is controversial. Before treating such a patient, one should change the catheter and then repeat the culture to see if the catheter was simply colonized with organisms. Cultures with more than 100,000 CFU/mL should be treated with the appropriate antibiotics and the catheter changed or removed as soon as possible. Undertreatment or misdiagnosis of a UTI can lead to urosepsis and septic shock.

Recommendations are mixed on the proper way to treat *Candida albicans* fungal bladder infections. Continuous bladder washings with fungicidal solution for 72 hours have been recommended, but this is not always effective. Replacement of the urinary catheter and a course of fluconazole are appropriate treatments, but some infectious disease specialists claim that *C. albicans* in the urine may serve as an indication of fungal infection elsewhere in the body. If this is the case, then screening cultures for other sources of fungal infection should be performed whenever a fungal UTI is found.

**Empyema.** One of the most debilitating infections is an empyema, or infection of the pleural space. Frequently, an overwhelming pneumonia is the source of an empyema, but a retained hemothorax, systemic sepsis, esophageal perforation from any cause, and infections with a predilection for the lung (e.g., tuberculosis) are potential etiologies as well. The diagnosis is confirmed by chest X-ray or CT scan, followed by aspiration of pleural fluid for bacteriologic analysis. Gram’s stain, lactate dehydrogenase, protein, pH, and cell count are obtained, and broad-spectrum antibiotics are initiated while the laboratory studies are performed. Once the specific organisms are confirmed, anti-infective agents are tailored appropriately. Placement of a thoracostomy tube is needed to evacuate and drain the infected pleural fluid, but depending on the specific nidus of infection, video-assisted thoracoscopy may also be
helpful for irrigation and drainage of the infection. Refractory empyemas require specialized surgical approaches.

**Abdominal Abscesses.** Postoperative intra-abdominal abscesses can present with vague complaints of intermittent abdominal pain, fever, leukocytosis, and a change in bowel habits. Depending on the type and timing of the original procedure, the clinical assessment of these complaints is sometimes difficult, and a CT scan is usually required. When a fluid collection within the peritoneal cavity is found on CT scan, antibiotics and percutaneous drainage of the collection is the treatment of choice. Initial antibiotic treatment is usually with broad-spectrum antibiotics such as piperacillin-tazobactam or imipenem. Should the patient exhibit signs of peritonitis and/or have free air on X-ray or CT scan, then re-exploration should be considered.

For patients who present primarily (i.e., not postoperatively) with the clinical and radiologic findings of an abscess but are clinically stable, the etiology of the abscess must be determined. A plan for drainage of the abscess and decisions about further diagnostic studies with consideration of the timing of any definitive surgery all need to be balanced. This can be a complex set of decisions, depending on the etiology (e.g., appendicitis or diverticulitis), but if the patient exhibits signs of peritonitis, urgent surgical exploration should be performed.

**Necrotizing Fasciitis.** Postoperative infections that progress to the fulminant soft tissue infection known as necrotizing fasciitis are uncommon. Group A streptococcal (M types 1, 3, 12, and 28) soft tissue infections, as well as infections with *Clostridium perfringens* and *C. septicum*, carry a mortality of 30% to 70%. Septic shock can be present, and patients can become hypotensive less than 6 hours following inoculation. Manifestations of a group A *Streptococcus pyogenes* infection in its most severe form include hypotension, renal insufficiency, coagulopathy, hepatic insufficiency, ARDS, tissue necrosis, and erythematous rash.

These findings constitute a surgical emergency, and the mainstay of treatment remains wide debridement of the necrotic tissue to the level of bleeding, viable tissue. A gray serous fluid at the level of the necrotic tissue is usually noted, and as the infection spreads, thrombosed blood vessels are noted along the tissue planes involved with the infection. Typically, the patient requires serial trips to the OR for wide debridement until the infection is under control. Antibiotics are an important adjunct to surgical debridement, and broad-spectrum coverage should be used because these infections may be polymicrobial (i.e., so-called mixed-synergistic infections). *Streptococcus pyogenes* is eradicated with penicillin, and it should still be used as the initial drug of choice.

**Systemic Inflammatory Response Syndrome, Sepsis, and Multiple-Organ Dysfunction Syndrome.** The systemic inflammatory response syndrome (SIRS) and the multiple-organ dysfunction syndrome (MODS) carry significant mortality risks (Table 12-17). Specific criteria have been established for the diagnosis of SIRS (Table 12-18), but two criteria are not required for the diagnosis of SIRS: lowered blood pressure and blood cultures positive for infection. SIRS is the result of proinflammatory cytokines related to tissue malperfusion or injury. The dominant cytokines implicated in this process include interleukin (IL)-1, IL-6, and tissue necrosis factor (TNF). Other mediators include nitric oxide, inducible macrophage-type nitric oxide synthase, and prostaglandin $\alpha$.

Sepsis is categorized as sepsis, severe sepsis, and septic shock. Sepsis is SIRS plus infection. Severe sepsis is sepsis plus signs of cellular hypoperfusion or end-organ dysfunction. Septic shock is sepsis plus hypotension after adequate fluid resuscitation.

MODS is the culmination of septic shock and multiple end-organ failure. Usually there is an inciting event (e.g., perforated sigmoid diverticulitis), and as the patient undergoes resuscitation, he or she develops cardiac hypokinesis and oliguric or anuric renal failure, followed by the development of ARDS and eventually septic shock with death.

The international Surviving Sepsis Campaign (www.sccm.org/Documents/SSC-Guidelines.pdf) continues to demonstrate the importance of early recognition and initiation of specific treatment guidelines for optimal management of sepsis. Management of SIRS/MODS includes aggressive global resuscitation and support of end-organ perfusion, correction of the inciting etiology, control of infectious complications, and management of iatrogenic complications. Drotrecogin-$\alpha$, or recombinant activated protein C, appears to specifically counteract the cytokine cascade of SIRS/MODS, but its use is still limited. Other adjuncts for supportive therapy include tight glucose control, low tidal volumes in ARDS, vasopressin in septic shock, and steroid replacement therapy.

**Nutritional and Metabolic Support Complications**

**Nutrition-Related Complications.** A basic principle is to use enteral feeding whenever possible, but complications can intervene such as aspiration, ileus, and to a lesser extent, sinusitis. There is no difference in aspiration rates when a small-caliber feeding tube is placed postpyloric or if it remains in the stomach. Patients who are fed via nasogastric tubes are at risk for aspiration pneumonia because these large-bore tubes stent open the gastroesophageal junction, creating the possibility of gastric reflux. The use of enteric and gastric feeding tubes obviates

complications of TPN, such as pneumothorax, line sepsis, upper extremity DVT, and the related expense. There is growing evidence to support the initiation of enteral feeding in the early postoperative period, before the return of bowel function, where it is usually well tolerated.

In patients who have had any type of nasal intubation who are having high, unexplained fevers, sinusitis must be entertained as a diagnosis. CT scan of the sinuses is warranted, followed by aspiration of sinus contents so the organism(s) are appropriately treated.

Patients who have not been enterally fed for prolonged periods secondary to multiple operations, those who have had enteral feeds interrupted for any other reason, or those with poor enteral access are at risk for the refeeding syndrome, which is characterized by severe hypophosphatemia and respiratory failure. Slow progression of the enteral feeding administration rate can avoid this complication.

Common TPN problems are mostly related to electrolyte abnormalities that may develop. These electrolyte errors include deficits or excesses in sodium, potassium, calcium, magnesium, and phosphate. Acid-base abnormalities can also occur with the improper administration of acetate or bicarbonate solutions.

The most common cause for hypernatremia in hospitalized patients is under-resuscitation, and, conversely, hyponatremia is most often caused by fluid overload. Treatment for hyponatremia is fluid restriction in mild or moderate cases and the administration of hypertonic saline for severe cases. An overly rapid correction of the sodium abnormality may result in central pontine myelinolysis, which results in a severe neurologic deficit. Treatment for hyponatremic patients includes fluid restriction to correct the free water deficit by 50% in the first 24 hours. An overcorrection of hyponatremia can result in severe cerebral edema, a neurologic deficit, or seizures.

**Glycemic Control.** In 2001, Van den Berghe and colleagues demonstrated that tight glycemic control by insulin infusion is associated with a 50% reduction in mortality in the critical care setting. This prospective, randomized, controlled trial of 1500 patients had two study arms: the intensive-control arm, where the serum glucose was maintained between 80 and 110 mg/dL with insulin infusion; and the control arm, where patients received an insulin infusion only if blood glucose was greater than 215 mg/dL, but serum glucose was then maintained at 180 to 200 mg/dL.

The tight glycemic control group had an average serum glucose level of 103 mg/dL, and the average glucose level in the control group was 153 mg/dL. Hypoglycemic episodes (glucose <40 mg/dL) occurred in 39 patients in the tightly controlled group, while the control group had episodes in six patients. The overall mortality was reduced from 8% to 4.6%, but the mortality of those patients whose ICU stay lasted longer than 5 days was reduced from 20% to 10%. Secondary findings included an improvement in overall morbidity, a decreased percentage of ventilator days, less renal impairment, and a lower incidence of bloodstream infections. These finding have been corroborated by subsequent similar studies, and the principal benefit appears to be a greatly reduced incidence of nosocomial infections and sepsis. It is not known whether the benefits are due to strict euglycemia, to the anabolic properties of insulin, or both, but the maintenance of strict euglycemia between 140 and 180 mg/dL appears to be a powerful therapeutic strategy. A number of studies followed this sentinel publication of tight glycemic control. The NICE-SUGAR trials revisited the Van den Berghe study and found that the glycemic goals found initially to improve outcomes in critically ill patients were now found to be associated with a higher mortality when glucose was kept below 180 mg/dL, due to an increase in incidents of hypoglycemia. When targeted goals of 180 mg/dL are achieved, fewer occurrences of hypoglycemia have been documented, and improved survivorship has been achieved. In addition, some studies find no relationship between glycemic control and improved outcomes. Thus, glycemic control in the critically ill still remains unclear and elusive at best. Part of the difficulty in achieving “tight glycemic control” is the necessity for frequent (every 1–2 hours) blood glucose determinations. When this is performed, glycemic control is enhanced and hypoglycemia is avoided.

**Metabolism-Related Complications.** “Stress dose steroids” have been advocated for the perioperative treatment of patients on corticosteroid therapy, but recent studies strongly discourage the use of supraphysiologic doses of steroids when patients are on low or maintenance doses (e.g., 5–15 mg) of prednisone daily. Parenteral glucocorticoid treatment need only replicate physiologic replacement steroids in the perioperative period. When patients are on steroid replacement doses equal to or greater than 20 mg per day of prednisone, it may be appropriate to administer additional glucocorticoid doses for no more than 2 perioperative days.

Adrenal insufficiency may be present in patients with a baseline serum cortisol less than 20 μg/dL. A rapid provocative test with synthetic adrenocorticotropic hormone may confirm the diagnosis. After a baseline serum cortisol level is drawn, 250 μg of cosynotropin is administered. At exactly 30 and 60 minutes following the dose of cosynotropin, serum cortisol levels are obtained. There should be an incremental increase in the cortisol level of between 7 and 10 μg/dL for each half hour. If the patient is below these levels, a diagnosis of adrenal insufficiency is made, and glucocorticoid and mineralocorticoid administration is then warranted. Mixed results are common, but the complication of performing major surgery on an adrenally insufficient patient is sudden or profound hypotension that is not responsive to fluid resuscitation.

Thyroid hormone abnormalities usually consist of previously undiagnosed thyroid abnormalities. Hypothyroidism and the so-called sick-euthyroid syndrome are more commonly recognized in the critical care setting. When surgical patients are not progressing satisfactorily in the perioperative period, screening for thyroid abnormalities should be performed. If the results show mild to moderate hypothyroidism, then thyroid replacement should begin immediately, and thyroid function studies should be monitored closely. All patients should be reassessed after the acute illness has subsided regarding the need for chronic thyroid replacement therapy.

**Problems with Thermoregulation**

**Hypothermia.** Hypothermia is defined as a core temperature less than 35°C (95°F) and is divided into subsets of mild (35°C–32°C [95.5°F–89.6°F]), moderate (32°C–28°C [89.6°F–82.4°F]), and severe (<28°C [<82.4°F]) hypothermia. Shivering, the body’s attempt to reverse the effects of hypothermia, occurs between 37°C and 31°C (98.6°F and 87.8°F), but ceases at temperatures below 31°C (87.8°F). Patients who are moderately hypothermic are at higher risk for complications than are those who are more profoundly hypothermic.
Hypothermia creates a coagulopathy that is related to platelet and clotting cascade enzyme dysfunction. This triad of metabolic acidosis, coagulopathy, and hypothermia is commonly found in long operative cases and in patients with blood dyscrasias. The enzymes that contribute to the clotting cascade and platelet activity are most efficient at normal body temperatures; therefore, all measures must be used to reduce heat loss intraoperatively.\(^\text{146}\)

The most common cardiac abnormality is the development of arrhythmias when body temperature drops below 35°C (95°F). Bradycardia occurs with temperatures below 30°C (86°F). It is well known that hypothermia may induce CO\(_2\) retention, resulting in respiratory acidosis. Renal dysfunction of hypothermia manifests itself as a paradoxical polyuria and is related to an increased glomerular filtration rate, as peripheral vascular constriction creates central shunting of blood. This is potentially perplexing in patients who are undergoing resuscitation for hemodynamic instability because the brisk urine output provides a false sense of an adequate intravascular fluid volume.

Induced peripheral hypothermia for hyperpyrexia due to infection (not to include neurologic or cardiac disease) is likely deleterious and does not appear to be beneficial. Placing cooling blankets on or under the patient or ice packs in the axillae or groin may be effective in cooling the skin, and when this occurs, a subsequent feedback loop triggers the hypothalamus to raise the internally regulated set point, thus raising core temperature even higher. This paradoxical reaction may be why those who feel the need to treat a fever in the ICU by cooling the skin and arguably the core have worse outcomes. Cooling core temperatures can be achieved reliably with catheter-directed therapy with commercially available devices. Whether this is a worthwhile practice or not may be controversial. Poor data exist in support of treating fevers lower than 42°C in any fashion.\(^\text{147-149}\)

Adult trauma patients who underwent induced hypothermia had poor outcomes in a recent investigation, and thus, this remains a procedure to be avoided. In a similar vein, pediatric patients who were induced did not show any improvement, and therefore, induced hypothermia is not recommended. Complications with induced hypothermia include, but are not limited to, hypokalemia, diuresis, DVT (due to catheter-related vein injury), arrhythmias, shivering, undiagnosed catheter-related bloodstream infection, and bacteremia.\(^\text{150-152}\)

Neurologic dysfunction is inconsistent in hypothermia, but a deterioration in reasoning and decision-making skills progresses as body temperature falls, and profound coma (and profound unresponsiveness) occurs as the temperature drops below 30°C (86°F). The diagnosis of hypothermia is important, so accurate measurement techniques are required to get a true core temperature.

Methods used to warm patients include warm air circulation over the patient and heated IV fluids, as well as more aggressive measures such as bilateral chest tubes with warm solution lavage, intraperitoneal rewarming lavage, and extracorporeal membrane oxygenation. A rate of temperature rise of 2°C to 4°C (3.6°F–7.2°F) per hour is considered adequate, but the most common complication for nonbypass rewarming is arrhythmia with ventricular arrest.

**Hyperthermia.** Hyperthermia is defined as a core temperature greater than 38.6°C (101.5°F) and has a host of etiologies (Table 12-19).\(^\text{145}\) Hyperthermia can be environmentally induced (e.g., summer heat with inability to dissipate heat or control exposure), iatrogenically induced (e.g., heat lamps and medications), endocrine in origin (e.g., thyrotoxicosis), or neurologically induced (i.e., hypothalamic dysfunction).

Malignant hyperthermia occurs intraoperatively after exposure to agents such as succinylcholine and some halothane-based inhalational anesthetics. The presentation is dramatic, with rapid onset of increased temperature, rigors, and myoglobinuria related to myonecrosis. Medications must be discontinued immediately and dantrolene administered (2.5 mg/kg every 5 minutes) until symptoms subside. Aggressive cooling methods are also implemented, such as an alcohol bath, or packing in ice. In cases of severe malignant hyperthermia, the mortality rate is nearly 30%.\(^\text{153,154}\)

Thyrotoxicosis can occur after surgery due to undiagnosed Graves’ disease. Hallmarks of the syndrome include hyperthermia (>40°C [104°F]), anxiety, copious diaphoresis, congestive heart failure (present in about one fourth of episodes), tachycardia (most commonly atrial fibrillation), and hypokalemia (in up to 50% of patients). The treatment of thyrotoxicosis includes glucocorticoids, propylthiouracil, β-blockade, and iodide (Lugol’s solution) delivered in an emergent fashion. As the name suggests, these patients are usually toxic and require supportive measures as well. Acetaminophen, the cooling modalities noted in the previous paragraph, and vasoactive agents often are indicated.

QUALITY, PATIENT SAFETY, ASSESSMENTS OF CARE, AND COMPLICATIONS

Chapter 12

INTRODUCTION

The Latin verb *monere*, which means “to warn, or advise” is the origin for the English word *monitor*. In modern medical practice, patients undergo monitoring to detect pathologic variations in physiologic parameters, providing advanced warning of impending deterioration in the status of one or more organ systems. The intended goal of this endeavor is to allow the clinician to take appropriate actions in a timely fashion to prevent or ameliorate the physiologic derangement. Furthermore, physiologic monitoring is used not only to warn, but also to titrate therapeutic interventions, such as fluid resuscitation or the infusion of vasoactive or inotropic drugs. The intensive care unit (ICU) and operating room are the two locations where the most advanced monitoring capabilities are routinely employed in the care of critically ill patients.

In the broadest sense, physiologic monitoring encompasses a spectrum of endeavors, ranging in complexity from the routine and intermittent measurement of the classic vital signs (i.e., temperature, heart rate, arterial blood pressure, and respiratory rate) to the continuous recording of the oxidation state of cytochrome oxidase, the terminal element in the mitochondrial electron transport chain. The ability to assess clinically relevant parameters of tissue and organ status and employ this knowledge to improve patient outcomes represents the “holy grail” of critical care medicine. Unfortunately, consensus is often lacking regarding the most appropriate parameters to monitor in order to achieve this goal. Furthermore, making an inappropriate therapeutic decision due to inaccurate physiologic data or misinterpretation of good data can lead to a worse outcome than having no data at all. Of the highest importance is the integration of physiologic data obtained from monitoring into a coherent and evidenced-based treatment plan. Current technologies available to assist the clinician in this endeavor are summarized in this chapter. Also presented is a brief look at emerging techniques that may soon enter into clinical practice.

In essence, the goal of hemodynamic monitoring is to ensure that the flow of oxygenated blood through the microcirculation is sufficient to support aerobic metabolism at the cellular level. In general, mammalian cells cannot store oxygen for subsequent use in oxidative metabolism, although a relatively tiny amount is stored in muscle tissue as oxidized myoglobin. Thus, aerobic synthesis of adenosine triphosphate (ATP), the energy “currency” of cells, requires the continuous delivery of oxygen by diffusion from hemoglobin in red blood cells to the oxidative machinery within mitochondria. Delivery of oxygen to mitochondria may be insufficient for several reasons. For example, cardiac output, hemoglobin concentration of blood, or the oxygen content of arterial blood each can be inadequate...
Key Points

1. The delivery of modern critical care is predicated on the ability to monitor a large number of physiologic variables and formulate evidenced-based therapeutic strategies to manage these variables. Technological advances in monitoring have at least a theoretical risk of exceeding our ability to understand the clinical implications of the derived information. This could result in the use of monitoring data to make inappropriate clinical decisions. Therefore, the implementation of any new monitoring technology must take into account the relevance and accuracy of the data obtained, the risks for independent reasons. Alternatively, despite adequate cardiac output, perfusion of capillary networks can be impaired as a consequence of dysregulation of arteriolar tone, microvascular thrombosis, or obstruction of nutritive vessels by sequestered leukocytes or platelets. Hemodynamic monitoring that does not take into account all of these factors will portray an incomplete and perhaps misleading picture of cellular physiology.

Under normal conditions when the supply of oxygen is plentiful, aerobic metabolism is determined by factors other than the availability of oxygen. These factors include the hormonal milieu and mechanical workload of contractile tissues. However, in pathologic circumstances when oxygen availability is inadequate, oxygen utilization (VO₂) becomes dependent upon oxygen delivery (DO₂). The relationship of VO₂ to DO₂ over a broad range of DO₂ values is commonly represented as two intersecting straight lines (Fig. 13-1). In the region of higher DO₂ values, the slope of the line is approximately equal to zero, indicating that VO₂ is largely independent of DO₂. In contrast, in the region of low DO₂ values, the slope of the line is nonzero and positive, indicating that VO₂ is supply-dependent. The region where the two lines intersect is called the point of critical oxygen delivery (DO₂crit), and represents the transition from supply-independent to supply-dependent oxygen uptake. Below a critical threshold of oxygen delivery, increased oxygen extraction cannot compensate for the delivery deficit; hence, oxygen consumption begins to decrease. The slope of the supply-dependent region of the plot reflects the maximal oxygen extraction capability of the vascular bed being evaluated.

The subsequent sections will describe the techniques and utility of monitoring various physiologic parameters.

**ARTERIAL BLOOD PRESSURE**

The pressure exerted by blood in the systemic arterial system, commonly referred to simply as “blood pressure,” is a cardinal parameter measured as part of the hemodynamic monitoring of patients. Extremes in blood pressure are either intrinsically deleterious or are indicative of a serious perturbation in normal physiology. Arterial blood pressure is a complex function of both cardiac output and vascular input impedance. Thus, inexperienced clinicians may assume that the presence of a normal blood pressure is evidence that cardiac output and tissue perfusion are adequate. This assumption is frequently incorrect and is the reason why some critically ill patients may benefit from forms of hemodynamic monitoring in addition to measurement of arterial pressure.

Blood pressure can be determined directly by measuring the pressure within the arterial lumen or indirectly using a cuff around an extremity. When the equipment is properly set up and calibrated, direct intra-arterial monitoring of blood pressure provides accurate and continuous data. Additionally, intra-arterial catheters provide a convenient way to obtain samples of blood for measurements of arterial blood gases and other laboratory studies. Despite these advantages, intra-arterial catheters are invasive devices and occasionally are associated with serious complications.

**Noninvasive Measurement of Arterial Blood Pressure**

Both manual and automated means for the noninvasive determination of blood pressure use an inflatable sphygmomanometer cuff to increase pressure around an extremity and to detect the presence or absence of arterial pulsations. Several methods exist for this purpose. The time-honored approach is the auscultation of the Korotkoff sounds, which are heard over an artery distal to the cuff as the cuff is deflated from a pressure higher than systolic pressure to one less than diastolic pressure. **Systolic pressure** is defined as the pressure in the cuff when tapping sounds are first audible. **Diastolic pressure** is the pressure in the cuff when audible pulsations first disappear.

---

Figure 13-1. Graphical representation of the relationship between oxygen utilization (VO₂) and oxygen delivery (DO₂). Under most normal physiologic conditions oxygen utilization does not depend on oxygen delivery, but below the critical value DO₂crit oxygen utilization decreases linearly as a function of oxygen delivery, rendering tissues susceptible to ischemic injury.
Another means for pulse detection when measuring blood pressure noninvasively depends upon the detection of oscillations in the pressure within the bladder of the cuff. This approach is simple, and unlike auscultation, can be performed even in a noisy environment (e.g., a busy emergency department or medical helicopter). Unfortunately, this approach is neither accurate nor reliable. Other methods, however, can be used to reliably detect the reappearance of a pulse distal to the cuff and thereby estimate systolic blood pressure. Two excellent and widely available approaches for pulse detection are use of a Doppler stethoscope (reappearance of the pulse produces an audible amplified signal) or a pulse oximeter (reappearance of the pulse is indicated by flashing of a light-emitting diode).

A number of automated devices are capable of repetitively measuring blood pressure noninvasively. Some of these devices measure pressure oscillations in the inflatable bladder encircling the extremity to detect arterial pulsations as pressure in the cuff is gradually lowered from greater than systolic to less than diastolic pressure. Other automated noninvasive devices use a piezoelectric crystal positioned over the brachial artery as a pulse detector. The accuracy of these devices is variable, and often dependent on the size mismatch between the arm circumference and the cuff size. If the cuff is too narrow (relative to the extremity), the measured pressure will be artifactualy elevated. Therefore, the width of the cuff should be approximately 40% of its circumference.

Another noninvasive approach for measuring blood pressure relies on a technique called photoplethysmography. This method is capable of providing continuous information, since systolic and diastolic blood pressures are recorded on a beat-to-beat basis. Photoplethysmography uses the transmission of infrared light to estimate the amount of hemoglobin (directly related to the volume of blood) in a finger placed under a servocommanded inflatable cuff. A feedback loop controlled by a microprocessor continually adjusts the pressure in the cuff to maintain the blood volume of the finger constant. Under these conditions, the pressure in the cuff reflects the pressure in the digital artery. The measurements obtained using photoplethysmography generally agree closely with those obtained by invasive monitoring of blood pressure. However, these readings may be less accurate in patients with hypotension or hyperthermia.

**Invasive Monitoring of Arterial Blood Pressure**

Direct and continuous monitoring of arterial pressure in critically ill patients may be performed by using fluid-filled tubing to connect an intra-arterial catheter to an external strain-gauge transducer. The signal generated by the transducer is electronically amplified and displayed as a continuous waveform by an oscilloscope or computerized display. Digital values for systolic and diastolic pressure also are displayed. Mean pressure, calculated by electronically averaging the amplitude of the pressure waveform, can also be displayed. The fidelity of the catheter-tubing-transducer system is determined by numerous factors, including the compliance of the tubing, the surface area of the transducer diaphragm, and the compliance of the diaphragm. If the system is underdamped, then the inertia of the system, which is a function of the mass of the fluid in the tubing and the mass of the diaphragm, causes overshoot of the points of maximum positive and negative displacement of the diaphragm during systole and diastole, respectively. Thus, in an underdamped system, systolic pressure will be overestimated and diastolic pressure will be underestimated. In an overdamped system, displacement of the diaphragm fails to track the rapidly changing pressure waveform, and systolic pressure will be underestimated and diastolic pressure will be overestimated. It is important to note that even in an underdamped or overdamped system, mean pressure will be accurately recorded, provided the system has been properly calibrated. For these reasons, when using direct measurement of intra-arterial pressure to monitor patients, clinicians should make clinical decisions based primarily on the measured mean arterial blood pressure.

The radial artery at the wrist is the site most commonly used for intra-arterial pressure monitoring. Other sites include the femoral and axillary artery. It is important to recognize, however, that measured arterial pressure is determined in part by the site where the pressure is monitored. Central (i.e., aortic) and peripheral (e.g., radial artery) pressures typically are different as a result of the impedance and inductance of the arterial tree. Systolic pressures typically are higher and diastolic pressures are lower in the periphery, whereas mean pressure is approximately the same in the aorta and more distal sites.

Distal ischemia is an uncommon complication of intra-arterial catheterization. The incidence of thrombosis is increased when larger-caliber catheters are employed and when catheters are left in place for an extended period of time. The incidence of thrombosis can be minimized by using a 20-gauge (or smaller) catheter in the radial artery and removing the catheter as soon as feasible. The risk of distal ischemic injury can be reduced by ensuring that adequate collateral flow is present prior to catheter insertion. At the wrist, adequate collateral flow can be documented by performing a modified version of the Allen test, wherein the artery to be cannulated is digitally compressed while using a Doppler stethoscope to listen for perfusion in the palmar arch vessels.

Another potential complication of intra-arterial monitoring is retrograde embolization of air bubbles or thrombi into the intracranial circulation. In order to minimize this risk care should be taken to avoid flushing arterial lines when air is present in the system, and only small volumes of fluid (less than 5 mL) should be employed for this purpose. Catheter-related infections can occur with any intravascular monitoring device. However, catheter-related bloodstream infection is a relatively uncommon complication of intra-arterial lines used for monitoring, occurring in 0.4% to 0.7% of catheterizations. The incidence increases with longer duration of arterial catheterization.

**ELECTROCARDIOGRAPHIC MONITORING**

The electrocardiogram (ECG) records the electrical activity associated with cardiac contraction by detecting voltages on the body surface. A standard 3-lead ECG is obtained by placing electrodes that correspond to the left arm (LA), right arm (RA), and left leg (LL). The limb leads are defined as lead I (LA-RA), lead II (LL-RA), and lead III (LL-LA). The ECG waveforms can be continuously displayed on a monitor, and the devices can be set to sound an alarm if an abnormality of rate or rhythm is detected. Continuous ECG monitoring is widely available and applied to critically ill and perioperative patients. Monitoring of the ECG waveform is essential in patients with acute coronary syndromes or blunt myocardial injury because dysrhythmias are the most common lethal complication. In patients with shock or sepsis, dysrhythmias can occur as a consequence of inadequate myocardial oxygen delivery or as a complication of vasoactive or inotropic drugs used to support blood pressure and cardiac...
output. Dysrhythmias can be detected by continuously monitoring the ECG tracing, and timely intervention may prevent serious complications. With appropriate computing hardware and software, continuous ST-segment analysis also can be performed to detect ischemia or infarction.

Additional information can be obtained from a 12-lead ECG, which is essential for patients with potential myocardial ischemia or to rule out cardiac complications in other acutely ill patients. Continuous monitoring of the 12-lead ECG may be beneficial in certain patient populations. In a study of 185 vascular surgical patients, continuous 12-lead ECG monitoring was able to detect transient myocardial ischemic episodes in 20.5% of the patients. This study demonstrated that the precordial lead V₄₅, which is not routinely monitored on a standard 3-lead ECG, is the most sensitive for detecting perioperative ischemia and infarction. To detect 95% of the ischemic episodes, two or more precordial leads were necessary. Furthermore, in a prospective observational study, 51 peripheral artery vascular surgery patients underwent ambulatory continuous 12-lead ECG monitoring in the postoperative setting. Ischemic load, defined as the area under the curve defined by ischemic ST-segment deviation and ischemic time, was shown to predict perioperative myocardial infarction with an area under the receiver operating characteristics curve of 0.87. Notably, ischemia was asymptomatic in 14 of the 17 identified patients, demonstrating value of this modality as a warning tool. Thus, continuous 12-lead ECG monitoring may provide greater sensitivity than 3-lead ECG for the detection of perioperative myocardial ischemia, and may become standard for monitoring high-risk surgical patients.

Currently, there is considerable interest in using computerized approaches to analyze ECG waveforms and patterns to uncover hidden information that can be used to predict sudden cardiac death or the development of serious dysrhythmias. ECG patterns of interest include repetitive changes in the morphology of the T-wave (T-wave alternans; TWA) and heart rate variability.

**ALGORITHMIC INTEGRATIVE MONITORING**

Integrated monitoring systems employ software that integrates vital signs to produce a single-parameter index that allows early detection of physiologic perturbations. The input variables include noninvasive measurements of heart rate, respiratory rate, blood pressure, SpO₂, and temperature. The software uses neural networking to develop a probabilistic model of normality, previously developed from a representative sample patient training set. Variance from this data set is used to evaluate the probability that the patient-derived vital signs are within the normal range. An abnormal index can occur while no single vital sign parameter is outside the range of normal if their combined patterns are consistent with known instability patterns. Employing such an integrated monitoring system in step-down unit patients has been shown to be a sensitive method to detect early physiologic abnormalities that may precede hemodynamic instability. This subsequently was demonstrated to reduce the amount of overall patient instability by facilitating earlier identification and appropriate intervention by the medical team.

The large expansion of the electronic medical record (EMR) is also driving the development of new algorithmic assessment tools for inpatient monitoring. The Rothman Index (RI) is a proprietary data analysis toolkit encompassing a total of 26 variables including vital signs, nursing assessments, laboratory test values, and cardiac rhythms and was developed to make use of the vast amount of data input into the EMR on a real-time basis to help provide a global assessment of patient status. In the initial derivation, Rothman and colleagues demonstrated concordance of the RI with the Modified Early Warning Score (MEWS) system, which is designed to alert medical teams to clinical deterioration that precedes cardiac or pulmonary arrest events. Subsequent publications evaluated performance of the RI in predicting both readmission to surgical ICUs in the postoperative setting as well as for rapid response team activations. Although more work is required to evaluate the broad applicability of the RI and similar measures, the evidence to date is compelling. Furthermore, as EMR interfaces become more sophisticated, other real-time data analysis software packages will likely be developed that provide further insight into the care of postsurgical patients.

**CARDIAC OUTPUT AND RELATED PARAMETERS**

Bedside catheterization of the pulmonary artery was introduced into clinical practice in the 1970s. Although the pulmonary artery catheter initially was used primarily to manage patients with cardiogenic shock and other acute cardiac diseases, indications for this form of invasive hemodynamic monitoring gradually expanded to encompass a wide variety of clinical conditions. Clearly, many clinicians believe that information valuable for the management of critically ill patients is afforded by having a pulmonary artery catheter (PAC) in place. However, unambiguous data in support of this view are scarce, and several studies suggest that bedside pulmonary artery catheterization may not benefit most critically ill patients and in fact may lead to some serious complications (see “Effect of Pulmonary Artery Catheterization on Outcome”).

**Determinants of Cardiac Performance**

Cardiac performance requires the integration of multiple mechanical and physiologic parameters of both the heart itself and of the circulatory system through which blood flows. The following sections discuss some of these factors, including preload, contractility, and afterload. A brief review of some of the graphical tools for evaluating cardiac physiology is demonstrated in Fig. 13-2.

**Preload.** Starling’s law of the heart states that the force of muscle contraction depends on the initial length of the cardiac fibers. Using terminology that derives from early experiments using isolated cardiac muscle preparations, preload is the stretch of ventricular myocardial tissue just prior to the next contraction. Strictly speaking, preload is determined by end-diastolic volume (EDV). In practice, EDV is challenging to measure precisely during the cardiac cycle, and so clinicians utilize the end-diastolic pressure (EDP) as a reasonable surrogate. For the right ventricle, central venous pressure (CVP) approximates right ventricular EDP. For the left ventricle, pulmonary artery occlusion pressure (PAOP), which is measured by transiently inflating a balloon at the end of a pressure monitoring catheter positioned in a small branch of the pulmonary artery, approximates left ventricular EDP. The presence of atrioventricular valvular stenosis may alter this relationship.

There are limits to the utilization of EDP as a surrogate for EDV when evaluating preload. For example, EDP is determined not only by volume but also by the diastolic compliance of the ventricular chamber. Ventricular compliance is altered by
Figure 13-2 A-D. Left ventricular pressure-volume loops constructed for various clinically relevant scenarios. For further information refer to the text. A. Standard left ventricular pressure-volume loop, with stroke volume, end systolic volume, and end diastolic volume highlighted for reference. Note the directionality of the pressure-volume loop, which is not annotated in the other figures for clarity. B-D. Demonstration of the effect of changing preload (B), contractility (C), or afterload (D) on the pressure-volume relationships in the left ventricle. Note the differences in stroke volume for various conditions, as well as the end-systolic volume and pressures, as these represent clinically significant parameters that govern patient care.

various pathologic conditions and pharmacologic agents. Furthermore, the relationship between EDP and true preload is not linear, but rather is exponential (Fig. 13-2A,B). This fact limits the utility of EDP as a surrogate marker at extremes of EDV.

**Contractility.** Contractility is defined as the inotropic state of the myocardium. Contractility is said to increase when the force of ventricular contraction increases at constant preload and afterload. Clinically, contractility is difficult to quantify because virtually all of the available measures are dependent to a certain degree on preload and afterload. If pressure-volume loops are constructed for each cardiac cycle, small changes in preload and/or afterload will result in shifts of the point defining the end of systole. These end-systolic points on the pressure-versus-volume diagram describe a straight line, known as the end-systolic pressure-volume line. A steeper slope of this line indicates greater contractility, as illustrated in Fig. 13-2C.

**Afterload.** Afterload is another term derived from in vitro experiments using isolated strips of cardiac muscle and is defined as the force resisting fiber shortening once systole begins. Defined specifically for the in vivo system, afterload is the resistance to the expulsion of blood from the heart chamber of interest, usually the left ventricle. Several factors comprise the in vivo correlate of ventricular afterload, including ventricular chamber geometry, intracavitary pressure generation, and the arterial impedance in the systemic circulation. Since these factors are difficult to assess clinically, afterload is commonly approximated by calculating systemic vascular resistance (SVR), defined as mean arterial pressure (MAP) divided by cardiac output (Fig. 13-2D).

**PLACEMENT OF THE PULMONARY ARTERY CATHETER**

In its simplest form, the PAC has four channels. One channel terminates in a balloon at the tip of the catheter. The proximal end of this channel is connected to a syringe to permit inflation of the balloon with air. Prior to insertion of the PAC, the integrity of the balloon should be verified by inflating it. In order to minimize the risk of vascular or ventricular perforation by the relatively inflexible catheter, it also is important to verify that the inflated balloon extends just beyond the tip of the device. A second channel in the catheter contains wires that are connected
to a thermistor located near the tip of the catheter. At the proximal end of the PAC, the wires terminate in a fitting that permits connection to appropriate hardware for the calculation of cardiac output using the thermodilution technique. The final two channels are used for pressure monitoring and the injection of the thermal indicator for determinations of cardiac output. One of these channels terminates at the tip of the catheter; the other terminates 20 cm proximal to the tip.

Placement of a PAC requires access to the central venous circulation. Such access can be obtained at a variety of sites, including the antecubital, femoral, jugular, and subclavian veins. Percutaneous placement through either the jugular or subclavian vein generally is preferred. Right internal jugular vein cannulation carries the lowest risk of complications, and the path of the catheter from this site into the right atrium is straight. In the event of inadvertent arterial puncture, local pressure is significantly more effective in controlling bleeding from the carotid artery as compared to the subclavian artery. Nevertheless, it is more difficult to keep occlusive dressings in place on the neck than in the subclavian fossa. Furthermore, the anatomic landmarks in the subclavian position are quite constant, even in patients with anasarca or massive obesity; the subclavian vein is always attached to the deep (concave) surface of the clavicle. In contrast, the appropriate landmarks to guide jugular venous cannulation are sometimes difficult to discern in obese or very edematous patients. However, ultrasonic guidance, which should be used routinely, has been shown to facilitate bedside jugular venipuncture.14

Cannulation of the vein is normally performed percutaneously, using the Seldinger technique. A small-bore needle is inserted through the skin and subcutaneous tissue into the vein. After documenting return of venous blood, a guidewire with a flexible tip is inserted through the needle into the vein, and the needle is withdrawn. A dilator/introducer sheath is passed over the wire, and the wire and the dilator are removed. The proximal terminus of the distal port of the PAC is connected through low-compliance tubing to a strain-gauge transducer, and the tubing-catheter system is flushed with fluid. While constantly observing the pressure tracing on a monitor screen, the PAC is advanced with the balloon deflated until respiratory excursions are observed. The balloon is then inflated, and the catheter advanced further, while monitoring pressures sequentially in the right atrium and right ventricle en route to the pulmonary artery. The pressure waveforms for the right atrium, right ventricle, and pulmonary artery are each characteristic (Fig. 13-3). The catheter is advanced out the pulmonary artery until a damped tracing indicative of the “wedged” position is obtained. The balloon is then deflated, taking care to ensure that a normal pulmonary arterial tracing is again observed on the monitor; leaving the balloon inflated can increase the risk of pulmonary infarction or perforation of the pulmonary artery. Unnecessary measurements of the pulmonary artery occlusion pressure are discouraged as rupture of the pulmonary artery may occur.

HEMODYNAMIC MEASUREMENTS

Even in its simplest embodiment, the PAC is capable of providing clinicians with a remarkable amount of information about the hemodynamic status of patients. Additional information may be obtained if various modifications of the standard PAC are employed. By combining data obtained through use of the PAC with results obtained by other means (i.e., blood hemoglobin concentration and oxyhemoglobin saturation), derived estimates of systemic oxygen transport and utilization can be calculated. Direct and derived parameters obtainable by bedside pulmonary arterial catheterization, along with several associated approximate normal ranges, are summarized in Table 13-1.
