disease. CT scanning is inferior to ultrasonography in diagnosing gallstones but is similar in sensitivity for acute cholecystitis. The major application of CT scan, however, is to define the course and status of the extrahepatic biliary tree and adjacent structures, and to evaluate for alternate causes of a patient's clinical presentation. CT is also the initial test of choice in evaluating patients with suspected malignancy of the gallbladder, the extrahepatic biliary system, or nearby organs such as the head of the pancreas. Use of CT scan is an integral part of the differential diagnosis of obstructive jaundice of unknown origin (Fig. 32-7).

Hepatobiliary Scintigraphy
Hepatobiliary scintigraphy, or hepatobiliary iminodiacetic acid (HIDA) scanning, is another option for noninvasive evaluation of the liver, gallbladder, bile ducts, and duodenum that provides both anatomic and functional information. Technetium-labeled derivatives of iminodiacetic acid are injected intravenously, taken up by the Kupffer cells in the liver, and excreted in the bile. Uptake by the liver is usually detected within 10 minutes, and the gallbladder, bile ducts, and duodenum are typically visualized within 60 minutes in fasting subjects. The primary use of biliary scintigraphy is in the diagnosis of acute cholecystitis, which appears as a nonvisualized gallbladder, with prompt filling of the common bile duct and duodenum. The lack of gallbladder filling is due to inflammatory closure of the cystic duct preventing bile backflow into the gallbladder (Fig. 32-8). Evidence of cystic duct obstruction on biliary scintigraphy is highly diagnostic for acute cholecystitis. The sensitivity and specificity for the diagnosis are about 95% each. False-positive results can occur in patients in the nonfasting state, those receiving parenteral nutrition, or in the setting of gallbladder stasis, recent narcotic use, or alcoholism. Filling of the gallbladder and common bile duct with delayed or absent filling of the duodenum indicates an obstruction at the ampulla. Biliary leaks as a complication of surgery of the gallbladder or the biliary tree can be confirmed and frequently localized by biliary scintigraphy.

Magnetic Resonance Imaging
Available since the mid-1990s, MRI provides anatomic details of the liver, gallbladder, and pancreas similar to those obtained from CT. Many MRI techniques (i.e., heavily T2-weighted sequences, pulse sequences with or without contrast materials) can generate high-resolution anatomic images of the biliary tree and the pancreatic duct. MRI with magnetic resonance cholangiopancreatography (MRCP) offers a focused, noninvasive test for the diagnosis of biliary tract and pancreatic disease (Fig. 32-9). It has a sensitivity and specificity of 95% and 89%, respectively, for detecting choledocholithiasis. In many centers, MRCP is the preferred imaging modality for precise evaluation of biliary and pancreatic duct pathology, reserving endoscopic retrograde cholangiopancreatography (ERCP) for therapeutic purposes only.

Figure 32-7. Computed tomography scan of the upper abdomen from a patient with cancer of the distal common bile duct. The cancer obstructs the common bile duct as well as the pancreatic duct. 1 = the portal vein; 2 = a dilated intrahepatic bile duct; 3 = dilated cystic duct and the neck of the gallbladder; 4 = dilated common hepatic duct; 5 = the bifurcation of the common hepatic artery into the gastroduodenal artery and the proper hepatic artery; 6 = dilated pancreatic duct; 7 = the splenic vein.

Endoscopic Retrograde Cholangiopancreatography

While the use of endoscopic retrograde cholangiopancreatography (ERCP) in biliary disease is particularly valuable for its therapeutic capabilities, its diagnostic role should not be overlooked. Using a side-viewing endoscope, the common bile duct can be cannulated through the ampulla of Vater and a cholangiogram performed using fluoroscopy (Fig. 32-10). The procedure requires at least intravenous (IV) sedation and in some cases general anesthesia. The advantages of ERCP include direct visualization of the ampullary region and direct access to the distal common bile duct for cholangiography or choledochoscopy. The test is rarely needed for uncomplicated gallstone disease. However, for cases of choledocholithiasis, obstructive jaundice, biliary strictures, or cholangitis, ERCP has the advantage of being both diagnostic and therapeutic. If ductal stones are identified on the endoscopic cholangiogram, biliary sphincterotomy and stone extraction can be performed, clearing the common bile duct of stones. If another etiology such as a biliary stricture is found, diagnostic brushings can be obtained at the time of the procedure. In the hands of experts, the success rate of common bile duct cannulation and cholangiography is >90%. Notable complications of diagnostic ERCP include pancreatitis, which occurs in approximately 3.5% of patients, as well as rare occurrences of bleeding, perforation, or infection (cholangitis).16,17

Endoscopic Choledochoscopy

The development of small fiber-optic cameras that can be threaded through endoscopes used for endoscopic retrograde cholangiopancreatography (ERCP) has facilitated the development of intraductal endoscopy. By providing direct visualization of the biliary and pancreatic ducts, this technology has been shown to increase the effectiveness of ERCP in the diagnosis of certain biliary diseases.18 Intraductal endoscopy has been shown to have therapeutic applications that include biliary stone lithotripsy and directed stone extraction in high-risk surgical patients.19 It can also allow for direct visualization and sampling of concerning lesions in order to evaluate for malignancy (Fig. 32-11). Studies have thus far shown intraductal endoscopy to be safe and effective, though complications such as bile duct perforation, minor bleeding, and cholangitis have
been described. Further refinement of this technology will likely enhance ERCP as a diagnostic and therapeutic tool.

**Endoscopic Ultrasound**
Endoscopic ultrasound (EUS) has improved significantly in recent years and offers additional diagnostic utility to the workup of biliary disease. It requires a specialized 30° endoscope with either a radial or linear ultrasound transducer at its tip. The results are operator dependent and require a skilled endoscopist but offer noninvasive imaging of the bile ducts and adjacent structures. Endoscopic ultrasound can also be used to identify choledocholithiasis. It is useful for evaluation of the retroduodenal portion of the bile duct, which is difficult to visualize with transabdominal ultrasonography. Although EUS is less sensitive than ERCP for biliary stones, the technique is less invasive as it does not require cannulation of the sphincter of Oddi. EUS is also of particular value in the evaluation of tumors near or behind the duodenum and their resectability. Using a linear EUS scope that has a biopsy channel, fine-needle aspiration (FNA) of tumors or lymph nodes, therapeutic injections, or drainage procedures under direct ultrasonic guidance can be performed.

**Percutaneous Transhepatic Cholangiography**
In settings in which the biliary tree cannot be accessed endoscopically, antegrade cholangiography can be performed by accessing the intrahepatic bile ducts percutaneously with a small needle under fluoroscopic guidance. Once the position in a bile duct has been confirmed, a guidewire is inserted and a catheter is passed over the wire (Fig. 32-12). Through the catheter, an antegrade cholangiogram can be obtained and therapeutic interventions such as tissue sampling, biliary drain insertions, or stent placements performed. Percutaneous transhepatic cholangiography (PTC) can also be performed through previously placed percutaneous biliary drainage tubes, if present. PTC has little role in the management of patients with uncomplicated gallstone disease but can be useful in patients with bile duct strictures or tumors, as it can define the anatomy of the biliary tree proximal to the affected segment. As with any invasive procedure, there are potential risks. For PTC, these are mainly bleeding, cholangitis, bile leak, and other catheter-related problems.

**GALLSTONE DISEASE**

**Prevalence and Incidence**
Gallstone disease (cholelithiasis) is one of the most common afflictions of the digestive tract. Autopsy reports show that gallstones are present in between 10% and 15% of adults. The prevalence of gallstones is related to many factors, including diet, age, gender, BMI, and ethnic background with increased prevalence in patients of Native American and Latin American descent. Certain conditions also predispose to the development of gallstones including pregnancy, non-HDL hyperlipidemia, Crohn’s disease, and certain blood disorders such as hereditary spherocytosis, sickle cell disease, and thalassemia. Surgeries that alter the normal neural or hormonal regulation of the biliary tree including terminal ileal resection and gastric or duodenal surgery increase the risk of cholelithiasis. Rapid weight loss following bariatric surgery or lifestyle changes can also precipitate gallstone formation by creating an imbalance in bile composition. Medications such as somatostatin analogues and estrogen-containing oral contraceptives are also associated with an increased risk of developing gallstones. Women are three times more likely to develop gallstones than men, and first-degree relatives of patients with gallstones have a twofold greater prevalence, possibly indicating a genetic predisposition.

**Natural History**
Despite the high prevalence of cholelithiasis, most patients will remain asymptomatic from their gallstones throughout life. For unknown reasons, some patients progress to a symptomatic stage, with typical symptoms of postprandial right upper quadrant pain (biliary colic) caused by a stone obstructing the cystic duct. In addition to pain, gallstones may progress to cause complications such as acute cholecystitis, choledocholithiasis, cholangitis, gallstone pancreatitis, gallstone ileus, and gallbladder cancer. Rarely, one of these complications of gallstones may be the initial presenting picture.

Gallstones in patients without biliary symptoms are commonly diagnosed incidentally during unrelated abdominal imaging or at the time of surgery for an unrelated diagnosis. Several studies have examined the likelihood of developing biliary colic or developing significant complications of gallstone disease after incidental diagnosis in the asymptomatic patient. About 80% of these patients will remain symptom free. However, 2% to 3% will become symptomatic per year (i.e., develop biliary colic). Once symptomatic, patients tend to have recurring bouts of biliary colic. Complicated gallstone disease (cholecystitis, choledocholithiasis, gallstone pancreatitis, etc.) develops in 3% to 5% of symptomatic patients per year. Because few patients develop complications without previous biliary symptoms, prophylactic cholecystectomy in asymptomatic persons with gallstones is rarely indicated. Exceptions exist for individuals who will be isolated from medical care for extended periods of time, or in populations with increased risk of gallbladder cancer, in which case a prophylactic cholecystectomy may be advisable. The presence of porcelain gallbladder, marked by significant calcifications thought to be related to
gallstones, is a rare premalignant condition and is an absolute indication for cholecystectomy, even when asymptomatic.

**Gallstone Formation**
Gallstones form as a result of solids settling out of solution. The major organic solutes in bile are bilirubin, bile salts, phospholipids, and cholesterol. Gallstones are classified by their cholesterol content as either cholesterol stones or pigment stones. Pigment stones can be further classified as either black or brown. In Western countries, about 80% of gallstones are cholesterol stones and about 15% to 20% are black pigment stones. Brown pigment stones account for only a small percentage. Both types of pigment stones are more common in Asia.

**Cholesterol Stones.** Pure cholesterol stones are uncommon and account for <10% of all stones. They usually occur as a single large stone with a smooth surface. The majority of cholesterol stones are mixed but are at least 70% cholesterol by weight in addition to variable amounts of bile pigments and calcium. These stones are usually multiple, of variable size, and may be

hard and faceted or irregular, multilobed, and soft (Fig. 32-13). Colors range from whitish yellow to green or black. Most cholesterol stones (>90%) are radiolucent, though some have a high calcium carbonate component and become radioopaque.

The primary event in the formation of cholesterol stones is supersaturation of bile with cholesterol. Cholesterol is highly nonpolar and its solubility in water and bile depends on the relative concentration of cholesterol, bile salts, and lecithin (the main phospholipid in bile). Cholesterol is secreted into bile and is surrounded by bile salts and phospholipids to form a soluble vesicle complex. When cholesterol hyperssecretion is present, either through increased intake or dysfunctional processing, supersaturation occurs. When cholesterol concentrations exceed the ability of the bile salts and phospholipids to maintain solubility, the cholesterol precipitates out of solution into a solid, forming a cholesterol stone (Fig. 32-14).26 Cholesterol hyperssecretion is almost always the cause of supersaturation rather than reduced secretion of phospholipid or bile salts.2

**Pigmented Stones.** Pigmented stones contain <20% cholesterol and are dark because of the presence of calcium bilirubinate. Black and brown pigment stones have little in common and should be considered as separate entities.

Black pigment stones are usually small, brittle, dark, and sometimes spiculated. They are formed by supersaturation of unconjugated bilirubin within the bile. Deconjugation of bilirubin occurs normally in bile at a slow rate. Thus, excessive levels of conjugated bilirubin excretion, as occurs in hemolytic disorders like hereditary spherocytosis and sickle cell disease will lead to an increased rate of production of unconjugated bilirubin. Cirrhosis and hepatic dysfunction may also lead to increased secretion of unconjugated bilirubin directly from the liver. The insoluble unconjugated bilirubin will then precipitate with calcium as insoluble calcium bilirubinate, forming a pigment stone. Due to their high calcium content, pigment stones are often radiopaque. Like cholesterol stones, they almost always form in the gallbladder. In Asian countries such as Japan, black stones account for a much higher percentage of gallstones than in the Western hemisphere.

Brown stones are usually <1 cm in diameter, brownish-yellow, soft, and often mushy. They may form either in the gallbladder or in the bile ducts secondary to bacterial infection and bile stasis. Bacteria such as *Escherichia coli* secrete β-glucuronidase that enzymatically cleaves conjugated bilirubin to produce the insoluble unconjugated bilirubin. This unconjugated bilirubin then precipitates with calcium, and along with dead bacterial cell bodies, forms soft brown stones in the biliary tree. Brown stones are typically found in Asian populations and are associated with stasis secondary to parasite infection with *Ascaris lumbricoides*.

**Figure 32-13.** Gallbladder with cholesterol stones. **A.** Stones of multiple shapes and sizes. **B.** Solitary large stone. **C.** Multiple stones of varying composition. (Reproduced with permission from Slesinger MH, Fordtran JS: Gastrointestinal Diseases. Philadelphia, PA: Elsevier/Saunders; 1989.)

**Figure 32-14.** The three major components of bile plotted on triangular coordinates, cholesterol, bile salts and phospholipids (lecithin). A given point represents the relative molar ratios of each. The area labeled “micellar liquid” shows the range of concentrations in which cholesterol is fully solubilized. The shaded area directly above this region corresponds to a metastable zone, supersaturated with cholesterol. Above the shaded area, bile has exceeded the solubilization capacity of cholesterol and precipitation of cholesterol crystals and stones occurs.
Symptomatic Gallstones

Symptomatic Cholelithiasis. Patients with symptomatic gallstone disease typically present with recurrent attacks of pain. The pain develops when a stone obstructs the cystic duct, resulting in a progressive increase of tension in the gallbladder wall as it contracts in response to a meal. This postprandial right upper quadrant or epigastric pain is often referred to as biliary colic. If untreated, about two-thirds of these patients will develop chronic noninfectious inflammation of the gallbladder wall, termed chronic cholecystitis. The pathologic changes, which often do not correlate well with symptoms, vary from an apparently normal gallbladder with minor chronic inflammation in the mucosa, to a shrunken, nonfunctioning gallbladder with transmural fibrosis and adhesions to nearby structures. The mucosa is initially normal or hypertrophied but later becomes atrophied, with the epithelium protruding into the muscle coat, leading to the formation of the so-called Aschoff-Rokitansky sinuses.

Clinical Manifestations The chief symptom associated with symptomatic cholelithiasis is pain (biliary colic). The pain is constant and increases in severity over the first half hour or so after a meal and can last 1 to 5 hours. It is located in the epigastrium or right upper quadrant and frequently radiates to the right upper back or between the scapulae (Fig. 32-15). The pain is severe and comes on abruptly, typically during the night or after a fatty meal. It often is associated with nausea and sometimes vomiting. Patients generally suffer discrete, recurrent attacks of pain, between which they feel well. Physical examination may reveal mild right upper quadrant tenderness during an episode of pain. If the patient is pain free, the physical examination is usually unremarkable. Laboratory values, such as WBC count and liver function tests, are usually normal in patients with uncomplicated gallstones.

Atypical presentations of gallstone disease are common and a high index of suspicion for biliary disease must be maintained when evaluating patients with abdominal complaints. Association with meals is present in only about 50% of patients. Some patients report milder attacks of pain but relate it to meals. The pain may be located primarily in the back or the left upper or right lower quadrant. Bloating and belching may be present and associated with the attacks of pain. In patients with atypical presentations, other conditions that may be causing upper abdominal pain should be ruled out, even in the presence of gallstones. These include but are not limited to peptic ulcer disease, gastroesophageal reflux disease, herpes zoster, abdominal wall hernias, inflammatory bowel disease, diverticular disease, pancreatitis, liver disease, renal calculi, pleuritic pain, and cardiac pain.

When the pain lasts >24 hours without resolving, an impacted stone in the cystic duct or acute cholecystitis (see later “Acute Cholecystitis” section) should be suspected. An impacted stone without cholecystitis will result in what is called hydrops of the gallbladder. Bile will be unable to enter the gallbladder due to the obstructed cystic duct, but the gallbladder epithelium will continue to secrete mucus, and the gallbladder will become distended with clear-white mucinous material. The gallbladder may be palpable but usually is not tender. Hydrops of the gallbladder may result in edema of the gallbladder wall, inflammation, infection, and perforation. Although hydrops may persist with few consequences, early cholecystectomy is generally indicated to avoid complications.

Diagnosis The diagnosis of symptomatic cholelithiasis or chronic cholecystitis depends on the presence of typical symptoms and the demonstration of stones on diagnostic imaging. An abdominal ultrasound is the standard diagnostic test for gallstones as it is noninvasive and highly sensitive (see earlier “Ultrasonography” section). Gallstones are occasionally identified on abdominal CT scans that were obtained as part of a broader workup of abdominal pain. In these cases, if the patient has typical symptoms, it is reasonable to proceed with intervention. Stones diagnosed incidentally on CT or plain radiographs in patients without symptoms should be left in place. Occasionally, patients with typical attacks of biliary pain have no evidence of stones on ultrasound but have evidence of sludge in the gallbladder. If a patient has attacks of typical biliary pain and sludge is detected, cholecystectomy is warranted.

In addition to sludge and stones, cholesterolosis and adenomyomatosis of the gallbladder may cause typical biliary symptoms and may be detected on ultrasound or CT. Cholesterolosis is caused by the accumulation of cholesterol in macrophages in the
gallbladder lamina propria, either locally or as polyps. It produces the classic studded macroscopic appearance of a “strawberry gallbladder.” Adenomyomatosis (cholecystitis glandularis proliferans) is characterized on microscopy by hypertrophic smooth muscle bundles and by the ingrowths of mucosal glands into the muscle layer (epithelial sinus formation). Granulomatous polyps develop in the lumen at the fundus, and the gallbladder wall is thickened. Septae or strictures may be seen within the gallbladder. In symptomatic patients, cholecystectomy is the treatment of choice for patients with these conditions.29

Treatment. Nonsurgical management of gallstone disease using medications or lithotripsy has had disappointing long-term results. These modalities are not considered to be part of the primary treatment algorithm for gallstone disease.30 Surgical cholecystectomy offers the best long-term results for patients with symptomatic gallstones. About 90% of patients with typical biliary symptoms and stones are rendered symptom free after cholecystectomy. For patients with atypical symptoms such as dyspepsia, flatulence, belching, bloating, and dietary fat intolerance, the results are not as favorable. The laparoscopic approach has been proven to be safe and effective and has become the standard of care for symptomatic gallstone disease, replacing open cholecystectomy in routine cases.30,31

Due to the possibility of developing complications related to gallstone disease, patients with symptomatic cholelithiasis should be offered elective cholecystectomy. While waiting for surgery, and if surgery has to be postponed, the patient should be advised to avoid dietary fats and large meals. Diabetic patients with symptomatic gallstones should be encouraged to have a cholecystectomy promptly, as they are more prone to developing severe acute cholecystitis. Pregnant women with symptomatic gallstones who cannot be managed expectantly with diet modifications can safely undergo laparoscopic cholecystectomy. The operation should be performed during the second trimester if possible.

Acute Cholecystitis. Acute cholecystitis, or infection of the gallbladder, is associated with gallstones in 90% to 95% of cases. Rarely, acalculous cholecystitis can occur, usually in patients with other acute systemic diseases (see later “Acalculous Cholecystitis” section). Obstruction of the cystic duct by a gallstone is the initiating event that leads to gallbladder distention, inflammation, and edema of the gallbladder wall. In <1% of acute cholecystitis, the cause is a tumor obstructing the cystic duct. Why inflammation develops only occasionally with cystic duct obstruction is unknown, but it is probably related to the duration of obstruction. Initially, acute cholecystitis is an inflammatory process, probably mediated by the mucosal toxin lysolecithin, a product of lecithin, as well as bile salts and platelet-activating factor. An increase in prostaglandin synthesis amplifies the inflammatory response. In acute cholecystitis, the gallbladder wall becomes grossly thickened and reddish with subserosal hemorrhages. Pericholecystic fluid often is present. The mucosa may show hyperemia and patchy necrosis. In severe cases, about 5% to 10%, the inflammatory process progresses and leads to ischemia and necrosis of the gallbladder wall. More frequently, the gallstone is dislodged and the inflammation resolves.

Not all episodes of uncomplicated acute cholecystitis involve infection. Secondary bacterial contamination is thought to occur in only 15% to 30% of patients. With some severe infections, gangrenous cholecystitis can develop, and an abscess or perforation may occur. When they happen, perforations are usually contained in the subhepatic space by the omentum and adjacent organs. However, free perforation with peritonitis, intrahepatic perforation with intrahepatic abscesses, and perforation into adjacent organs (duodenum or colon) with cholecystoenteric fistula have been described. When gas-forming organisms are part of the secondary bacterial infection, gas may be seen in the gallbladder lumen and in the wall of the gallbladder on abdominal radiographs and CT scans, an entity called emphysematous cholecystitis.

Clinical Manifestations. About 80% of patients with acute cholecystitis give a history compatible with chronic cholecystitis. Acute cholecystitis often begins as an attack of biliary colic with relapsing and remitting pain in the right upper quadrant or epigastrium that may radiate to the right back or interscapular area. In contrast to biliary colic, the pain of acute cholecystitis does not subside. It is unremitting, may persist for several days, and is usually more severe than the pain associated with uncomplicated gallstone disease. The patient is often febrile, complains of anorexia, nausea, and vomiting, and may be reluctant to move as the inflammatory process creates focal peritonitis. On physical examination, tenderness and guarding are usually present in the right upper quadrant. A mass, the gallbladder and adherent omentum, is occasionally palpable; however, guarding may prevent identification of this. Murphy’s sign, an inspiratory arrest with deep palpation in the right subcostal area, is characteristic of acute cholecystitis.

Laboratory evaluation commonly reveals a mild to moderate leukocytosis (12,000–15,000 cells/mm³). However, a normal WBC does not rule out the diagnosis. An unusually high WBC count (>20,000 cells/mm³) suggests a complicated form of cholecystitis such as gangrenous cholecystitis, perforation, or associated cholangitis. In uncomplicated acute cholecystitis, serum liver chemistries are usually normal, but a mild elevation of serum bilirubin (<4 mg/dL) may be present along with mild elevation of alkaline phosphatase, transaminases, and amylase.28 Severe jaundice is suggestive of obstruction of the bile ducts. This can be a result of common bile duct stones or severe pericholecystic inflammation secondary to impaction of a stone in the infundibulum of the gallbladder that mechanically obstructs the bile duct, known as Mirizzi’s syndrome (Fig. 32-16). In elderly patients and in those with diabetes mellitus, acute cholecystitis may have a subtle

Figure 32-16. Mirizzi’s syndrome. Impaction of a large stone in the neck of the gallbladder causing obstruction at the level of the confluence of the cystic duct and common hepatic duct.
presentation resulting in a delay in diagnosis. These patients may also have higher rates of treatment related morbidity compared to younger and healthier patients.

The differential diagnosis for acute cholecystitis includes but is not limited to peptic ulcer disease, pancreatitis, appendicitis, hepatitis, perihepatitis (Fitz-Hugh–Curtis syndrome), myocardial ischemia, pneumonia, pleuritis, and herpes zoster involving the intercostal nerve.

**Diagnosis** Ultrasonography is considered the most useful initial radiologic test for diagnosing acute cholecystitis, with a sensitivity and specificity of 70% to 90%. Ultrasound is effective at documenting the presence or absence of stones, and it can show gallbladder wall thickening and pericholecystic fluid, both of which are highly suggestive of acute cholecystitis (Fig. 32-17). Focal tenderness over the gallbladder when compressed by the sonographic probe (sonographic Murphy’s sign) also supports the diagnosis of acute cholecystitis. Biliary scintigraphy (HIDA scanning) may be of help in atypical cases if the diagnosis remains in question after initial workup. Lack of filling of the gallbladder after 4 hours indicates an obstructed cystic duct and, in the clinical setting of suspected acute cholecystitis, confirms the diagnosis with a reported sensitivity above 90%.32 Conversely, a normal HIDA scan with clear filling of the gallbladder rules out the diagnosis of acute cholecystitis. CT scans are frequently performed on patients with acute abdominal pain of unknown etiology, as they can evaluate for a number of potential pathologic processes at once. In patients with acute cholecystitis, a CT scan can demonstrate thickening of the gallbladder wall, pericholecystic fluid, and the presence of gallstones, but it is somewhat less sensitive than ultrasonography.

**Treatment** Patients who present with acute cholecystitis should receive IV fluids, broad-spectrum antibiotics, and analgesia. The antibiotics should cover gram-negative enteric organisms as well as anaerobes. Although the inflammation in acute cholecystitis may be sterile in some patients, it is difficult to know who is secondarily infected. Therefore, antibiotics have become a standard part of the initial management of acute cholecystitis in most centers.

Cholecystectomy is the definitive treatment for acute cholecystitis. In the past, the timing of cholecystectomy has been a matter of debate. Early cholecystectomy performed within 72 hours of the onset of the illness is preferred over delayed cholecystectomy that is performed 6 to 10 weeks after initial medical treatment and recuperation. Several studies have shown that unless the patient is unfit for surgery, early cholecystectomy should be recommended as soon as possible, as it offers the patient a definitive solution in one hospital admission, quicker recovery times, similar complication rates, and an earlier return to work.33,34

Laparoscopic cholecystectomy is the procedure of choice for acute cholecystitis. The conversion rate to an open cholecystectomy has fallen in recent years to less than 5% as laparoscopic equipment and experience has improved.35 While laparoscopic cholecystectomy for acute cholecystitis may be more tedious and take longer than an elective cholecystectomy for symptomatic choledolithiasis, the laparoscopic approach remains safe and effective, even in the setting of acute and sometimes severe inflammation. Open cholecystectomy must remain an option in particularly difficult cases, or in patients suspected of having prohibitive intraabdominal adhesions, but it is rarely the primary treatment choice.

When patients are medically unfit for surgery due to the severity of their illness or medical comorbidities, they can be treated with antibiotics and biliary decompression with cholecystostomy tube placement, which is usually effective in stabilizing the patient.36 For those who do recover after cholecystostomy, the tube can be removed once the track is mature (approximately 4 weeks) and cholangiography through it shows a patent cystic duct. Elective laparoscopic cholecystectomy can be scheduled within approximately 6 to 8 weeks, assuming their medical fitness recovers.37 Failure to improve after cholecystostomy may be due to gangrene of the gallbladder or perforation, in which case, damage control surgery may be unavoidable.

**Choledocholithiasis.** Common bile duct (CBD) stones may be small or large, single or multiple, and are found in 6% to 12% of patients with stones in the gallbladder. The incidence increases with age. About 20% to 25% of patients above the age of 60 with symptomatic gallstones have stones in the common bile duct as well as in the gallbladder.38 The vast majority of ductal stones in...
Western countries are formed within the gallbladder and migrate down the cystic duct into the common bile duct. These are classified as secondary CBD stones, in contrast to the primary CBD stones that form in the bile duct itself. Secondary stones are usually cholesterol stones, whereas primary stones are usually of the brown pigment type. The primary stones are associated with biliary stasis and infection, and they are more commonly seen in Asian populations. Biliary stasis leading to the development of primary CBD stones can be caused by biliary strictures, papillary stenosis, tumors, or other (secondary) stones.

**Clinical Manifestations** Choleodochal stones may be silent and often are discovered incidentally. They may cause complete or incomplete obstruction, or they may manifest with cholangitis or gallstone pancreatitis. The typical pain caused by a stone in the bile duct is very similar to that of biliary colic caused by impaction of a stone in the cystic duct. Nausea and vomiting are common. Physical examination may be normal, but mild epigastric or right upper quadrant tenderness as well as mild icterus are common. The symptoms may also be intermittent, such as pain and transient jaundice caused by a stone that temporarily impacts the ampulla but subsequently moves away, acting as a ball valve. A small stone may pass through the ampulla spontaneously with resolution of symptoms. Finally, the stones may become completely impacted, causing severe progressive jaundice. Elevation of serum bilirubin, alkaline phosphatase, and transaminases are commonly seen in patients with bile duct stones. However, in about one-third of patients with common bile duct stones, the liver chemistries are normal, particularly if the obstruction is incomplete or intermittent.

**Diagnosis** Ultrasonography is useful for documenting stones in the gallbladder (if still present), as well as determining the size of the common bile duct. As stones in the bile ducts tend to move down to the distal part of the common duct behind the duodenum, bowel gas can preclude their detection on ultrasonography. A dilated common bile duct (>8 mm in diameter) on ultrasonography in a patient with gallstones, jaundice, and biliary pain is highly suggestive of common bile duct stones. If the presence of bile duct stones is in question, magnetic resonance cholangiopancreatography (MRCP) provides excellent anatomic detail and has a sensitivity and specificity of 95% and 89%, respectively, for detecting choledocholithiasis. Endoscopic retrograde cholangiopancreatography (ERCP) is highly effective at diagnosing choledocholithiasis and in experienced hands, cannulation of the ampulla of Vater and diagnostic cholangiography are achieved in >90% of cases. However, due to the risks associated with the procedure, it is rarely used as a purely diagnostic modality, rather being reserved for cases in which a therapeutic intervention such as stone extraction or sphincterotomy is planned. Endoscopic ultrasound has been demonstrated to be as good as ERCP for detecting common bile duct stones (sensitivity of 95% and specificity of 97%). However, EUS has fewer therapeutic capabilities and requires endoscopic expertise, making it less desirable except in specific clinical scenarios. Percutaneous transhepatic cholangiography (PTC) is rarely needed in patients with common bile duct stones but can be performed for both diagnostic and therapeutic reasons in patients with contraindications to endoscopic or surgical approaches.

**Treatment** For patients with symptomatic gallstones and suspected common bile duct stones, bile duct clearance and cholecystectomy are indicated. This may be safely achieved either with preoperative ERCP followed by surgery or by going directly to surgery with intraoperative cholangiogram and common bile duct exploration to address retained stones. Both approaches are considered safe and effective, and no formal recommendation exists to definitively support one over the other.

If upfront laparoscopic cholecystectomy is pursued, the surgery should include an intraoperative cholangiogram to document the presence or absence of bile duct stones. If stones are identified, laparoscopic common bile duct exploration via the cystic duct or with formal choledochotomy allows the stones to be retrieved in the same setting (see “Cholecystectomy” section). If the expertise and/or instrumentation for laparoscopic common bile duct exploration are not available, the patient can be awoken and scheduled for ERCP with sphincterotomy the following day. An open common bile duct exploration is an option if the endoscopic and laparoscopic methods are not feasible. If a choledochotomy is performed, primary repair can be considered in large ducts, while smaller ducts should be repaired over a T-tube. To do this, a standard T-tube should be modified by cutting the ends short enough to allow placement within the duct and dividing the T longitudinally to facilitate easy removal from the duct later on (Fig. 32-18). If a common

---

**Figure 32-18.** T-tube placement. A. A standard T-tube that has been cut and modified for use in the biliary tract. B. The T-tube is placed through a ductotomy in the common bile duct with the defect closed over the tube. The opposite end is brought out through the abdominal wall for decompression of the bile ducts.
bile duct exploration was performed and a T tube left in place, a T-tube cholangiogram should be obtained before its removal, at least several weeks after its placement.

In very severe cases, stones impacted in the ampulla may be unable to be cleared by endoscopic approaches or common bile duct exploration (open or laparoscopic). In these cases, transduodenal sphincterotomy can be considered. If one is entirely unable to disimpact the duct, choledochooduodenostomy or Roux-en-Y choledochojejunostomy may be the only option to restore biliary continuity.42

If the stones were left in place at the time of surgery or diagnosed shortly after the cholecystectomy, they are classified as retained. Those diagnosed months or years later are termed recurrent (Fig. 32-19). Retained or recurrent stones following cholecystectomy are best treated endoscopically. A generous sphincterotomy will allow for stone retrieval as well as spontaneous passage of stones. Alternately, retained stones can be cleared via a mature T-tube tract (4 weeks) if one was placed at the time of surgery. To do this, the T-tube is removed and a catheter passed through the tract into the common bile duct. Under fluoroscopic guidance, the stones can be retrieved with baskets or balloons. A similar approach will allow for stone clearance by percutaneous transhepatic cholecystostomy (PTC) if there is no other way to reach the duct. Repeat surgery should be a last resort if other interventions have failed.

Cholangitis. Cholangitis is one of the main complications of choledochal stones. Acute cholangitis is an ascending bacterial infection associated with partial or complete obstruction of the bile ducts.43 Hepatic bile is sterile, and bile in the bile ducts is kept sterile by continuous antegrade bile flow and by the presence of antibacterial substances in bile, such as immunoglobulin. Mechanical hindrance to bile flow facilitates ascending bacterial contamination from the bowel. Positive bile cultures are common in the presence of bile duct stones as well as with other causes of obstruction. Biliary bacterial contamination alone does not lead to clinical cholangitis; the combination of both significant bacterial contamination and biliary obstruction is required for its development. Gallstones are the most common cause of obstruction in cholangitis. Other causes include primary sclerosing cholangitis, benign and malignant strictures, parasites, instrumentation of the ducts, and indwelling stents, as well as partially obstructed biliary-enteric anastomoses. The most common organisms cultured from bile in patients with cholangitis include E coli, Klebsiella pneumoniae, Streptococcus faecalis, Enterobacter, and Bacteroides fragilis.43

Clinical Manifestations Cholangitis may present as anything from a mild, self-limited episode to a fulminating, potentially life-threatening septicemia. Patients with gallstone-induced cholangitis are most commonly older and female. The most common presentation is fever, epigastric or right upper quadrant pain, and jaundice. These classic symptoms, known as Charcot’s triad, are present in about two-thirds of patients. The illness can progress rapidly with the development of shock and altered mental status, known as Reynolds’ pentad (e.g., fever, jaundice, right upper quadrant pain, septic shock, and mental status changes). However, the presentation may be atypical, with little if any fever, jaundice, or pain. This occurs most commonly in the elderly, who may have unremarkable symptoms until the process is already quite advanced. Patients with indwelling stents are at particularly high risk for cholangitis, though rarely become jaundiced as a patent stent will prevent the obstruction of bile flow. On abdominal examination, the findings are indistinguishable from those of acute cholecystitis.44

Diagnosis Leukocytosis, hyperbilirubinemia, and elevation of alkaline phosphatase and transaminases are common and, when present, support the clinical diagnosis of cholangitis. Ultrasonography is helpful, as it will document the presence of gallbladder stones, demonstrate dilated ducts, and possibly pinpoint a site of obstruction. CT scanning and MRI can show pancreatic and periampullary masses, if present, in addition to the ductal dilatation. However, abdominal imaging will rarely elucidate the exact cause of cholangitis, and the initial diagnosis is generally made clinically.

Treatment The initial treatment of patients with cholangitis includes broad-spectrum IV antibiotics to cover enteric organisms and anaerobes, fluid resuscitation, and rapid biliary...
decompression. This is most often accomplished through ERCP and sphincterotomy. ERCP will show the level and the reason for the obstruction, allow for culture of the bile, permit the removal of stones if present, and accomplish drainage of the bile ducts. Placement of drainage catheters or stents can also be performed if needed. In cases in which ERCP is not available, PTC, EUS, or surgical drainage can be utilized. The selection of the appropriate approach will depend on the type and location of the suspected obstruction as well as the availability of local resources and expertise. Cholecystostomy tubes are not indicated in the acute management of cholangitis as the primary source of the infection is extrinsic to the gallbladder.

Patients with cholangitis can deteriorate rapidly and may require intensive care unit monitoring and vasopressor support. However, most patients will respond to biliary decompression and supportive measures. In the current era, acute cholangitis is associated with an overall mortality rate of approximately 5%. When associated with renal failure, cardiac impairment, hepatic abscesses, and malignacies, the morbidity and mortality rates are much higher. Patients who have suffered an episode of acute cholangitis related to gallstone disease should be recommended to undergo elective cholecystectomy approximately 6 weeks after the resolution of their cholangitis. Those whose cholangitis was related to another cause of biliary obstruction should be followed and treated for the specific etiology of their obstruction but do not necessarily require cholecystectomy if gallstones were not the causative etiology of their cholangitis. Patients with indwelling stents and cholangitis usually require repeated imaging and stent exchange to mitigate the risk of recurrent infections.

Gallstone Pancreatitis. Gallstones in the common bile duct can provoke attacks of acute pancreatitis through transient or persistent obstruction of the pancreatic duct by a stone passing through or impacted in the ampulla. The exact mechanism by which obstruction of the pancreatic duct leads to pancreatitis is unclear, but it may be related to increased ductal pressures causing leakage of pancreatic enzymes into the glandular tissue. The initial management of gallstone pancreatitis is supportive, including admission for bowel rest, IV hydration, and pain control. Antibiotics are not indicated in the absence of signs of infected pancreatic necrosis. Imaging of the biliary tree with ultrasound, CT, or MRCP is essential to confirm the diagnosis. When gallstones are present and the pancreatitis is mild and self-limited, the stone has probably passed. For these patients, a cholecystectomy with intraoperative cholangiogram is indicated as soon as the pancreatitis has clinically resolved. It is strongly recommended that cholecystectomy be performed during the same admission whenever possible due to the high rate of recurrence and increased morbidity of subsequent attacks of pancreatitis. If gallstones are present obstructing the duct and the pancreatitis is severe, an ERCP with sphincterotomy and stone extraction may be necessary. This must be balanced with the risk of ERCP-induced pancreatitis and thus is usually only employed if supportive measures are failing.

Gallstone Ileus. Gallstone ileus can occur when a large gallstone erodes through the wall of the gallbladder directly into the intestine via a choledochoenteric fistula (Fig. 32-20A). These stones can then pass through the intestinal tract until they reach an area of fixed obstruction. Proximal stones can become impacted in the pylorus or proximal duodenum causing gastric outlet obstruction (Bouveret syndrome). Those that travel distally may become lodged at surgical anastomoses or the ileocecal valve, where they can become impacted and cause small bowel obstruction. Gallstone ileus is responsible for less than 1% of all intestinal obstructions.

These patients present with symptoms of obstipation, nausea, and abdominal pain. Plain films may show an obstructive bowel gas pattern but may fail to identify a radiolucent stone. Ultrasound evaluation may be limited by extensive bowel gas. CT is highly sensitive and specific for gallstone ileus and will help to determine the location of the obstruction. Management of gallstone ileus focuses on relieving the intestinal obstruction and removing the stone. In cases of very proximal obstructions in the stomach or duodenum, endoscopic retrieval can be effective. For more distal stones, surgical enterolitotomy can be accomplished either laparoscopically or open. This procedure entails the removal of the stone through...
an enterotomy that is then either repaired or resected depending on its size (Fig. 32-20B). Stones that have successfully traversed the ileocecal valve are likely to pass without further intervention. The role of pursuing cholecystectomy and/or choledochoenteric fistula closure at the time of enterolithotomy or addressing it at a later time remains a topic of debate, but it should be considered to reduce the risk of recurrence. 47

**Cholangiohepatitis**

Cholangiohepatitis, also known as recurrent pyogenic cholangitis, is endemic to the Orient. It also has been encountered in Asian population in the United States, Europe, and Australia. It affects both sexes equally and occurs most frequently in the third and fourth decades of life. Cholangiohepatitis is caused by bacterial contamination (commonly *E. coli*, *Klebsiella* species, *Bacteroides* species, or *Enterococcus faecalis*) of the biliary tree, and often it is associated with biliary parasites such as *Clonorchis sinensis*, *Opisthorchis viverrini*, and *A. lumbricoides*. Bacterial enzymes cause deconjugation of bilirubin, which precipitates as bile sludge. The sludge and dead bacterial cell bodies form brown pigment stones, the nucleus of which may contain an adult *Clonorchis* worm, an ovum, or an ascariid. These stones can form throughout the biliary tree and cause partial obstructions that contribute to repeated bouts of cholangitis, biliary strictures, further stone formation, infection, hepatic abscesses, or liver failure (secondary biliary cirrhosis). 58

Patients with cholangiohepatitis usually present with pain in the right upper quadrant or epigastrum, fever, and jaundice. Relapsing symptoms are one of the most characteristic features of the disease. The episodes may vary in severity but, without intervention, will gradually lead to malnutrition and hepatic insufficiency. An ultrasound may detect stones in the biliary tree, pneumobilia from infection by gas-forming organisms, liver abscesses, and, occasionally, strictures. The gallbladder may be thickened and inflamed in about 20% of patients but rarely contains gallstones. ERCP or MRCP can be utilized for biliary imaging for cholangiohepatitis. They can detect obstructions and define strictures and stones. ERCP (or PTC if necessary) has the additional benefit of allowing for emergent decompression of the biliary tree in the septic patient. Hepatic abscesses may be drained percutaneously. The long-term goal of therapy is to extract stones and debris and relieve strictures. It may take several procedures, and in severe, refractory cases in which stones and strictures cannot be relieved, it may require a hepatochojunostomy to reestablish biliary–enteric continuity. Occasionally, resection of involved areas of the liver may offer the best form of treatment. Recurrences are common, and the prognosis is poor once hepatic insufficiency has developed. 49

**PROCEDURAL INTERVENTIONS FOR GALLSTONE DISEASE**

**Percutaneous Transhepatic Cholecystostomy Tubes**

In cases in which a patient with cholecystitis is deemed to be too ill to safely undergo cholecystectomy, a cholecystostomy tube may be placed into the gallbladder to decompress and drain a distended, inflamed, hydropic, or purulent gallbladder. 50 Surgical cholecystostomy with a large catheter placed under local anesthesia is rarely required today. Rather, percutaneous transhepatic cholecystostomy (PTC) tubes are most often pigtail catheters inserted percutaneously under ultrasound guidance. 50

![Figure 32-21. Percutaneous cholecystostomy. A pigtail catheter has been placed through the abdominal wall, the right lobe of the liver, and into the gallbladder.](image)

The catheter is inserted over a guidewire that has been passed through the abdominal wall, the liver, and into the gallbladder (Fig. 32-21). By passing the catheter through the liver, the risk of uncontrolled bile leak around the catheter and into the peritoneal cavity is minimized. The catheter can be removed when the inflammation has resolved and the patient’s condition has improved. A patent cystic duct should be confirmed by a tube cholangiogram prior to its removal. Interval cholecystectomy should be considered if the patient’s fitness has improved, particularly in individuals whose etiology of cholecystitis was gallstones.

**Endoscopic Interventions**

Endoscopic advances in the last few decades have made endoscopy and ERCP a valuable therapeutic tool in the management of gallstone disease, particularly in the setting of common bile duct stones or abnormalities. Using a 90-degree side-viewing endoscope, the duodenum can be entered and the ampulla of Vater on the medial wall of the second portion of the duodenum visualized. This can then be cannulated to allow wire and catheter access to the biliary tree, facilitating retrograde cholangiogram, diagnostic brushings, stenting, dilations, or fluoroscopically guided basket or balloon retrieval of common bile duct stones. When CBD stones are present, endoscopic sphincterotomy should be performed, which will allow for passage of larger stones both at the time of bile duct clearance and in the case of any ongoing choledocholithiasis (Fig. 32-22). In the hands of experts, ERCP has high rates of successful cannulation and bile duct clearance, and it is a safe and tolerable procedure. Debate remains when comparing ERCP to surgical common bile duct exploration in terms of timing and outcomes for cholecystectomy, but both are considered acceptable treatments. 41 In special cases, such as the presence of Roux-en-Y anatomy or a previous hepaticojejunostomy, ERCP can be difficult. However, such anatomy does not preclude the option for endoscopic intervention. Laparoscopic-assisted ERCP (in which the remnant stomach is accessed surgically and the endoscope passed into the duodenum) or double-balloon ERCP can be utilized to reach the biliary tree.

**Cholecystectomy**

Cholecystectomy is one of the most common abdominal surgeries performed in Western countries, with over 750,000
being performed each year in the United States alone. Carl Langenbuch performed the first successful open cholecystectomy in 1882, and for >100 years, it was the standard treatment for symptomatic gallbladder stones. In 1987, laparoscopic cholecystectomy was introduced by Philippe Mouret in France and quickly revolutionized the treatment of gallstone disease. It not only supplanted open cholecystectomy, but it also more or less ended attempts for noninvasive management of gallstones (such as extracorporeal shock wave or cholangioscopic lithotripsy) or medical therapies (such as bile salts). Laparoscopic cholecystectomy offers a cure for gallstones with a minimally invasive procedure, minor pain and scarring, and early return to full activity. Today, laparoscopic cholecystectomy is the treatment of choice for symptomatic gallstones and the complications of gallstone disease.

Few absolute contraindications exist to laparoscopic cholecystectomy, but they include hemodynamic instability, uncontrolled coagulopathy, or frank peritonitis. In addition, patients with severe obstructive pulmonary disease (COPD) or congestive heart failure (e.g., cardiac ejection fraction <20%) might not tolerate the increased intraabdominal pressures of pneumoperitoneum with carbon dioxide and may require open cholecystectomy. Conditions formerly believed to be relative contraindications such as acute cholecystitis, gangrene and empyema of the gallbladder, biliary-enteric fistulae, obesity, pregnancy, ventriculoperitoneal shunts, cirrhosis, and previous upper abdominal procedures are now considered risk factors for a potentially difficult cholecystectomy, but they do not preclude an attempt at laparoscopy. While laparoscopic outcomes have steadily improved and laparoscopic cholecystectomy has been shown multiple times to be safe and feasible, conversion to an open operation should always remain an option, and it is not a failure. Conversion to open may be necessary if the patient is unable to tolerate pneumoperitoneum, a complication occurs that cannot be fixed laparoscopically, important anatomic structures cannot be clearly identified, or when no progress is made over a set period of time. In the elective setting, conversion to an open procedure is needed in about 5% of patients. Emergent procedures or patients with complicated gallstone disease can be more challenging, and the incidence of conversion has been reported to be between 10% and 30%. The possibility of conversion to open should always be discussed with the patient preoperatively.

Serious complications of cholecystectomy are rare. The mortality rate for laparoscopic cholecystectomy is about 0.1%. Wound infection and cardiopulmonary complication rates are considerably lower following laparoscopic cholecystectomy than are those for an open procedure. While laparoscopic cholecystectomy has historically been associated with a higher rate of injury to the bile ducts than the open approach, modern data appears to show this trend disappearing as familiarity with laparoscopic techniques and technologies have improved.

Patients undergoing cholecystectomy should have a complete blood count and liver function tests preoperatively. Prophylaxis against deep venous thrombosis with either low molecular weight heparin or compression stockings is indicated.
The patient should be instructed to empty their bladder before coming to the operating room to avoid the need for urinary catheterization. An orogastric tube can be placed if the stomach is distended with gas, but it is generally removed at the end of the operation.

**Laparoscopic Cholecystectomy.** The patient is typically positioned supine with the operating surgeon standing at the patient’s left side. Split-leg positioning with the surgeon standing between the patient’s legs can also provide ergonomic access to the right upper quadrant. Tucking one arm can be helpful if a cholangiogram is planned to allow easier maneuvering of the fluoroscopy machine around the patient. Pneumoperitoneum is established with carbon dioxide gas, either with an open technique (Hasson), optical viewing trocar, or closed-needle technique (Veress). Typical access is at the supraumbilical region, though in the case of previous surgery or scars, alternate access sites should be considered. Once an adequate pneumoperitoneum is established, a 5- or 10-mm trocar is inserted through the supraumbilical incision, through which a 5- or 10-mm 30° laparoscope is introduced. Traditionally, three additional ports are then placed with a 10- or 12-mm port in the epigastrium, a 5-mm port in the right midclavicular line, and a 5-mm port in the right flank (Fig. 32-23). Additional ports may be placed as needed to aid with retraction in difficult cases.

Through the lateral-most port, the assistant uses a locking instrument to grasp the gallbladder fundus and retract it over the liver edge and upward towards the patient’s right shoulder. This will help visualize the body of the gallbladder and the hilar area. Exposure may be facilitated by placing the patient

---

**Figure 32-23.** Laparoscopic cholecystectomy. **A.** The trocar placement. **B.** The fundus has been grasped and retracted cephalad to expose the proximal gallbladder and the hepatoduodenal ligament. Another grasper retracts the gallbladder infundibulum posterolaterally to better expose the triangle of Calot (hepatocystic triangle bound by the common hepatic duct, cystic duct, and liver margin). **C.** Intraoperative photo of the critical view of safety. The hepatocystic triangle has been cleared of fat and fibrous tissue, the lower one-third of the gallbladder is separated from the liver to expose the cystic plate, and two and only two structures are seen entering the gallbladder. **D.** A clip is being placed on the cystic duct–gallbladder junction. **E.** A small opening has been made in the cystic duct, and a cholangiogram catheter is being inserted. **F.** Additional clips have been placed, the cystic duct has been divided, and the cystic artery is being divided.
in reverse Trendelenburg position with slight tilting of the table to bring the right side up. Through the midclavicular port, the surgeon uses a grasper in the left hand to retract the gallbladder infundibulum laterally and expose the neck of the gallbladder and hepatoduodenal ligament. It may be necessary to take down any adhesions between the omentum, duodenum, or colon to the gallbladder in order to reach the infundibulum. The majority of the dissection can then be performed with the right hand through the epigastric port, utilizing a combination of electrocautery and sharp and blunt dissection.

Dissection starts at the infundibulum of the gallbladder, just above the takeoff of the cystic duct. The peritoneum, fat, and loose areolar tissue around the gallbladder and the cystic duct–gallbladder junction is dissected off and reflected inferiorly toward the bile duct. This is continued until the gallbladder neck and the proximal cystic duct are clearly identified. The next step is the identification of the cystic artery, which usually runs parallel to and somewhat behind the cystic duct, and often lies behind a prominent lymph node (Lund’s node, often called Calot’s node). At this point, a critical view of safety should be obtained. This requires that the hepatocystic triangle is cleared of fat and fibrous tissue, the lower third of the gallbladder is separated from the liver to expose the cystic plate, and two and only two structures (cystic duct and cystic artery) are going into the gallbladder (see Fig. 32-19). At this point, an intraoperative cholangiogram can be performed if indicated (see “Intraoperative Cholangiogram” section).

With a critical view of safety obtained, the cystic duct and artery are clipped with two clips at the base and one clip on the gallbladder side. They can then be safely divided. Sometimes, a very dilated cystic duct may be too large for clips. Such ducts can be successfully managed by ligation with an endoloop, laparoscopic stapler, or suture closure. Finally, the gallbladder is dissected off the liver bed using electrocautery while watching for potential abnormal posterior branches of ducts or arteries. Before the gallbladder is completely removed from the liver edge, it can be used as a retractor for a final evaluation of the operative field. The surgeon should be sure to evaluate for bleeding points or bile staining, and confirm placement of the clips on the cystic duct and artery. The gallbladder is then divided from its final attachments and removed either through the epigastric or umbilical incision, often with the aid of a retrieval bag. The fascial defect and skin incision may need to be enlarged in order to remove the specimen, particularly if the stones are large or the gallbladder is very inflamed. Any bile or blood that has accumulated during the procedure should be cleaned away, and if stones were spilled, they should be retrieved and removed. If the gallbladder was severely inflamed or gangrenous, or if any bile or blood is expected to accumulate, a closed-suction drain can be placed through one of the 5-mm ports and left underneath the right liver lobe close to the gallbladder fossa, though this is not routinely required.

Open Cholecystectomy. The same surgical principles apply for laparoscopic and open cholecystectomies. Open cholecystectomy has become an uncommon procedure, usually performed either as a conversion from laparoscopic cholecystectomy or as a second procedure in patients who require laparotomy for another reason. The approach can either be through a midline laparotomy, or more commonly through a right subcostal incision. The gallbladder is dissected free from the liver bed, usually starting at the fundus and working proximally toward the hepatocystic triangle. Once the cystic artery and cystic duct have been dissected and clearly identified, they are ligated and divided, and the gallbladder is removed. In particularly difficult cases, in which the gallbladder is partially obliterated or ductal or arterial anatomy cannot be identified, a partial cholecystectomy may be performed. This includes removal of as much gallbladder mucosa as possible and attempted closure of the cystic duct stump with wide drainage of the area.

Intraoperative Cholangiogram. Intraoperative cholangiogram is an optional but valuable tool for evaluating the extrahepatic bile ducts, identifying common bile duct stones, or clarifying aberrant ductal anatomy. The use of routine versus selective cholangiography remains a topic of debate with a lack of definitive evidence on either side. However, routine intraoperative cholangiography will detect stones in approximately 7% of patients, and it assists with outlining anatomy and detecting injury. Selective intraoperative cholangiogram should be performed when the patient has a history of abnormal liver function tests, pancreatitis, jaundice, a large duct and small stones, a dilated duct on preoperative ultrasonography, or if preoperative endoscopic cholangiography for the aforementioned reasons was unsuccessful. Although there is no consensus recommendation on the use of routine versus selective cholangiography, all surgeons performing cholecystectomy should be familiar with the procedure. If a cholangiogram is to be performed, a clip is placed on the proximal cystic duct, and a small incision is made on its anterior surface, just inferior to the clip. A cholangiogram catheter is passed into the cystic duct and secured with a clamp or clip. The fluoroscopy machine is then positioned over the patient and a cholangiogram performed by injection of contrast through the cholangiocatheter during live fluoroscopic dynamic imaging. An ideal cholangiogram includes filling of the right and left hepatic ducts, emptying into the duodenum, and no visualized filling defects (Fig. 32-24). Care must be taken not to introduce air bubbles into the system during contrast injection as these will appear as filling defects on the cholangiogram images. If no contrast is visualized in the duodenum, a dose of glucagon can be utilized to relax the sphincter of Oddi and facilitate contrast flow. Once the cholangiogram is completed, the catheter is removed. Laparoscopic ultrasonography is as accurate as intraoperative cholangiography in detecting common bile duct stones, and it is less invasive. However, it requires more skill to perform and interpret and is not always readily available.

Common Bile Duct Exploration

Common bile duct stones that are detected pre- or intraoperatively may be managed with common bile duct exploration (CBDE) at the time of the cholecystectomy. While preoperative ERCP is also an appropriate option for known bile duct stones, laparoscopic CBDE can be used as a primary approach to choledocholithiasis safely and with good outcomes, even in higher risk populations such as the elderly. If stones in the duct are small, they may sometimes be simply flushed into the duodenum with saline irrigation via the cholangiography catheter. This can be facilitated by the administration of IV glucagon to relax the sphincter of Oddi. If irrigation is unsuccessful, several options exist to clear the duct, including fluoroscopic or endoscopic approaches.

With access to the cystic duct by a small ductotomy, a balloon catheter is used to dilate the cystic duct, and a wire basket can be passed down the common bile duct under fluoroscopic
guidance to catch and remove the stones (Fig. 32-25). Alternatively, endoscopic evaluation with a flexible choledoscope will allow for direct visualization and retrieval of the stones within the common duct. To do this, reliable catheter access must be obtained with an introducer sheath placed either through one of the laparoscopic ports or a new stab incision in the anterior abdominal wall. The cystic duct should first be dilated with a small balloon catheter to allow for passage of the introducer and scope and for effective retrieval of larger stones. Once the scope is within the common bile duct, irrigation is used to distend the lumen. Stones may then be caught in a wire basket under direct visualization or simply pushed into the duodenum. Once the common bile duct has been cleared of stones, the cystic duct is ligated below the level of the ductotomy and divided, and the cholecystectomy is completed.

While the cystic duct is the preferred route of access for common bile duct exploration, occasionally an incision into the common bile duct itself (choledochotomy) is necessary. The flexible choledochoscope is then passed into the duct for visualization and clearance of stones. The choledochotomy can be closed primarily if the duct is very large, or over a T-tube. If available, common bile duct exploration can be highly advantageous as it provides the opportunity to treat the entirety of the disease in a single event, rather than subjecting patients to multiple procedures. However, the procedure can be technically challenging to perform and requires the availability of the proper equipment and surgical expertise.

Common Bile Duct Drainage Procedures
In very rare cases in which stones or obstructions cannot be cleared by either ERCP with sphincterotomy or CBDE, and the patient is suffering clinical effects from their common duct stones, an additional choledochal drainage procedure may become necessary. In the case of an open operation, transduodenal sphincterotomy can be attempted by incising the duodenum transversely and cutting the sphincter of Oddi at the 11 o’clock position, taking care to avoid injury to the pancreatic duct. The impacted stones can then be manually removed or simply allowed to pass through the sphincterotomy.

Bypass procedures can also be used to restore continuity of bile flow in the setting of irretrievable impacted stones. For short distance bypasses, a Cholecodochoduodenostomy is performed by mobilizing the second part of the duodenum (a Kocher maneuver) and anastomosing it side to side with the common bile duct (Fig. 32-26A-C). If the distance is too great to safely complete a cholecodochoduodenostomy without tension, a choledochojejunostomy can be done by bringing up a roughly 45-cm limb of jejunum and anastomosing it end to side to the common bile duct (Fig. 32-26D-E). If the entirety of the extrahepatic biliary tree must be bypassed, hepaticojejunostomy allows for drainage of the hepatic ducts directly a loop of jejunum (Fig. 32-26F-G). These choledochal drainage procedures can also be used to manage common bile duct strictures or as a palliative procedure for malignant obstruction in the peripancreatic region.

OTHER BENIGN DISEASES AND LESIONS
Biliary Dyskinesia and Sphincter of Oddi Dysfunction
Biliary dyskinesia is an umbrella term that refers to disorders affecting the normal motility and function of the gallbladder and sphincter of Oddi. These disorders are becoming increasingly recognized as improvements in imaging allow for more detailed evaluations of biliary tract function. Patients with biliary dyskinesia may present with typical biliary type symptoms, but without evidence of stones or sludge on abdominal imaging.
A decreased gallbladder ejection fraction on HIDA scanning (EF <35%) is considered diagnostic of biliary dyskinesia. In these patients, studies suggest that symptoms will be improved or resolved by cholecystectomy in up to 90% of cases.\(^\text{62}\)

Sphincter of Oddi dysfunction can occur as a primary presentation of episodic biliary type pain with abnormal liver function tests or as recurrent biliary type pain after cholecystectomy. More severe cases may present with recurrent jaundice or pancreatitis. If other causes are ruled out, such as retained stones, strictures or periampullary tumors, a stenotic or dyskinetic sphincter of Oddi should be suspected. A benign stenosis of the outlet of the common bile duct is usually associated with inflammation, fibrosis, or muscular hypertrophy. The pathogenesis is unclear, but trauma from the passage of stones, sphincter motility disorders, and congenital anomalies have been suggested. A dilated common bile duct that is difficult to cannulate during ERCP or delayed emptying of contrast from the biliary tree after ERCP are useful diagnostic features. Ampullary manometry and specific provocation tests are available in specialized units to aid in the diagnosis. Once identified, sphincterotomy will typically yield good results.\(^\text{63}\)

**Acalculous Cholecystitis**

Acalculous cholecystitis is an acute inflammation of the gallbladder that occurs in the absence of gallstones. It is a rare entity that typically develops in critically ill patients in the intensive care unit.\(^\text{64}\) Patients on parenteral nutrition, with extensive burns, sepsis, major operations, multiple trauma, or prolonged illness with multiple organ system failure are at risk for developing acalculous cholecystitis. The cause is unknown, but gallbladder distention, bile stasis, and ischemia have been implicated as causative factors. After resection, pathologic examination of the gallbladder wall after an episode of acalculous cholecystitis reveals edema of the serosa and muscular layers, with patchy thrombosis of arterioles and venules.\(^\text{65}\)

The ability to recognize the symptoms and signs of acalculous cholecystitis can depend on the condition and mental status of the patient, but acalculous cholecystitis can be similar to acute calculous cholecystitis, with right upper quadrant pain and tenderness, fever, and leukocytosis. In the sedated or unconscious patient, the clinical features are often masked, but fever and elevated WBC count, as well as elevation of alkaline phosphatase and bilirubin, are indications for
Figure 32-26. Biliary enteric anastomoses. There are three types. I. Choledochoduodenostomy. A. The distal common bile duct is opened longitudinally, as is the duodenum. B. Interrupted sutures are placed between the common bile duct and the duodenum. C. Completed choledochoduodenostomy. II. Choledochojejunostomy. D. The common bile duct and small bowel are divided. E. A limb of jejunum is brought up in a Roux-en-Y configuration and anastomosed to the bile duct. III. Hepaticojejunostomy. F. The entire extrahepatic biliary tree has been resected and the reconstruction completed with a Roux-en-Y limb of jejunum. G. Percutaneous transhepatic stents are placed across hepaticojejunostomy (optional).
further investigation. Ultrasonography is usually the diagnostic test of choice, as it can be done bedside in the intensive care unit. It can demonstrate the distended gallbladder with thickened wall, biliary sludge, pericholecystic fluid, and the presence or absence of abscess formation. CT scanning can aid in the diagnosis of acalculous cholecystitis and additionally allows a more general evaluation of the abdomen and chest to rule out other sources of infection. A HIDA scan can also be useful if it shows nonvisualization of the gallbladder, but it is less sensitive and can have higher false-positive rates in patients who are in a prolonged fasting state, on total parenteral nutrition, or have liver disease. Once the diagnosis is confirmed, acalculous cholecystitis requires urgent intervention as rapid deterioration can occur. This should include early broad-spectrum antibiotics and fluid resuscitation. If the patient is stable to undergo an abdominal operation, laparoscopic cholecystectomy is the most definitive treatment, and it can be safely performed even in the setting of severe acute inflammation. However, if patients are critically ill and unfit for surgery, percutaneous cholecystostomy is the best treatment choice (see Fig. 32-18). About 90% of patients will improve with a percutaneous cholecystostomy tube. Interval cholecystectomy can be discussed with the patient after they have recovered from their acute illness, but it is not strictly required in the absence of gallstone or other identified gallbladder pathology.

**Choledochal (Biliary) Cysts**

Choledochal cysts are congenital cystic dilatations of the extrahepatic and/or intrahepatic biliary tree. They are rare, with an incidence of between 1:100,000 and 1:150,000 in populations of Western countries, but are more common in populations of Eastern countries occurring in as many as 1:1000 individuals. Choledochal cysts affect females three to eight times more often than males. Although frequently found in infancy or childhood, nearly one-half are diagnosed in adults. The cause is unknown, but it is believed that weakness of the bile duct wall and increased pressure secondary to partial biliary obstruction can contribute to biliary cyst formation. More than 90% of patients have an anomalous pancreaticobiliary duct junction, with the pancreatic duct joining the common bile duct outside the duodenal wall, creating a long common channel (>1.5 cm). This may allow free reflux of pancreatic secretions into the biliary tract, leading to inflammatory changes, increased biliary pressure, and cyst formation. The cysts are lined with cuboidal epithelium and can vary in size from small dilations to giant cystic masses. The typical clinical triad of biliary cysts includes abdominal pain, jaundice, and a palpable mass, though this constellation is seen in less than one-half of patients. Adults may present with cholangitis. Blood tests will often be normal though elevations of transaminases can be seen in cases of infection or obstruction. Ultrasonography or CT scanning will confirm the diagnosis, but ERCP or MRCP are essential to formally assess the biliary anatomy and to plan the appropriate surgical treatment. The risk of cholangiocarcinoma in patients with choledochal cysts is 20- to 30-fold higher than in the general population and varies with the patient’s age and type of cyst. For this reason, excision is recommended whenever possible when high-risk choledochal cysts are diagnosed.

Choledochal cysts are classified into five types depending on the location and structure of the cysts. The subcategories of choledochal cysts are defined in Fig. 32-27. Type I cysts (fusiform CBD dilations) are the most common form, accounting for approximately 50% of cases, and have the highest risk of malignancy (>60%). For types I and II (saccular diverticula of the common bile duct), excision of the cystic dilations in the extrahepatic biliary tree, including cholecystectomy, with either simple cyst excision or duct resection with Roux-en-Y hepaticojejunostomy is ideal. Type III cysts (intraduodenal) create a treatment challenge as full resection would require pancreaticoduodenectomy. Given that type III cyst are associated with the lowest malignancy risk of any choledochal cyst (~2%), sphincterotomy and surveillance is generally recommended over formal excision. In Type IV (multiple cysts), excision of all cystic tissue and reconstruction is again recommended. For type IVa, which is characterized by multiple cysts with intrahepatic involvement, additional segmental resection of the liver may be required if intrahepatic stones, strictures, or abscesses are present. Type V choledochal cysts (Caroli disease) are very rare and account for less than 1% of patients with choledochal cysts. These cysts are multiple and can affect the entire liver. In advanced stages, this may result in cirrhosis and liver failure necessitating liver transplantation.

**Primary Sclerosing Cholangitis**

Primary sclerosing cholangitis (PSC) is an uncommon disease characterized by inflammatory strictures involving the intrahepatic and extrahepatic biliary tree. It is a progressive disease that eventually results in secondary biliary cirrhosis. Sometimes, biliary strictures are clearly secondary to bile duct stones, acute cholangitis, previous biliary surgery, or toxic agents, and are termed secondary sclerosing cholangitis. However, primary sclerosing cholangitis is a disease entity of its own, with no clear attributing cause. Autoimmune reaction, chronic low-grade bacterial or viral infection, toxic reaction, and genetic factors have all been suggested to play a role in its pathogenesis. PSC is commonly associated with other autoimmune diseases including ulcerative colitis in about two-thirds of patients, Riedel’s thyroiditis, and retroperitoneal fibrosis. The human leukocyte antigen haplotypes HLA-B8, DR3, DQ2, and DRw52A, commonly found in patients with autoimmune diseases, also are more frequently seen in patients with primary sclerosing cholangitis than in controls. The mean age of presentation for PSC is 30 to 45 years, and men are affected twice as often as women. Most patients are symptomatic when diagnosed, and may complain of intermittent jaundice, fatigue, weight loss, pruritus, or abdominal pain. Initial presentation with acute cholangitis is rare without preceding biliary tract intervention or surgery. A minority of patients are diagnosed incidentally by elevated liver function tests, particular when found in a patient with ulcerative colitis. While the clinical presentation and laboratory results may suggest the PSC, ERCP revealing multiple dilatations and strictures (beading) of the intra- and extrahepatic biliary tree confirms the diagnosis. The hepatic duct bifurcation is often the most severely affected segment. A liver biopsy may not be diagnostic, but it is important to determine the degree of hepatic fibrosis and the presence of cirrhosis.

The clinical course in sclerosing cholangitis is highly variable, but cyclic remissions and exacerbations are typical. Some patients will remain asymptomatic for years, while others progress rapidly with the obliterative inflammatory changes leading to secondary biliary cirrhosis and liver failure. In patients with associated ulcerative colitis, the course of each disease seems independent of the other and colectomy has no effect on the
course of primary sclerosing cholangitis. Of the patients with sclerosing cholangitis, 10% to 15% will develop cholangiocarcinoma, which can present at any time during the disease process and does not necessarily correlate with the extent of the sclerosing cholangitis or the development of liver failure. Cholangiocarcinoma in the setting of PSC frequently follows an aggressive course. Patients need to be followed by serial ERCP and liver biopsies to evaluate for the development of complications such as strictures, cancers, or cirrhosis.

There is no known curative treatment for primary sclerosing cholangitis and medical management is largely supportive. Corticosteroids, immunosuppressants, ursodeoxycholic acid, and antibiotics have been attempted with disappointing results. If biliary strictures occur, they can be dilated and stented either endoscopically or percutaneously. These measures have given short-term improvements in symptoms and serum bilirubin levels but provide long-term results in less than half of patients. Surgical management with resection of the extrahepatic biliary tree and hepaticojejunostomy has produced reasonable results in patients with extrahepatic and bifurcation strictures, but without cirrhosis or significant hepatic fibrosis. In patients with primary sclerosing cholangitis and advanced liver disease, liver transplantation is the only option. It offers excellent results, with overall 5-year survival as high as 85%. Unfortunately, recurrence of PSC can occur in 10% to 20% of patients and may require retransplantation.

**Bile Duct Strictures**

Benign bile duct strictures can have numerous causes. However, the vast majority are related to operative injury, most commonly during cholecystectomy. Other causes include fibrosis due to chronic pancreatitis, common bile duct stones, acute cholangitis, biliary obstruction due to cholecystolithiasis (Mirizzi’s syndrome), sclerosing cholangitis, cholangiohepatitis, and strictures of a biliary-enteric anastomosis. Bile duct strictures that go unrecognized or are improperly managed can lead to severe complications such as recurrent cholangitis, secondary biliary cirrhosis, and portal hypertension.

Bile duct strictures most commonly result in recurrent episodes of cholangitis but may present with isolated jaundice without infection. Liver function tests usually show evidence of cholestasis with elevations of bilirubin and alkaline phosphatase. Imaging with ultrasound or CT can show dilated bile ducts proximal to the stricture, as well as provide information about the level of the stenosis. MRCP gives more detailed anatomic information about the location and the degree of dilatation. If the diagnosis remains in question, cholangiography (endoscopic or more rarely percutaneous) will outline the biliary tree, define the stricture and its location, and allow for therapeutic interventions (Fig. 32-28). The treatment of biliary strictures depends on the location and the cause of the stricture. Percutaneous or endoscopic dilatation and/or stent placement will provide good results in more than one half of
patients. For persistent or complex strictures, surgical resection and reconstruction with Roux-en-Y choledochojejunostomy or hepaticojejunostomy may be necessary and will result in good or excellent outcomes in 80% to 90% of patients.70 Choledochoduodenostomy may be a choice for strictures in the distal-most part of the common bile duct if a tension-free repair can be achieved.

**INJURY TO THE BILIARY TRACT**

**Gallbladder**

Injuries to the gallbladder itself are uncommon but can occur in the setting of penetrating trauma (gunshot or stab wounds) or medical procedures (liver biopsy or surgery). Nonpenetrating trauma to the gallbladder is extremely rare but can cause contusion, avulsion, laceration, rupture, or traumatic cholecystitis. Regardless of the etiology of gallbladder injury, the treatment of choice is cholecystectomy. The prognosis is typically good but depends on the extent of related injury, as damage to nearby organs is not uncommon.

**Extrahepatic Bile Ducts**

Rarely, penetrating trauma to the extrahepatic bile ducts does occur, and it is usually associated with trauma to other viscera. The vast majority of injuries to the extrahepatic biliary system, however, are iatrogenic, usually occurring during cholecystectomy. These injuries are among the most feared and litigated complications in surgery, and can result in significant morbidity.71,72 Biliary tract injury can also occur during common bile duct exploration, division or mobilization of the duodenum during gastrectomy, or dissection of the hepatic hilum during liver resections.

The incidence of bile duct injury during cholecystectomy is estimated to be relatively low (about 0.2%).73 While initial experience with laparoscopic cholecystectomy appeared to show a higher rate of injury to the bile ducts compared to the open approach, these trends appear to be disappearing as laparoscopic technology and familiarity with the techniques of the procedure have improved.53 A number of different factors are thought to be associated with bile duct injury during laparoscopic cholecystectomy. These include acute or chronic inflammation, obesity, anatomic variations, and surgical technique. Inadequate exposure or failure to correctly identify structures before ligating or dividing them are the most common causes of significant biliary injury (see “Anatomic Variants” section). Excessive cephalad retraction of the gallbladder may align the cystic duct with the common bile duct, and the latter may then be mistakenly clipped and divided. Careless use of electrocautery can lead to thermal injury. Dissection deep into the liver parenchyma may cause injury to intrahepatic ducts, and poor clip placement close to the hilar area or to structures not well visualized can result in a clip across a bile duct.74,75

Techniques to avoid injury to the bile ducts during cholecystectomy are important to understand. The use of an angled, 30° or 45° laparoscope instead of an end-viewing camera will help visualize the anatomic structures, in particular those around the triangle of Calot. An angled scope also will aid in the proper placement of clips. The routine use of intraoperative cholangiography during every cholecystectomy as a method to prevent bile duct injury remains controversial.55 Nonetheless, the frequency of bile duct injuries is cut by 50% when an intraoperative cholangiogram is performed. Critical to the successful use of cholangiography is accurate interpretation of the imaging. It is important to check that the whole biliary system fills with contrast, including both major ducts on the right and the left hepatic duct, and that there is no extravasation of contrast. While routine use may reduce or limit the extent of injury, or help identify it early, it does not seem to prevent it entirely.76 No consensus recommendation exists on the use of selective versus routine cholangiography.

Perhaps the most universally agreed upon method for mitigating the risk of bile duct injury during laparoscopic cholecystectomy is obtaining the critical view of safety. This requires that the hepatocystic triangle is dissected free of fat and fibrous tissue, the lower third of the gallbladder is separated from the cystic plate, and there are two and only two structures running into the gallbladder, the cystic duct, and the cystic artery (see Fig. 32-23).54 Newer technologies such as fluorescence cholangiography to help identify biliary anatomy intraoperatively have shown promising early results, though large-scale applications remain to be seen.77

**Diagnosis.** Only about 25% of major bile duct injuries (common bile duct or hepatic duct) are recognized at the time of surgery. In these cases, intraoperative bile leakage, recognition of the correct anatomy, or an abnormal cholangiogram led to the diagnosis of a bile duct injury. In those that go unrecognized at the time of surgery, more than half will re-present within the first month postoperatively, though some can present months or years later with strictures, cholangitis, or cirrhosis from a remote bile duct injury.
Bile duct injuries typically result in either leaks or obstructions related to strictures. Bile leak, most commonly from the cystic duct stump, a transected aberrant right hepatic duct, or a lateral injury to the main bile duct, usually presents with abdominal pain, fever, and a mild elevation of liver function tests. If a drain was placed at the time of surgery, bilious fluid may be seen. A CT scan or ultrasound can show either a fluid collection in the gallbladder fossa (biloma), or free fluid ( bile) in the peritoneum (Fig. 32-29A). ERCP (Fig. 32-29B) or HIDA scan can be utilized to better localize the site of the bile leak.

Obstruction or stricture should be suspected in patients with progressive elevations of liver function tests or jaundice after cholecystectomy. CT scan or ultrasound can demonstrate the dilated part of the biliary tree, and may identify the level of the bile duct obstruction. MRI cholangiography, if available, provides an excellent, noninvasive delineation of the biliary anatomy both proximal and distal to the injury. Endoscopic or percutaneous cholangiography may also be helpful to confirm the diagnosis, depending on the location and type of injury.

Management. The management of bile duct injuries depends on the type, extent, and level of the injury, as well as the timing of its diagnosis. Initial proper treatment of bile duct injury can avoid the development of further complications or bile duct strictures. If an injury is discovered that exceeds the capacity of the available surgical expertise, the patient should be transferred to a tertiary care center. In these situations, drains should be placed in the surgical bed and antibiotics initiated. If a complete obstructive transection has occurred, it may also be necessary to place a percutaneous transhepatic drainage catheter to decompress the biliary tree prior to transfer.

If identified at the time of surgery, bile leaks from small bile ducts (<3 mm) or those draining a single hepatic segment can safely be ligated. If the injured duct is ≥4 mm, however, it is likely to drain multiple segments or an entire lobe and thus needs to be repaired or reimplanted. Minor injuries to the common bile duct or the common hepatic duct are traditionally managed with placement of a T-tube that has been modified by cutting the ends to allow for its placement in and removal from the bile duct (see Fig. 32-18). If the injury is small, the T-tube may be placed through it as if it were a formal choledochotomy.

In more extensive injuries, the T-tube should be placed through a separate choledochotomy and the injury closed over the T-tube end to minimize the risk of subsequent stricture formation.

Major bile duct injuries identified intraoperatively such as complete transection of the common hepatic or common bile duct are best managed at the time of injury. In many of these major injuries, the bile duct has not only been transected, but a variable length of the duct may have been removed with the surgical specimen. This injury usually requires reconstruction with a biliary-enteric anastomosis, and is best performed as soon as possible following the injury. If there is no or minimal loss of ductal length, a duct-to-duct repair may be done over a T-tube that is placed through a separate incision. In any repair that is chosen, it is critical to perform a tension-free anastomosis to minimize the high risk of postoperative stricture formation.

Bile leaks identified postoperatively can usually be managed with percutaneous drainage of intra-abdominal fluid collections followed by endoscopic biliary stenting. With most leaks, regardless of the location, stenting of the common bile duct will provide a low resistance route for bile flow into the duodenum, decreasing flow through the leak and allowing it to heal. This is particularly effective for leaks from the cystic duct stump. Rarely, surgery is required to repair a large leak if endoscopic interventions have failed or peritonitis is present.

Major bile duct injuries diagnosed in the later postoperative period may not be amenable to immediate reconstruction due to acute inflammation. They may need to be managed with transhepatic biliary catheter placement for biliary decompression as well as percutaneous drainage of intra-abdominal bile collections, if any. When the acute inflammation has resolved 6 to 8 weeks later, operative repair is performed.

Patients with bile duct stricture from an injury or as a sequela of previous repair usually present with either progressive elevation of liver function tests or cholangitis. The initial management usually includes endoscopic attempts at dilation or stenting. Balloon dilatation of a stricture usually requires multiple procedures and rarely provides long-term relief. Self-expanding metal or plastic stents can provide temporary or, in the high-risk patient, permanent drainage of the biliary tree. If the stricture is unable to be addressed endoscopically,
percunaneous transhepatic biliary drainage catheter placement may be necessary for decompression, and to define the anatomy, location and extent of the damage. Definitive treatment of refractory biliary strictures entails resection of the affected segment and reconstruction with a biliary-enteric anastomosis.

Outcome. Good results can be expected in the majority of patients with bile duct injuries, with the best results coming when the injury is recognized immediately and repaired by an experienced biliary tract surgeon. The perioperative mortality rate is reported to be less than 10%, but common morbidities associated with bile duct repairs include cholangitis, external biliary fistula, bile leak, subhepatic and subphrenic abscesses, and hemobilia. Restenosis of a biliary enteric anastomosis occurs in about 10% of patients, and typically presents within 2 years, but can manifest up to 20 years after the initial procedure. In general, treatment of proximal strictures is associated with a lower success rate than distal ones. The worst results are seen in patients with many operative revisions and in those who have evidence of liver failure or portal hypertension. However, previous repair does not preclude a successful outcome, particularly in patients with good liver function. In the most severe cases, patients with refractory strictures and deteriorating liver function may become candidates for liver transplant.

TUMORS

Carcinoma of the Gallbladder

Cancer of the gallbladder is a rare malignancy that occurs predominantly in the elderly. It is an aggressive tumor, with a poor prognosis that is usually not diagnosed until it has become advanced and is causing symptoms. The median survival for gallbladder cancer is around 6 months with a reported 5-year survival rate of 5%. In a minority of cases, early cancers are identified incidentally following cholecystectomy for cholelithiasis, in which case, 5-year survival is over 80%.

Incidence. Gallbladder cancer is the sixth most common GI malignancy in Western countries. It accounts for 2% to 4% of all malignant GI tumors, with about 4000 new cases diagnosed annually in the United States. It is two to six times more common in females than males, and the peak incidence is in the seventh decade of life. Its occurrence in random autopsy series is about 0.4%, but 0.3% to 3% of patients undergoing cholecystectomy for gallstone disease are found incidentally to have gallbladder cancer.

There are also significant ethnic variations in the incidence of gallbladder cancer, with rates being particularly high in native populations of the United States, Mexico, and Chile. The overall incidence of gallbladder cancer in the United States is approximately 1.5 cases per 100,000 residents. For Native American females with gallstones, the incidence is around 7.1 per 100,000. For women in the native populations of Chile, gallbladder cancer occurs in 27.3 per 100,000 individuals. Asian populations, particularly those of Korean descent, are also at increased risk of developing gallbladder cancer.

Etiology. The pathogenesis of gallbladder cancer has not been fully defined but is likely related to a combination of chronic inflammation, infection, genetics, and environmental exposures such as heavy metals and tobacco. Cholelithiasis is the most important risk factor for gallbladder carcinoma, and up to 85% of patients with carcinoma of the gallbladder have gallstones. However, <3% of patients with gallstones have gallbladder cancer, and the 20-year risk of developing cancer remains low; <0.5% for the overall population and 1.5% for high-risk groups. Larger stones (>3 cm) are associated with a 10-fold increased risk of cancer. The risk of developing cancer of the gallbladder is higher in patients with symptomatic than asymptomatic gallstones, and it is more commonly seen in the setting of cholesterol stones.

Polyloid lesions of the gallbladder, which are present in as many as 5% of adults, are also associated with increased risk of cancer. This is particularly true for polyps measuring >10 mm, which carry a 25% risk of malignancy. Solitary or sessile polyps, or those showing rapid growth on serial imaging, particularly if in the presence of gallstones or age >50 are also concerning for malignancy. When such findings are identified, the patient should have their gallbladder removed, even if they are asymptomatic. Polyps that are not removed should be monitored on serial imaging. The finding of a “Porcelain” gallbladder, or dense circumferential calcifications of the gallbladder wall, is associated with an approximately 10% risk of gallbladder carcinoma. While this condition was previously considered to be an absolute indication for cholecystectomy, more recent studies suggest that given the low rate of malignancy, observation is safe and acceptable. Nevertheless, resection remains a reasonable option, particularly if the patient is symptomatic, and the decision should ultimately be made only after discussing risks and benefits of each approach with the patient.

Patients with certain types of choledochal cysts also have an increased risk of developing cancer anywhere in the biliary tree, but the incidence is highest in the gallbladder and cholecystectomy should be performed with any surgical intervention on the choledochal cyst. Primary sclerosing cholangitis, anomalous pancreaticobiliary duct junction, and exposure to carcinogens (azotoluene, nitrosamines) also are associated with cancer of the gallbladder, and screening with abdominal ultrasound should be considered in these patients.

Pathology. Between 80% and 90% of gallbladder cancers are adenocarcinomas. Squamous cell, adenosquamous, oat cell, and other anaplastic lesions rarely occur. The histologic subtypes of gallbladder adenocarcinomas include papillary, nodular, and tubular. Less than 10% are of the papillary type, but these are associated with an overall better outcome, as they are most commonly diagnosed while localized to the gallbladder. Cancer of the gallbladder can spread through lymphatics, venous drainage, or by direct invasion into the liver parenchyma. Lymphatic flow from the gallbladder drains first to the cystic duct node (Lund’s node or Calot’s node), then pericholedochal and hilar nodes, and finally to the peripancreatic, duodenal, perportal, celiac, and superior mesenteric artery nodes. The gallbladder veins drain directly into the adjacent liver, usually segments Vb and V, where tumor invasion is common (Fig. 32-30). The gallbladder wall differs histologically from the intestines in that it lacks a muscularis mucosa and submucosa. Lymphatics are present in the subserosal layer only. Therefore, cancers that have not grown through the muscular layer have minimal risk of nodal disease. Unfortunately, only a small portion of gallbladder cancers (10–25%) are identified while they are still localized to the gallbladder. The majority will already have nodal involvement, extension into adjacent liver, or distant metastasis at the time of diagnosis.

Clinical Manifestations and Diagnosis. Signs and symptoms of carcinoma of the gallbladder are generally indistinguishable from those associated with cholecystitis and cholelithiasis, and this can lead to delays in treatment or misdiagnosis. These include abdominal discomfort, right upper quadrant pain, nausea, and vomiting. Jaundice, weight loss, anorexia, ascites,
and abdominal masses are less common presenting symptoms. Common misdiagnoses include chronic cholecystitis, acute cholecystitis, choledocholithiasis, hydrops of the gallbladder, and pancreatic cancer. Laboratory findings, if abnormal, are most often consistent with biliary obstruction. Ultrasonography often reveals a thickened, irregular gallbladder wall (>3mm) with hypervascularity or a mass replacing the gallbladder. It may also visualize tumor invasion of the liver, lymphadenopathy, or a dilated biliary tree. The sensitivity of ultrasonography in detecting gallbladder cancer ranges from 70% to 100%. A CT scan may be helpful in identifying a gallbladder mass and evaluating for nodal spread or local invasion into adjacent organs or vasculature. If questions about local invasion remain, MRCP allows for complete assessment of biliary, vascular, nodal, hepatic, and adjacent organ involvement.\(^6\) Endoscopic ultrasound (EUS) can be a useful tool in staging and evaluating for local invasion, as well as obtaining tissue diagnosis through fine needle aspiration (FNA). Tissue diagnosis can also be obtained by CT or ultrasound-guided biopsy of the tumor, though this is not required prior to cholecystectomy if the tumor appears resectable on imaging. In jaundiced patients, a percutaneous transhepatic cholangiogram may be helpful to delineate the extent of biliary tree involvement. The role of PET scanning in gallbladder cancer is yet to be fully defined but can be utilized in both staging and surveillance.

**Treatment.** Surgical resection remains the only curative option for gallbladder cancer. While most patients are unresectable at the time of diagnosis, if preoperative staging suggests a potentially resectable tumor, exploration for tissue diagnosis, formal pathologic staging, and possible curative resection are warranted.

Tumors limited to the lamina propria or muscular layer of the gallbladder (T1) are usually identified incidentally, after laparoscopic cholecystectomy for gallstone disease. There is near universal agreement that simple laparoscopic cholecystectomy is an adequate treatment for T1 lesions and results in a near 100% overall 5-year survival rate. When the tumor invades the perimuscular connective tissue without extension beyond the serosa or into the liver (T2 tumors), an extended cholecystectomy should be performed.\(^6\) This includes additional resection of liver segments IVb and V, as well as lymphadenectomy of the celiac and paraaortic lymph nodes. Given the extent of this operation, an open approach is standard. One-half of patients with T2 tumors are found to have nodal disease on pathologic examination, highlighting the importance of regional lymphadenectomy as part of surgery for T2 cancers.\(^6\) For tumors that grow beyond the serosa, or invade the liver or other adjacent organs (T3), there is a higher likelihood of intraperitoneal or distant spread. However, if no peritoneal or nodal involvement is found, complete tumor excision with an extended right hepatectomy and caudate lobectomy with lymphadenectomy must be performed for adequate tumor clearance. In addition, if a T2 or T3 tumor is identified incidentally after laparoscopic cholecystectomy, and the patient is returning to the OR for liver resection and lymphadenectomy, the previous laparoscopic port sites must also be excised due to the high risk of recurrence in these locations. T4 tumors are those that have grown into major blood vessels or two or more structures outside the liver, and they are typically considered unresectable.

Due to the high frequency of late diagnosis, palliative procedures for unresectable cancer, jaundice, or duodenal obstructions remain the most frequently performed surgery for gallbladder cancers. Today, patients with obstructive jaundice can frequently be managed with either endoscopic or percutaneously placed biliary stents. Various regimens of neoadjuvant, adjuvant, and definitive chemoradiotherapy have been trialed in gallbladder cancer. Overall, benefits have been marginal, but treatment may improve survival time by several months. These therapies can be offered to patients in conjunction with resection for curative intent or as definitive therapy, but no standard recommendation exists for their use.\(^85-87\)

**Prognosis.** Most patients with gallbladder cancer have unresectable disease at the time of diagnosis. The overall 5-year survival rate of all patients with gallbladder cancer is <5%, with a median survival of 6 months.\(^87\) However, patients with T1 disease treated with cholecystectomy have an excellent prognosis (85–100% 5-year survival rate). The 5-year survival rate for T2 lesions treated with an extended cholecystectomy (liver segment IVb/V resection) and lymphadenectomy is >70% compared to 25% to 40% for T2 patients treated with simple cholecystectomy. Patients with advanced (T3 or T4) but resectable gallbladder cancer are reported to have 5-year survival rates of 20% to 50%, supporting aggressive resection in those patients who can tolerate surgery. The median survival for patients with distant metastasis at the time of presentation is only 1 to 3 months.

Recurrence after resection of gallbladder cancer occurs most commonly in the liver or in the celiac or retropancreatic nodes. The prognosis for recurrent disease is very poor, and the main goal of follow-up is to provide palliative care. The most common problems are pruritus and cholangitis associated with obstructive jaundice, bowel obstruction secondary to carcinoma, and pain. Death occurs most commonly secondary to biliary sepsis or liver failure.

---

**Figure 32-30.** Computed tomography scan of a patient with gallbladder cancer. The image shown is at the level of the liver hilum. The portal vein is bifurcating into the left and right portal branch. The tumor has invaded segment IV of the liver (arrowheads) and obstructed the common hepatic duct, resulting in intrahepatic ductal dilatation (arrows).
Cholangiocarcinoma
Cholangiocarcinoma is a rare tumor arising from the biliary epithelium and may occur anywhere along the biliary tree. About half are located at the hepatic duct bifurcation (Klatskin tumors), with 40% occurring more distally and 10% being intrahepatic. Surgical resection offers the only chance for cure, but unfortunately many patients have advanced disease at the time of diagnosis. Therefore, palliative procedures aimed to provide biliary drainage and prevent liver failure and cholangitis are often the only therapeutic possibilities available.

Incidence. The autopsy incidence of bile duct carcinoma is about 0.3%. The overall incidence of cholangiocarcinoma in the United States is about 1 per 100,000 people per year, with approximately 2500 new cases diagnosed annually. The disease has a slight male predominance and an average age of presentation between 50 and 70 years.

Etiology. Most cases of extrahepatic cholangiocarcinoma develop de novo with no identifiable risk factors. However, there is an increased risk of cholangiocarcinoma in patients with choledochal cysts, ulcerative colitis, hepatolithiasis, biliary-enteric anastomoses, hepatitis B and C, cirrhosis, biliary tract infections with Clonorchis (liver flukes), and chronic typhoid carriers. Exposure to dietary nitrosamines, Thorotrast, or dioxin also puts patients at increased risk for cholangiocarcinoma. Patients with primary sclerosing cholangitis have a 5% to 10% lifetime risk of developing cholangiocarcinoma with typical disease onset in their 40s. For this reason, these patients require regular screening. Features common to most risk factors include biliary stasis, bile duct stones, and infection.

Pathology. Over 95% of bile duct cancers are ductal adenocarcinomas with the vast majority occurring in the extrahepatic biliary tree. Morphologically, they are divided into nodular (the most common type), scirrhous, diffusely infiltrating, or papillary. Anatomically, they are divided into distal, perihilar or intrahepatic tumors. Intrahepatic cholangiocarcinomas make up approximately 10% of cases and are typically treated like hepatocellular carcinoma, with hepatectomy when possible and transplant when unresectable. About half of all cholangiocarcinomas are located in the perihilar region with the remaining 40% occurring more distally in the common bile duct.

Perihilar cholangiocarcinomas, also referred to as Klatskin tumors, are further classified based on anatomic location by the Bismuth-Corlette classification (Fig. 32-31). Type I tumors are confined to the common hepatic duct, but type II tumors involve the bifurcation without involvement of the secondary intrahepatic ducts. Type IIIa and IIIb tumors extend into the right and left secondary intrahepatic ducts, respectively. Type IV tumors involve both the right and left secondary intrahepatic ducts.

Clinical Manifestations and Diagnosis. Painless jaundice is the most common initial presentation in patients with cholangiocarcinoma. Pruritus, mild right upper quadrant pain, anorexia, fatigue, and weight loss may also be present. Cholangitis is the presenting symptom in about 10% of patients. Except for jaundice, physical examination is usually normal in patients with cholangiocarcinoma. Occasionally, asymptomatic patients are found to have cholangiocarcinoma while being evaluated for elevated liver function tests. Tumor markers, such as CA 125 and carcinoembryonic antigen (CEA), can be elevated in cholangiocarcinoma but tend to be nonspecific because they also increase in other GI and gynecologic malignancies. The tumor marker most commonly used to aid the diagnosis of cholangiocarcinoma is CA 19-9, which has a sensitivity of 79% and specificity of 98% if the serum value is >129 U/mL. However, mild elevations in CA 19-9 can also be seen in cholangitis, biliary obstruction, other GI and gynecologic neoplasms, and patients who lack the Lewis blood type antigen.

The initial workup for suspected cholangiocarcinoma includes abdominal imaging with ultrasound or CT scanning. Perihilar tumors will cause dilatation of the intrahepatic biliary tree, but a normal or collapsed gallbladder and extrahepatic bile ducts distal to the tumor. Distal bile duct cancer will lead to dilatation of the extra- and intrahepatic bile ducts as well as the gallbladder. Initial imaging is important to determine the level of obstruction and to rule out the presence of bile duct stones as the cause of the obstructive jaundice (Fig. 32-32). It is usually difficult to visualize the tumor itself on ultrasound, CT, or even MRCP, but any of these modalities can provide an outline of biliary anatomy, an estimate of the level of obstruction, evaluation of portal vein patency, and screening for nearby lymphadenopathy. Detailed evaluation of the biliary anatomy and tumor itself is best completed through cholangiography. ERCP is generally adequate, but in cases where the proximal extent of the tumor remains in question, PTC may be required to determine resectability.

Tissue diagnosis may be difficult to obtain. Current diagnostic techniques including fine-needle aspiration (percutaneous or endoscopic), and biliary brushings have been shown to have a low sensitivity in detecting malignancy, anywhere between 15% and 60%. Cholangioscopy with direct visualization and sampling of intraluminal masses may be able to improve diagnosis rates but is only available in specialized centers (see Fig. 32-10). Patients with potentially resectable disease should, therefore, be offered surgical exploration based on radiographic findings and clinical suspicion.
**Treatment.** Surgical excision is the only potentially curative treatment for cholangiocarcinoma. In the past one to two decades, improvements in surgical techniques have resulted in lower mortality and better outcomes for patients undergoing aggressive surgical excision for cholangiocarcinoma.\(^9\)

Despite improvements in ultrasonography, CT scanning, and MRI, more than one-half of patients who are explored are found to have peritoneal implants, nodal or hepatic metastasis, or locally advanced disease that precludes resection. Patients suspected of having resectable disease should first undergo diagnostic laparoscopy. Those who are found to have previously unidentified metastatic disease should undergo cholecystectomy and surgical bypass for biliary decompression.\(^3\)

For curative resection, the location and local extent of the tumor dictates the extent of the surgery required. Distal bile duct tumors are often resectable but may require pancreaticoduodenectomy (Whipple procedure). For patients with distal bile duct cancer found to be unresectable on surgical exploration, Roux-en-Y hepaticojunostomy, cholecystectomy, and gastrojejunostomy to prevent gastric outlet obstruction should be performed. Perihilar tumors involving the bifurcation or proximal common hepatic duct (Bismuth-Corlette type I or II) with no signs of vascular involvement are candidates for local tumor excision with portal lymphadenectomy. If the tumor involves the right or left hepatic duct (Bismuth-Corlette type IIIa or IIIb), right or left hepatic lobectomy, respectively, should also be performed. Frequently, resection of the adjacent caudate lobe is required because of direct extension into caudate biliary radicals or parenchyma.\(^9\) Type IV Klatskin tumors, those with more extensive involvement of both hepatic ducts and intrahepatic spread, are often considered unresectable or only treatable with liver transplantation.

The best outcomes in perihilar cholangiocarcinoma are seen in patients who undergo neoadjuvant chemoradiation followed by liver transplantation. However, there are very strict inclusion criteria for transplantation, and few patients qualify.\(^3\) Patients with primary sclerosing cholangitis who develop cholangiocarcinoma should be treated with liver transplant whenever possible.

Nonoperative biliary decompression can be performed for patients with unresectable disease on initial presentation. Endoscopic placement of expandable metal stents is often the preferred approach. For very proximal or intrahepatic tumors, percutaneous drainage catheters may be necessary to fully decompress the biliary tree (see Fig. 32-12). There is a significantly higher risk of cholangitis in patients with drainage catheters or stents compared to those with surgical bypasses. In addition, stent occlusion is not uncommon. Nevertheless, operative intervention is not warranted in patients with metastatic disease.\(^9\)

There is no proven role for adjuvant chemotherapy in the treatment of cholangiocarcinoma. Adjuvant radiation therapy has also not been shown to increase either quality of life or survival in resected patients. Patients with unresectable disease can be offered palliative chemotherapy, typically with gemcitabine and cisplatin, but the response rates are low (10–20%), and the survival benefit is marginal. The combination of radiation and chemotherapy may be more effective than either treatment alone for unresectable disease, but no data from randomized trials are available. Giving chemoradiation to these patients can be difficult because of the high incidence of cholangitis. External-beam radiation has not been shown to be an effective treatment for unresected disease. The use of interstitial (intraoperative) radiation, brachytherapy with iridium-192 via percutaneous or endoscopic stents, and combined interstitial and external-beam radiation for unresectable cholangiocarcinoma has been reported with some encouraging results. However, no randomized, prospective trials have been reported.\(^9\) Photodynamic therapy has been proposed as a palliative measure for patients with unresectable disease and

**Figure 32-32.** A. An endoscopic retrograde cholangiogram in a patient with cancer of the common hepatic duct (arrowheads). The common bile duct is of normal size, as is the cystic duct (arrow), but the proximal biliary tree is dilated. The gallbladder is not visualized because of tumor obstructing its neck. B. An ultrasound from the same patient showing dilated ducts and tumor obstructing the common hepatic duct (arrow). The walls of the bile ducts adjacent to the obstruction are thickened by tumor infiltration (arrowheads).
has been found to prolong survival and improve quality of life in patients with biliary stents.\textsuperscript{95,96}

**Prognosis.** Most patients with perihilar cholangiocarcinoma present with advanced, unresectable disease. Median survival in this population is between 5 and 8 months. The most common causes of death are hepatic failure and cholangitis. The overall 5-year survival rate for patients with resectable perihilar cholangiocarcinoma is between 10% and 30%, but for patients with negative margins, it may be as high as 40%. The operative mortality for perihilar cholangiocarcinoma is 6% to 8%. Patients with distal cholangiocarcinoma are more likely to have resectable disease and improved prognosis compared to perihilar cholangiocarcinoma. The overall 5-year survival rate for resectable distal disease is 30% to 50%, and the median survival is 32 to 38 months. Patients who receive liver transplantation for cholangiocarcinoma can experience 5-year disease free survival rates as high as 68%.

The greatest risk factors for recurrence after resection are the presence of positive margins and lymph node–positive tumors. Therapy for recurrent disease concentrates on palliation of symptoms and additional surgery is not recommended for patients with recurrent disease.

ANATOMY

The pancreas is perhaps the most unforgiving organ in the human body, leading most surgeons to avoid even palpating it unless necessary. Situated deep in the center of the abdomen, the pancreas is surrounded by numerous important structures and major blood vessels. Seemingly minor trauma to the pancreas can result in the release of pancreatic enzymes and cause life-threatening pancreatitis. Therefore, knowledge of the relationships of the pancreas to surrounding structures is critically important for all surgeons to ensure that pancreatic injury is avoided during abdominal surgery.

Gross Anatomy

The pancreas is a retroperitoneal organ that lies in an oblique position, sloping upward from the C-loop of the duodenum to the splenic hilum (Fig. 33-1). In an adult, the pancreas weighs 75 to 100 g and is about 15 to 20 cm long. The fact that the pancreas is situated so deeply in the abdomen and is sealed in the retroperitoneum explains the poorly localized and sometimes ill-defined nature with which pancreatic pathology presents. Patients with pancreatic cancer without bile duct obstruction usually present after months of vague upper abdominal discomfort, or no antecedent symptoms at all. Due to its retroperitoneal location, pain associated with pancreatitis often is characterized as penetrating through to the back.

Regions of the Pancreas

Surgeons typically describe the location of pathology within the pancreas in relation to four regions: the head, neck, body, and tail. The head of the pancreas is nestled in the C-loop of the duodenum and is posterior to the transverse mesocolon. Just posterior to the head of the pancreas lie the vena cava, the right renal artery, and both renal veins. The neck of the pancreas lies directly anterior to the portal vein. At the inferior border of the neck of the pancreas, the superior mesenteric vein joins the splenic vein and then continues toward the porta hepatis as the portal vein. The inferior mesenteric vein often joins the splenic vein near
Key Points

1. Incomplete fusion of the dorsal and ventral pancreatic ducts results in pancreas divisum, but a variety of ductal anomalies can be seen. Magnetic resonance cholangiopancreatography as well as endoscopic retrograde cholangiopancreatography can identify these ductal anomalies, and clarification of the ductal pattern of the pancreas is important before attempts at interventions.

2. The “replaced right hepatic artery” occurs in 15% of patients and needs to be identified preoperatively to prevent inadvertent injury with resulting hepatic necrosis. Anomalous hepatic arterial anatomy can result in hepatic ischemia during dissection of the porta hepatis as well. “Thin cut” multidetector computed tomographic images are usually able to identify the relevant arterial and venous patterns around the pancreas.

3. Regardless of the etiology, the management of the early phase of acute pancreatitis is critical to achieve a successful outcome. Aggressive fluid resuscitation and early enteral feeding both reduce the risk of complications. It is no longer considered appropriate to “rest the pancreas” if the patient can tolerate enteral nutrients.

4. Surgical intervention in acute pancreatitis is reserved for patients with infected collections or infected necrosis only, or to relieve an impacted gallstone in the ampulla if endoscopic or radiologic treatments are unsuccessful. Infection is usually confirmed by a pattern of air in the retroperitoneum on computed tomographic scan or by documentation of bacteria on Gram’s stain or culture from fine-needle aspiration of a suspected infected fluid collection. Fine-needle aspiration of suspicious fluid collections should not be converted to percutaneous drainage unless infection is confirmed and the consensus decision has been made that percutaneous drainage is appropriate for the individual patient.

5. The appearance of chronic pancreatitis on computed tomographic scan varies dramatically, and multiple diagnostic studies are usually needed to establish the extent of disease. Calcific pancreatitis is not a marker of alcoholic pancreatitis alone, and it rarely indicates autoimmune pancreatitis. Endoscopic ultrasound provides a better assessment of the disease than computed tomography and is useful to disclose indolent or unsuspected cancer, which can occur in up to 10% of patients.

6. The nidus of inflammation in chronic pancreatitis due to any cause is the head of the gland. Therefore, treatment approaches that address the disease in the head have the best long-term results. The Whipple procedure, the Beger procedure, and the Frey procedure, with or without longitudinal duct drainage, are the best surgical options, as all three approaches remove all or most of the disease in the head of the gland. Although the limited pancreatic procedures (Beger/Frey) have a lower initial rate of endocrine dysfunction, the long-term risk of diabetes is more related to the progression of the underlying disease than to the effects of operation. Level 1 studies confirm that the duodenum preserving options are associated with a lower immediate morbidity and mortality and therefore, in the absence of a mass or concerns about cancer, are better options than a Whipple procedure for chronic pancreatitis.

7. The precursor lesion that probably leads to most cases of ductal adenocarcinoma is the ductal epithelial hyperplasia/dysplasia process described by the pancreatic intraepithelial neoplasia classification system. Pancreatic intraepithelial neoplasia 2 and pancreatic intraepithelial neoplasia 3 lesions may be associated with other, nonspecific changes in pancreatic morphology seen on imaging studies, or they may only be seen histologically. Resection margins for pancreatic neoplasms should be examined for advanced pancreatic intraepithelial neoplasia stage patterns of ductal hyperplasia to ensure adequate resection status.

8. A low threshold for ordering a computed tomography scan with “pancreatic protocol” should be maintained for older adult patients with unexplained, persistent, although vague, abdominal pain. New-onset diabetes in an older adult patient, especially if combined with vague abdominal pain, should prompt a search for pancreatic cancer.

9. Intraductal papillary mucinous neoplasms are small macroscopic polypoid or plaque-like adenomas that develop in the main pancreatic duct or in side-branch ducts, and secrete mucus. They are often silent symptomatically but cause characteristic appearances of small cyst-like collections of mucus or diffuse dilatation of the main pancreatic duct with mucus. These premalignant lesions may be multifocal or single and can evolve into invasive adenocarcinoma in a similar pattern as with other adenomatous polypoid lesions of the gastrointestinal tract. They have been diagnosed with increasing frequency and account for more than one-third of pancreatic resections at some centers. Main-duct intraductal papillary mucinous neoplasms are an indication for resection; side-branch intraductal papillary mucinous neoplasms have a lower incidence of malignancy and are sometimes followed with serial imaging surveillance.
Figure 33-1. Pancreatic anatomy as seen on computed tomography. Knowledge of the relationship of the pancreas with surrounding structures is important to ensure that injury is avoided during abdominal surgery. IMV = inferior mesenteric vein; SMA = superior mesenteric artery; SMV = superior mesenteric vein.

Figure 33-2. Variations in portal venous anatomy. The superior mesenteric vein joins the splenic vein and then continues toward the porta hepatis as the portal vein. The inferior mesenteric vein often joins the splenic vein near its junction with the portal vein, but sometimes joins the superior mesenteric vein; or the three veins merge as a trifurcation to form the portal vein.
Pancreatic Duct Anatomy

An understanding of embryology is required to appreciate the common variations in pancreatic duct anatomy. The pancreas is formed by the fusion of a ventral and dorsal bud (Fig. 33-3). The duct from the smaller ventral bud, which arises from the hepatic diverticulum, connects directly to the common bile duct. The duct from the larger dorsal bud, which arises from the duodenum, drains directly into the duodenum. The duct of the ventral anlage becomes the duct of Wirsung, and the duct from the dorsal anlage becomes the duct of Santorini. With gut rotation, the ventral anlage rotates to the right and around the posterior side of the duodenum to fuse with the dorsal bud. The ventral anlage becomes the inferior portion of the pancreatic head and the uncinate process, while the dorsal anlage becomes the body and tail of the pancreas. The ducts from each anlage usually fuse together in the pancreatic head such that most of the pancreas drains through the duct of Wirsung, or main pancreatic duct, into the common channel formed from the bile duct and pancreatic duct. The length of the common channel is variable. In about one-third of patients, the bile duct and pancreatic duct remain distinct to the end of the papilla, the two ducts merge at the end of the papilla in another one-third, and in the remaining one-third, a true common channel is present for a distance of several millimeters. Commonly, the duct from the dorsal anlage, the duct of Santorini, persists as the lesser pancreatic duct, and sometimes drains directly into the duodenum through the lesser papilla just proximal to the major papilla. In approximately 30% of patients, the duct of Santorini ends as a blind accessory duct and does not empty into the duodenum. In 10% of patients, the ducts of Wirsung and Santorini fail to fuse. This results in the majority of the pancreas draining through the duct of Santorini and the lesser papilla, while the inferior portion of the pancreatic head and uncinate process drains through the duct of Wirsung and major papilla. This normal anatomic variant, which occurs in one out of 10 patients, is referred to as pancreas divisum (Fig. 33-3). In a minority of these patients, the minor papilla can be inadequate to handle the flow of pancreatic juices from the majority of the gland. This relative outflow obstruction can result in pancreatitis and is sometimes treated by sphincteroplasty of the minor papilla.

The main pancreatic duct is usually only 2 to 3 mm in diameter and runs midway between the superior and inferior borders of the pancreas, usually closer to the posterior than to the anterior surface. Pressure inside the pancreatic duct is about twice that in the common bile duct, which is thought to prevent reflux of bile into the pancreatic duct. The main pancreatic duct joins with the common bile duct and empties at the ampulla of Vater or major papilla, which is located on the medial aspect of the second portion of the duodenum. The muscle fibers around the ampulla form the sphincter of Oddi, which controls the flow of pancreatic and biliary secretions into the duodenum. Contraction and relaxation of the sphincter is regulated by complex neural and hormonal factors. When the accessory pancreatic duct or lesser duct drains into the duodenum, a lesser papilla can be identified approximately 2 cm proximal to the ampulla of Vater.

Figure 33-3. Embryology of pancreas and duct variations. The duct of Wirsung from the ventral bud connects to the bile duct, while the duct of Santorini from the larger dorsal bud connects to the duodenum. With gut rotation, the two ducts fuse in most cases such that the majority of the pancreas drains through the duct of Wirsung to the major papilla. The duct of Santorini can persist as a blind accessory duct or drain through the lesser papilla. In a minority of patients, the ducts remain separate, and the majority of the pancreas drains through the duct of Santorini, a condition referred to as pancreas divisum.
Vascular and Lymphatic Anatomy

The blood supply to the pancreas comes from multiple branches from the celiac and superior mesenteric arteries (Fig. 33-4). The common hepatic artery gives rise to the gastroduodenal artery before continuing toward the porta hepatis as the proper hepatic artery. The right gastric artery branches off the gastroduodenal artery just superior to the duodenum. The gastroduodenal artery also supplies the superior pancreaticoduodenal artery which divides into the anterior and superior pancreaticoduodenal arteries. These travel inferiorly within the pancreaticoduodenal groove giving off small branches to the duodenum and head of the pancreas. The superior pancreaticoduodenal arteries join the inferior pancreaticoduodenal arteries to complete the arcade. The inferior pancreaticoduodenal artery is a branch off the superior mesenteric artery. Therefore, it is impossible to resect the head of the pancreas without devascularizing the duodenum unless a rim of pancreas containing the pancreaticoduodenal arcade is preserved. The inferior pancreaticoduodenal artery needs to be controlled when dissecting the head of the pancreas off the SMA during a Whipple procedure. The gastroduodenal artery travels inferiorly anterior to the neck of the pancreas and posterior to the duodenal bulb. A posterior ulcer in the duodenal bulb can erode into the gastroduodenal artery in this location. At the inferior border of the duodenum, the gastroduodenal artery then gives rise to the right gastroepiploic artery then can continue on to join the inferior pancreaticoduodenal artery.

Variations in the arterial anatomy occur in one out of five patients. The right hepatic artery, common hepatic artery, or gastroduodenal arteries can arise from the superior mesenteric artery. In 15% to 20% of patients, the right hepatic artery will arise from the superior mesenteric artery and travel upwards toward the liver along the posterior aspect of the head of the pancreas (referred to as a replaced right hepatic artery). It is important to look for this variation on preoperative computed tomographic (CT) scans and in the operating room so the replaced hepatic artery is recognized and injury is avoided. The body and tail of the pancreas are supplied by multiple branches of the splenic artery. The splenic artery arises from the celiac trunk and travels along the posterior-superior border of the body and tail of the pancreas toward the spleen. The inferior pancreatic artery usually arises from the superior mesenteric artery and runs to the left along the inferior border of the body and tail of the pancreas, parallel to the splenic artery. Three vessels run perpendicular to the long axis of the pancreatic body and tail and connect the splenic artery and inferior pancreatic artery. They are, from medial to lateral, the dorsal, great, and caudal pancreatic arteries. These arteries form arcades within the body and tail of the pancreas and account for the rich blood supply of the organ.

The venous drainage of the pancreas follows a pattern similar to that of the arterial supply (Fig. 33-5). The veins are usually superficial to the arteries within the parenchyma of the pancreas. There is an anterior and posterior venous arcade within the head of the pancreas. Typically, the superior vein drains directly into the portal vein just above the neck of the pancreas and is often a larger branch of the portal vein which is divided during the Whipple procedure. The posterior inferior arcade drains directly into the inferior mesenteric vein at the inferior border of the neck of the pancreas and this is also divided during a Whipple procedure. The anterior inferior pancreaticoduodenal vein joins the right gastroepiploic vein and the middle colic vein to form a common venous trunk, which enters into the superior mesenteric vein. Traction on the transverse colon during colectomy can tear these fragile veins, which then retract into the parenchyma of the pancreas, making control tedious. There also are numerous small venous branches coming from the pancreatic parenchyma directly into the lateral and posterior aspect of the portal vein. Venous return from the body and tail of the pancreas drains into the splenic vein.

The lymphatic drainage from the pancreas is diffuse and widespread (Fig. 33-6). The profuse network of lymphatic
Figure 33-5. Venous drainage from the pancreas. The venous drainage of the pancreas follows a pattern similar to the arterial supply, with the veins usually superficial to the arteries. Anterior traction on the transverse colon can tear fragile branches along the inferior border of the pancreas, which then retract into the parenchyma of the pancreas. Venous branches draining the pancreatic head and uncinate process enter along the right lateral and posterior sides of the portal vein. There are usually no anterior venous tributaries, and a plane can usually be developed between the neck of the pancreas and the portal and superior mesenteric veins.

Figure 33-6. Lymphatic supply to the pancreas. The lymphatic drainage from the pancreas is diffuse and widespread, which explains the high incidence of lymph node metastases and local recurrence of pancreatic cancer. The pancreatic lymphatics also communicate with lymph nodes in the transverse mesocolon and mesentery of the proximal jejunum. Tumors in the body and tail of the pancreas are often unresectable because they metastasize to these lymph nodes. (Reproduced with permission from Bell RH, Rikkers LF, Mulholland M: Digestive Tract Surgery: A Text and Atlas. Philadelphia, PA: Lippincott Williams & Wilkins; 1996.)
vessels and lymph nodes draining the pancreas provides egress to tumor cells arising from the pancreas. This diffuse lymphatic drainage contributes to the fact that pancreatic cancer often presents with positive lymph nodes and a high incidence of local recurrence after resection. Lymph nodes can be palpated along the distal bile duct and posterior aspect of the head of the pancreas in the pancreaticoduodenal groove, where the mesenteric vein passes under the neck of the pancreas, along the inferior border of the body, at the celiac axis and along the hepatic artery ascending into the porta hepatitis, and along the splenic artery and vein. The pancreatic lymphatics also communicate with lymph nodes in the transverse mesocolon and mesentery of the proximal jejunum. Tumors in the body and tail of the pancreas often metastasize to these nodes and lymph nodes along the splenic vein and in the hilum of the spleen.

**Neuroanatomy**

The pancreas is innervated by the sympathetic and parasympathetic nervous systems. The acinar cells responsible for exocrine secretion, the islet cells responsible for endocrine secretion, and the islet vasculature are innervated by both systems. The parasympathetic system stimulates endocrine and exocrine secretion and the sympathetic system inhibits secretion.² The pancreas is also innervated by neurons that secrete amines and peptides, such as somatostatin, vasoactive intestinal peptide (VIP), calcitonin gene-related peptide (CGRP), and galanin. The exact role of these neurons in pancreatic physiology is uncertain, but they do appear to affect both exocrine and endocrine function. The pancreas also has a rich supply of afferent sensory fibers, which are responsible for the intense pain associated with advanced pancreatic cancer, as well as acute and chronic pancreatitis. These somatic fibers travel superiorly to the celiac ganglia (Fig. 33-7). Interruption of these somatic fibers with a celiac plexus block can stop transmission of pain sensation.

**HISTOLOGY AND PHYSIOLOGY**

The exocrine pancreas accounts for about 85% of the pancreatic mass; 10% of the gland is accounted for by extracellular matrix, and 4% by blood vessels and the major ducts, whereas only 2% of the gland is comprised of endocrine tissue. The endocrine and exocrine pancreas are sometimes thought of as functionally separate, but these different components of the organ are coordinated to allow an elegant regulatory feedback system for digestive enzyme and hormone secretion. This complex system regulates the type of digestion, its rate, and the processing and distribution of absorbed nutrients. This coordination is facilitated by the physical approximation of the islets and the exocrine pancreas, the presence of specific islet hormone receptors on the plasma membranes of pancreatic acinar cells, and the existence of an islet-acinar portal blood system.

Although patients can live without a pancreas when insulin and digestive enzyme replacement are administered, the loss of this islet-acinar coordination leads to impairments in digestive function. Although only approximately 20% of the normal pancreas is required to prevent insufficiency, in many patients undergoing pancreatic resection, the remaining pancreas is not normal, and pancreatic endocrine and exocrine insufficiency can develop with removal of smaller portions of the gland.

**Exocrine Pancreas**

The pancreas secretes approximately 500 to 800 mL per day of colorless, odorless, alkaline, isosmotic pancreatic juice. Pancreatic juice is a combination of acinar cell and duct cell secretions. The acinar cells secrete amylase, proteases, and lipases, enzymes responsible for the digestion of all three food types: carbohydrate, protein, and fat. The acinar cells are pyramid-shaped, with their apices facing the lumen of the acinus. Near the apex of each cell are numerous enzyme-containing zymogen...
granules that fuse with the apical cell membrane (Fig. 33-8). Unlike the endocrine pancreas, where islet cells specialize in the secretion of one hormone type, individual acinar cells secrete all types of enzymes. However, the ratio of the different enzymes released is adjusted to the composition of digested food through nonparallel regulation of secretion.

Pancreatic amylase is secreted in its active form and completes the digestive process already begun by salivary amylase. Amylase is the only pancreatic enzyme secreted in its active form, and it hydrolyzes starch and glycogen to glucose, maltose, maltotriose, and dextrins. These simple sugars are transported across the brush border of the intestinal epithelial cells by active transport mechanisms. Gastric hydrolysis of protein yields peptides that enter the intestine and stimulate intestinal endocrine cells to release cholecystokinin (CCK)-releasing peptide, CCK, and secretin, which then stimulate the pancreas to secrete enzymes and bicarbonate into the intestine.

The proteolytic enzymes are secreted as proenzymes that require activation. Trypsinogen is converted to its active form, trypsin, by another enzyme, enterokinase, which is produced by the duodenal mucosal cells. Trypsin, in turn, activates the other proteolytic enzymes. Trypsinogen activation within the pancreas is prevented by the presence of inhibitors that are also secreted by the acinar cells. A failure to express a normal trypsinogen inhibitor, pancreatic secretory trypsin inhibitor (PSTI), also known as serine protease inhibitor Kazal type 1 (SPINK1), is a cause of familial pancreatitis. Inhibition of trypsinogen activation ensures that the enzymes within the pancreas remain in an inactive precursor state and are activated only within the duodenum. Trypsinogen is expressed in several isoforms, and a missense mutation on the cationic trypsinogen, or PRSS1, results in premature, intrapancreatic activation of trypsinogen. This accounts for about two-thirds of cases of hereditary pancreatitis. Chymotrypsinogen is activated to form chymotrypsin. Elastase, carboxypeptidase A and B, and phospholipase are also activated by trypsin. Trypsin, chymotrypsin, and elastase cleave bonds between amino acids within a target peptide chain, and carboxypeptidase A and B cleave amino acids at the end of peptide chains. Individual amino acids and small dipeptides are then actively transported into the intestinal epithelial cells. Pancreatic lipase hydrolyzes triglycerides to 2-monoglyceride and fatty acid. Pancreatic lipase is secreted in an active form. Colipase is also secreted by the pancreas and binds to lipase, changing its molecular configuration and increasing its activity. Phospholipase A2 is secreted by the pancreas as a proenzyme that becomes activated by trypsin. Phospholipase A2 hydrolyzes phospholipids and, as with all lipases, requires bile salts for its action. Carboxylic ester hydrolase and cholesterol esterase hydrolyze neutral lipid substrates like esters of cholesterol, fat-soluble vitamins, and triglycerides. The hydrolyzed fat is then packaged into micelles for transport into the intestinal epithelial cells, where the fatty acids are reassembled and packaged inside chylomicrons for transport through the lymphatic system into the bloodstream (Table 33-1).

The centroacinar and intercalated duct cells secrete the water and electrolytes present in the pancreatic juice. About 40 acinar cells are arranged into a spherical unit called an acinus. Centroacinar cells are located near the center of the acinus and are responsible for fluid and electrolyte secretion. These cells contain the enzyme carbonic anhydrase, which is needed for bicarbonate secretion. The amount of bicarbonate secreted varies with the pancreatic secretory rate, with greater concentrations of bicarbonate being secreted as the pancreatic secretory rate increases. Chloride secretion varies inversely with bicarbonate secretion such that the sum of these two remains constant. In contrast, sodium and potassium concentrations are kept constant throughout the spectrum of secretory rates (Fig. 33-9). The hormone secretin is released from cells in the duodenal mucosa in response to acidic chyme passing through the pylorus into the duodenum. Secretin is the major stimulant for bicarbonate secretion, which buffers the acidic fluid entering the duodenum from the stomach. CCK also stimulates bicarbonate secretion, but to a much lesser extent than secretin. CCK potentiates secretin-stimulated bicarbonate secretion. Gastrin and acetylcholine, both stimulants of gastric acid secretion, are also weak stimulants of pancreatic bicarbonate secretion.

Truncal vagotomy produces a myriad of complex effects on the downstream digestive tract, but the sum effect on the exocrine pancreas is a reduction in bicarbonate and fluid secretion. The endocrine pancreas also influences the adjacent exocrine pancreatic secretions. Somatostatin, pancreatic polypeptide (PP), and glucagon are all thought to inhibit exocrine secretion.

The acinar cells release pancreatic enzymes from their zymogen granules into the lumen of the acinus, and these proteins combine with the water and bicarbonate secretions of the centroacinar cells. The pancreatic juice then travels into small intercalated ducts. Several small intercalated ducts join to form an interlobular duct. Cells in the interlobular ducts contribute fluid and electrolytes to adjust the final concentrations of the pancreatic fluid. Interlobular ducts then join to form about 20 secondary ducts that empty into the main pancreatic duct.

Destruction of the branching ductal tree from recurrent inflammation, scarring, and deposition of stones in chronic pancreatitis eventually contributes to destruction of the exocrine pancreas and exocrine pancreatic insufficiency.

Endocrine Pancreas
There are nearly 1 million islets of Langerhans in the normal adult pancreas. They vary greatly in size from 40 to 900 μm. Larger islets are located closer to the major arterioles and smaller islets are embedded more deeply in the parenchyma of the pancreas. Most islets contain 3000 to 4000 cells of five major types: alpha cells that secrete glucagon, beta-cells that secrete insulin, delta cells that secrete somatostatin, epsilon cells that secrete ghrelin, and PP cells that secrete PP (Table 33-2).

Insulin is the best-studied pancreatic hormone. The discovery of insulin in 1920 by Frederick Banting, an orthopedic

Part II
Specific Considerations

Insulin secretion by the beta-cell is also influenced by plasma levels of amino acids such as arginine, lysine, leucine, and free fatty acids. Glucagon, GIP, GLP-1, and CCK stimulate insulin release, while somatostatin, amylin, and pancreastatin inhibit insulin release. Cholinergic fibers and alpha-sympathetic fibers stimulate insulin release, while beta-sympathetic fibers inhibit insulin secretion.

Insulin’s glucoregulatory function is to inhibit endogenous (hepatic) glucose production and to facilitate glucose transport into cells, thus lowering plasma glucose levels. Insulin also inhibits glycogenolysis, fatty acid breakdown, and ketone formation, and stimulates protein synthesis. There is a considerable amount of functional reserve in insulin secretory capacity. If the remaining portion of the pancreas is healthy, about 80% of the pancreas can be resected without the patient becoming diabetic. In patients with chronic pancreatitis, or other conditions in which much of the gland is diseased, resection of a smaller fraction of the pancreas can result in pancreateogenic, or type 3c diabetes (Table 33-3).

Insulin receptors are dimeric, tyrosine kinase–containing transmembrane proteins that are located on all cells. Insulin deficiency (seen in type 1 and type 3c diabetes) results in an overexpression or upregulation of insulin receptors, which causes an enhanced sensitivity to insulin in muscle and adipocytes (and therefore increases the risk of insulin-induced hypoglycemia). Type 2 diabetes is associated with a downregulation of insulin receptors and relative hyperinsulinemia, with resulting insulin resistance. Some forms of diabetes are associated with selected impairments of hepatic or peripheral insulin receptors, such as pancreateogenic or type 3c diabetes (T3cDM) or maturity-onset diabetes of the young (MODY).

Glucagon is a 29-amino-acid, single-chain peptide that promotes hepatic glycogenolysis and gluconeogenesis and counteracts the effects of insulin through its hyperglycemic action. Glucose is the primary regulator of glucagon secretion, as it is with insulin, but it has an inhibitory rather than stimulatory effect. Glucagon release is stimulated by hypoglycemia and by the amino acids arginine and alanine. GLP-1 inhibits glucagon secretion in vivo, and insulin and somatostatin inhibit glucagon

secretion in a paracrine fashion within the islet. The same neural impulses that regulate insulin secretion also regulate glucagon secretion, so that the two hormones work together in a balance of actions to maintain glucose levels. Cholinergic and alpha-sympathetic fibers stimulate glucagon release, while beta-sympathetic fibers inhibit glucagon release. In pancreaticogenic or type 3c diabetes, glucagon responsiveness to a fall in blood glucose is lost, thereby increasing the risk for hypoglycemia.

Although originally isolated from the hypothalamus, somatostatin is a peptide that is now known to have a wide anatomic distribution, not only in neurons but also in the pancreas, gut, and other tissues. It is a highly conserved peptide hormone, as it is found in lower vertebrates, and is now realized to be of fundamental importance in regulatory processes throughout the body. One gene encodes for a common precursor that is differentially processed to generate tissue-specific amounts of two bioactive products, somatostatin-14, and somatostatin-28. These peptides inhibit endocrine and exocrine secretion and affect neurotransmission, GI and biliary motility, intestinal absorption, vascular tone, and cell proliferation.

Five different somatostatin receptors (SSTRs) have been cloned and the biologic properties of each are different. The hexapeptide and octapeptide analogues such as octreotide bind only to SSTR2, SSTR3, and SSTR5. These analogues have a longer serum half-life, and their potent inhibitory effect has been used clinically to treat both endocrine and exocrine disorders. For example, octreotide has been shown to decrease fistula output and speed the time it takes for enteric and pancreatic fistulas to close.

Endocrine release of somatostatin occurs during a meal. The major stimulant is probably intraluminal fat. Acidification of the gastric and duodenal mucosa also releases somatostatin in isolated perfused organ preparations. Acetylcholine from the cholinergic neurons inhibits somatostatin release.

Pancreatic polypeptide (PP) is a 36-amino-acid, straight-chain peptide discovered by Kimmel in 1968 during the process of insulin purification. Protein is the most potent enteral stimulator of PP release, closely followed by fat, whereas glucose has a weaker effect. Hypoglycemia, whether or not it is insulin induced, strongly stimulates PP secretion through cholinergic stimulation. Phenylalanine, tryptophan, and fatty acids in the duodenum stimulate PP release, probably by inducing CCK, GIP, and secretin release. Vagal stimulation of the pancreas is the most important regulator of PP secretion. In fact, vagotony eliminates the rise in PP levels usually seen after a meal. This can be used as a test for the completeness of a surgical vagotomy or for the presence of diabetic autonomic neuropathy.

PP has been shown to inhibit cholerasis (bile secretion), gallbladder contraction, and secretion by the exocrine pancreas. However, PP’s most important role is in glucose regulation through its regulation of hepatic insulin receptor gene expression. A deficiency in PP secretion due to proximal pancreatectomy, severe chronic pancreatitis, or cystic fibrosis, is associated with diminished hepatic insulin sensitivity due to reduced hepatic insulin receptor availability. This effect is reversed by PP administration.

Recent studies have shown that a fifth islet peptide, ghrelin, is secreted from a distinct population of islet cells, called epsilon cells. Ghrelin also is present in the gastric fundus in large amounts and stimulates growth hormone secretion via growth hormone releasing hormone release from the pituitary. It is an orexigenic, or appetite-stimulating, peptide the plasma levels of which are increased in obesity. Ghrelin has also been shown to block insulin effects on the liver, and inhibits the beta-cell response to incretin hormones and glucose. Therefore, ghrelin secretion from and within the islet may modulate the responses of other islet cells to nutrient and hormonal stimuli.

In addition to the five main peptides secreted by the pancreas, there are a number of other peptide products of the islet cells, including amylin, peptide YY (PYY), and pancreastatin, as well as neuropeptides such as VIP, galanin, and serotonin. Amylin or islet amyloid polypeptide (IAPP) is a 37-amino-acid polypeptide that is predominantly expressed by the pancreatic beta-cells, where it is stored along with insulin in secretory granules. The function of IAPP seems to be the modulation or counterregulation of insulin secretion and function. Pancreastatin is a recently discovered pancreatic islet peptide product that inhibits insulin, and possibly somatostatin release, and augments glucagon release. In addition to this effect on the endocrine pancreas, pancreastatin inhibits pancreatic exocrine secretion.

PYY is structurally related to PP and was initially found in hormone-secreting “L” cells of the small intestine, where it colocalizes with GLP-1. Recently, PYY has been localized to the islets where it appears to regulate insulin secretion through an autocrine mechanism.

**Islet Distribution**

The beta-cells are generally located in the central portion of each islet and make up about 70% of the total islet cell mass. The other cell types are located predominately in the periphery. The delta cells are least plentiful, making up only 5%; the ε-cells make up 10%, and the PP cells make up 15%. In contrast to the acinar cells that secrete the full gamut of exocrine enzymes, the islet cells seem to specialize in the secretion of predominantly one hormone. However, individual islet cells can secrete multiple hormones. For example, the beta-cells secrete both insulin and amylin, which counter regulates the actions of insulin. In reality, more than 20 different hormones are secreted by the islets, and the exact functions of this milieu are very complex. There is diversity among the islets depending on their location within the pancreas. The beta and delta cells are evenly distributed throughout the pancreas, but islets in the head and uncinate process (ventral anlage) have a higher percentage of PP cells and fewer alpha cells, whereas islets in the body and tail (dorsal anlage) contain the majority of alpha cells and few PP cells. This is clinically significant because pancreateoduodenectomy removes 95% of the PP cells in the pancreas. This may partially explain the higher incidence of glucose intolerance after the Whipple procedure compared to a distal pancreatectomy with an equivalent amount of tissue resected. In addition, chronic pancreatitis, which disproportionately affects the pancreatic head, is associated with PP deficiency and pancreaticogenic diabetes.

The relative preponderance of alpha cells in the body and tail of the pancreas explains the typical location of glucagonomas.

**ACUTE PANCREATITIS**

**Definition, Incidence, and Epidemiology**

Acute pancreatitis is an inflammatory disorder of the pancreas that is characterized by edema and, when severe, necrosis. It is a common and challenging disease that can develop local and systemic complications. As such, it ranges from a mild, self-limiting inflammation of the pancreas to severe and critical disease characterized by infected pancreatic necrosis, multiple...
organ failure, and a high mortality. The traditional view is that acute pancreatitis completely resolves with no morphological, functional, or symptomatic sequelae. But necrotizing pancreatitis can leave significant scarring, strictures, and impairment of exocrine and endocrine pancreatic function. The overall clinical outcome has improved over recent decades, even in the absence of specific treatments that target outcome-determining pathophysiology, probably because of a more standardized approach to diagnosis, monitoring, and management.

Acute pancreatitis is the most common inpatient principal gastrointestinal discharge diagnosis in the United States (274,119 in 2009), with an increasing incidence (30% since 2000) and is associated with the highest aggregate inpatient costs at 2.6 billion dollars per year. The crude mortality rate of 1 per 100,000 population ranks it as the 14th most common overall and the 9th most common noncancer cause of gastrointestinal deaths. Worldwide, the incidence of acute pancreatitis ranges from 5 to 80 per 100,000 population, with the highest incidence recorded in Finland and the United States. The incidence of acute pancreatitis also shows significant variation related to the prevalence of etiological factors and ethnicity. The annual incidence of acute pancreatitis in Native Americans is 4 per 100,000 population; in whites, it is 5.7; and in blacks it is 20.7. Smoking is an independent risk factor for acute pancreatitis.

### Etiology

Many factors are causally related to the onset of acute pancreatitis, but the mechanism is often poorly understood. The most common causes are gallstones and alcohol (Table 33-4), accounting for up to 80% of cases, but it is not uncommon to diagnose acute pancreatitis in the absence of these etiological factors (“idiopathic acute pancreatitis”), and it is important that a systematic approach is taken to the identification of other, less common and potentially modifiable factors. The median age at index presentation of acute pancreatitis varies with etiology; with alcohol- and drug-induced pancreatitis presenting in the third or fourth decade compared with gallstone and trauma in the sixth decade. The gender difference is probably more related to etiology: in males alcohol is more often the cause while in females it is gallstones.

#### Gallstones

Evidence that passage of a gallstone is related to the onset of acute pancreatitis comes from the characteristic transient derangement of liver function tests and the high retrieval rate of gallstones from feces within 10 days of an attack of acute pancreatitis compared with those without acute pancreatitis (88% vs. 11%). The mechanism by which small gallstones cause acute pancreatitis in migrating through to the duodenum is not clear. Opie made the seminal observation of a gallstone impacted in the sphincter of Oddi in two fatal cases of acute pancreatitis, which lead to the “common channel” hypothesis. It was proposed that this allowed bile to reflux into the pancreatic duct, but this cannot be reliably reproduced in experimental models. Another proposal was that transient incompetence caused by the passage of a stone through the sphincter might allow duodenal fluid and bile to reflux into the pancreatic duct, but this is not supported by the failure of this to commonly occur after endoscopic sphincterotomy. A third possibility is that acute pancreatitis is due to the gallstone obstructing the pancreatic duct and leading to ductal hypertension. It has been postulated that this backpressure might lead to minor ductal disruption, extravasation of pancreatic juice into the less alkaline interstitium of the pancreas, and promotion of enzyme activation. When gallstones and other etiological factors cannot be identified, there is still the possibility of finding microolithiasis, seen as birefringent crystals, on bile microscopy. This occult microolithiasis is probably responsible for up to half of those with idiopathic acute pancreatitis.

#### Alcohol

Alcohol ingestion is associated with acute pancreatitis, and sustained alcohol ingestion is associated with recurrent acute pancreatitis and development of chronic pancreatitis in susceptible individuals who have been drinking for more than a decade. The type of alcohol consumed is less important than the amount consumed (typically 100–150 grams per day) and the pattern of drinking. It is common for patients with alcohol-associated acute pancreatitis to have a history of excess alcohol consumption prior to the first attack. There are several mechanisms by which ethanol causes acute pancreatitis by acting on the acinar and stellate cells. The acinar cell metabolizes ethanol by oxidative and nonoxidative pathways, and exhibits changes that predispose the cell to autodigestive injury, necroinflammation, and cell death. The stellate cells are activated on exposure to ethanol to a myofibroblast phenotype, stimulating synthesis of proinflammatory mediators and cytokines. Ethanol causes a brief secretory increase followed by inhibition. The secretory burst coupled with ethanol induced spasm of the sphincter of Oddi probably incites acute pancreatitis. Ethanol also induces ductal permeability, which allows prematurely activated enzymes to cause damage to the pancreatic parenchyma. Ethanol also increases the protein content of pancreatic juice and decreases bicarbonate levels and trypsin inhibitor concentration. The formation of protein plugs may also contribute by causing an obstructive element to pancreatic outflow, more often seen in chronic pancreatitis.

Iatrogenic
Acute pancreatitis can occur due to trauma to the ducts or parenchyma after surgical procedures, including biopsy, bile duct exploration, distal gastrectomy, and splenectomy. As the pancreas is susceptible to ischemia, it can also occur secondary to splanchnic hypoperfusion with cardiopulmonary bypass, cardiac transplant, hemorrhagic shock, and major trauma. The most common iatrogenic cause is ERCP in which acute pancreatitis occurs after about 5% to 10% of procedures, and in many series, it is the third most common identified etiological factor. The risk of post-ERCP acute pancreatitis is increased if the contrast agent is infused repeatedly under high pressure by the endoscopist and in patients with sphincter of Oddi dysfunction. Recent evidence demonstrates that the risk can be decreased with prophylactic rectal nonsteroidal drugs, and this may be a better strategy than prophylactic pancreatic duct stenting.

Hereditary Pancreatitis
Hereditary pancreatitis is an autosomal dominant disorder usually related to mutations of the cationic trypsinogen gene (PRSS1). Mutations in this gene cause premature activation of trypsinogen to trypsin and causes abnormalities of ductal secretion, both of which promote acute pancreatitis. Mutations in the SPINK1 protein, which blocks the active binding site of trypsin, is likely to also have a role in predisposing to acute pancreatitis. Variations in penetration and phenotype are common, and there are many other mutations that have become implicated. Mutant enzymes activated within acinar cells can overwhelm the first line of defense (pancreatic secretory trypsin inhibitor) and resist backup defenses (e.g., proteolytic degradation, enzyme Y, and trypsin itself) allowing activated mutant cationic trypsin to trigger the entire zymogen activation cascade.

Tumors
A pancreatic or periampullary tumor should be considered in patients with idiopathic acute pancreatitis, especially in those over 50 years old. Approximately 1% to 2% of patients with acute pancreatitis have a pancreatic tumor, and an episode of acute pancreatitis can be the first clinical indicator. Cross-sectional imaging after the resolution of the acute pancreatitis is required.

Hyperlipidemia
Patients with types I and V hyperlipoproteinemia can experience episodes of abdominal pain, and these often occur in association with marked hypertriglyceridaemia. Lipase is thought to liberate toxic fatty acids into the pancreatic microcirculation, leading to microcirculatory impairment and ischemia. Dietary modifications and drug treatment are used to lower triglycerides.

Drugs
Isolated cases of acute pancreatitis have been associated with exposure to certain drugs, such as thiazide diuretics, furosemide, estrogen replacement therapy, and steroid therapy in children. In addition, certain chemotherapy agents and anti-immune drugs have been associated with acute pancreatitis, and lipid-based drugs or solutions, such as propofol, have been shown to cause acute pancreatitis.

Pathophysiology
Acute pancreatitis occurs in various degrees of severity, the determinants of which are multifactorial. The generally prevalent belief today is that pancreatitis begins with the activation of digestive zymogens inside acinar cells, which cause acinar cell injury. Studies suggest that the ultimate severity of the resulting pancreatitis may be determined by the events that occur subsequent to acinar cell injury. These include inflammatory cell recruitment and activation, as well as generation and release of cytokines and other chemical mediators that cause systemic inflammation and multiple organ dysfunction/failure (Figure 33-10).

Precipitating Events
In 1896, Chiari proposed that pancreatitis was due to the premature, intrapancreatic activation of digestive enzymes, resulting in “auto-digestion” of the organ. Since then the

---

**Figure 33-10.** Schema of key loco-regional pathophysiological events in the pancreas and intestine and how they interact to drive the severity and outcome of acute pancreatitis. (Adapted with permission from Flint RS, Windsor JA: The role of the intestine in the pathophysiology and management of severe acute pancreatitis, HPB (Oxford). 2003;5(2):69-85.)
Intra-acinar activation of zymogens has been demonstrated consistently in multiple animal models of acute pancreatitis and is considered a key precipitating event.\textsuperscript{37,38} The key role of trypsin activation in acute pancreatitis has gained additional support from recent studies showing that mice lacking trypsinogen-7 (the isoform of trypsinogen that is activated during acute pancreatitis in mice) have significantly less pancreatic injury during acute pancreatitis\textsuperscript{39} and that intra-acinar expression of active trypsin causes pancreatitis in mice.\textsuperscript{40} The role of trypsin activation in the pathophysiology of acute pancreatitis has also been suggested by clinical studies. Hereditary pancreatitis is associated with mutations that lead to elevated intracellular trypsin activation,\textsuperscript{41} and activation of trypsinogen causes clinical pancreatitis.\textsuperscript{42}

Significant progress has been made in understanding the mechanisms by which injurious stimuli lead to intra-acinar activation of trypsinogen and autodigestion of the gland (Figure 33-11). Under physiologic conditions, several protective mechanisms have evolved to prevent autodigestion of the pancreas by these enzymes. This includes synthesis of enzymes as inactive precursors, separation of the site of production, and activation of the enzymes and presence of trypsin inhibitors in the pancreas. It is thought that acute pancreatitis occurs when these protective mechanisms are overwhelmed by erroneously activated enzymes, causing injury. It has been shown that intra-acinar activation of trypsinogen goes hand-in-hand with inhibition of acinar secretion.\textsuperscript{43,44} Furthermore, with injurious stimuli the zymogens responsible for initiating the disease are not secreted outside, but colocalize with cytoplasmic vacuoles that contain lysosomal enzymes such as cathepsin B\textsuperscript{45} that activate trypsinogen. Thus, inhibition of cathepsin B by pharmacological inhibitors\textsuperscript{46} or by genetic deletion of cathepsin B eliminates trypsin activation and decreases the severity of pancreatitis in animal models.\textsuperscript{47} What leads to the colocalization of zymogens and lysosomal hydrolases is unclear, but injurious stimuli leading to sustained cytosolic calcium increase have been indicted. Blocking this calcium increase prevents colocalization and activation of trypsin, and it decreases injury due to pancreatitis.\textsuperscript{48} Based on these data, pre-ERCP supplementation of magnesium, a natural antagonist of calcium, is currently being evaluated as a strategy to decrease post-ERCP pancreatitis.\textsuperscript{49} Recent work has led to the novel hypothesis that the lysosomal hydrolase cathepsin B activates trypsinogen to trypsin within the colocalization vacuoles. Trypsin then permeabilizes these colocalization vacuoles causing the release of cathepsin B into the cytosol. Once in the cytosol, cathepsin B initiates apoptotic cell death by permeabilizing mitochondrial membranes, which allows cytochrome C to be released into the cytosol. This initiates the apoptotic cascade and results in the apoptotic death of the acinar cells\textsuperscript{50} (see Figure 33-11).

### Intrapancreatic Events

Although intra-acinar events initiate acute pancreatitis, events occurring subsequent to acinar cell injury determine the severity of pancreatitis. Activated neutrophils are attracted and activated in the pancreas releasing superoxide (the respiratory burst) and proteolytic enzymes (cathepsins, elastase, and collagenase) that cause further pancreatic injury. In addition, macrophages release cytokines (including tumor necrosis factor-alpha (TNF-$\alpha$) and interleukins (IL-1, IL-2, IL-6, and IL-8) that mediate local and systemic inflammation.\textsuperscript{38}

These inflammatory mediators cause an increased pancreatic vascular permeability, leading to hemorrhage, edema, and

![Figure 33-11](image-url). Schematic representation of the acinar cell events in acute pancreatitis. When acinar cells are pathologically stimulated, their lysosomal (L) and zymogen (Z) contents colocalize, and consequently trypsinogen is activated to trypsin by cathepsin B. Increased cytosolic calcium is required for colocalization. Once trypsin has permeabilized the contents of the cytosol, cathepsin B and other contents of these colocalized organelles are released. Once in the cytosol, cathepsin B activates apoptosis by causing cytochrome C to be released from the mitochondria. Activation of PKC results in a sudden activation of nuclear factor kappa beta (NFkB), which in turn triggers the release of cytokines that attract inflammatory response cells that mediate local and systemic inflammation cascades.
microthrombi. Fluid may collect in and around the pancreas. The failure of the pancreatic microcirculation, a feature of more severe acute pancreatitis, results in pancreatic hypoperfusion and necrosis. Acute inflammation of the pancreatic parenchyma and peripancreatic tissues, but with no recognizable necrosis, is termed interstitial edematous pancreatitis.25 When necrosis is present, as evidenced by pancreatic hypoperfusion with contrast CT, it is termed necrotizing pancreatitis (Figure 33-12). The updated morphological definitions and the contrast enhanced CT criteria for the diagnosis of the local complications of acute pancreatitis are in the revised Atlanta statement51 and summarized in Table 33-5.52

**Systemic Events**

An important aspect of the pathophysiology of acute pancreatitis is the mechanism by which events occurring in the pancreas induce systemic inflammation and multiorgan failure. The NFκB-dependent inflammatory pathway is an important mechanism (see Figure 33-11). Activation of NFκB parallels trypsin activation in acute pancreatitis but appears to be independent of it, as it occurs in trypsin knockout mice.50 Sustained calcium increase, which leads to trypsinogen activation, is critical for NFκB activation since attenuation of cytosolic calcium abrogates NFκB activation.53 Once activated, NFκB regulates synthesis of multiple cytokines and chemokines, leading to recruitment of various inflammatory cells that then magnify and propagate systemic inflammation.54 The infiltrating neutrophils can also further augment the pancreatic injury.55,56 Inhibition of many of these cytokines have led to reduced local and systemic injury in animal models of acute pancreatitis. But these results did not translate to clinical improvement.57 New strategies are required to reduce the systemic inflammatory response.58-60

Organ failure can develop at any stage of acute pancreatitis, associated with an overwhelming proinflammatory response early, or later secondary to the development of infected local complications. The drivers of the systemic response are poorly understood, although factors include the elaboration of proinflammatory cytokines, and it appears that mesenteric lymph, bypassing the liver and containing these constituents, may contribute to the development of organ failure64 (see Figure 33-10). The development of pancreatic necrosis, the breakdown of the intestinal barrier, and the suppression of the immune response through the compensatory inflammatory response contribute to the development of infected pancreatic necrosis, the incidence of which peaks in the third to fourth week. This is usually associated with deterioration in the patient’s condition and may be associated with the late development of the systemic inflammatory response syndrome (SIRS) and multiorgan dysfunction syndrome/failure (MODS/F).

Organ failure is scored using the Marshall or Sequential Organ Failure Assessment (SOFA) systems (Table 33-6). The three organ systems most frequently involved are cardiovascular, respiratory, and renal. Multiple organ failure is defined as two or more organs registering two or more points on these scoring systems.51 Monitoring organ failure over time and in response to treatment is important in the care and timing of intervention in these patients.

**Management of Acute Pancreatitis**

**General Considerations.** The management of acute pancreatitis covers a wide spectrum of severity. All patients with suspected acute pancreatitis should be admitted to hospital. Those with mild acute pancreatitis usually remain in hospital for less than a week, while those with severe and critical acute pancreatitis may require many weeks or months of intensive treatment. The risk of mortality reflects this spectrum of severity. The risk is less than 1% for those with mild disease, increasing to around 10% for those with moderate disease, but for severe (20–40%) and critical (>50%) disease the mortality risk is much higher. The earlier identification of these high-risk categories and their transfer to specialized centers is an important priority of management.52

The management of acute pancreatitis is multidisciplinary, and it is important that this is coordinated care plan is carefully supervised.63 The essential requirements of the management

of acute pancreatitis are accurate diagnosis, appropriate triage, high-quality supportive care, and monitoring for and treatment of complications.64

Diagnosis
The diagnosis of acute pancreatitis requires the patient to present with abdominal pain consistent with acute pancreatitis (acute onset of a severe constant epigastric pain that often radiates through to the mid back) and the elevation of serum amylase or lipase (>3 times upper limit of normal). Imaging (usually by contrast-enhanced CT scanning) is only required for the diagnosis of acute pancreatitis when these diagnostic criteria are not met.51 Because of the many causes of hyperamylasemia, it is important to use either the pancreatic isoenzyme of amylase or lipase.63

The serum amylase concentration increases almost immediately with the onset of disease and peaks within several hours and remains elevated for 3 to 5 days.64 There is no correlation between the extent of serum amylase elevation and severity of pancreatitis; in fact, a milder form of acute pancreatitis is often associated with higher levels of serum amylase compared with that in a more severe form of the disease. It is important to note that hyperamylasemia can also occur in association with other diseases. For example, it can occur in a patient with small bowel obstruction, perforated duodenal ulcer, or other intra-abdominal inflammatory conditions. In contrast, a patient with acute pancreatitis can have a normal serum amylase level, for several different reasons. In patients with hyperlipidemia, values might appear to be normal because of interference with chemical determination of serum amylase by lipids. In some cases, urinary clearance of pancreatic enzymes from the circulation increases during pancreatitis, meaning that urinary levels may be more sensitive than serum levels. For these reasons, it is recommended that amylase concentrations also be measured in the urine. Urinary amylase levels usually remain elevated for several days after serum levels have returned to normal. In patients with severe pancreatitis associated with significant necrosis, the pancreas may not have the capacity to release large amounts of enzymes into the circulation. With more severe disease, there is also hemoconcentration from third space fluid loss, and this can affect the serum concentration of amylase.

The clinical signs of acute pancreatitis include abdominal tenderness, often with signs of peritonitis in the upper abdomen. Rarely, pancreatic fluid and bleeding from the pancreas into the retroperitoneum may result in a bruise-like discoloration around the umbilicus (Cullen’s sign) or in the flanks (Grey Turner’s sign). Another rare sign is tetany as a result of hypocalcaemia. In addition to hemoconcentration, patients with acute pancreatitis often have azotemia with elevated blood urea nitrogen and creatinine levels, hyperglycemia, and hypoalbuminemia.

Pain Management
Pain is the cardinal symptom of acute pancreatitis, and its relief is a clinical priority. There is a lack of high-quality evidence to guide the choice of analgesic. Because of unpredictable absorption, analgesia should be administered intravenously, at least at the outset and before oral intake has been established. Those with mild pain can usually be managed with a nonsteroidal anti-inflammatory drugs (e.g., metamizole 2 g/8 h IV), while those with more severe pain are best managed with opioid analgesia (e.g., buprenorphine 0.3 mg/4 h IV). Administration of buprenorphine, pentazocine, procaine hydrochloride, and meperidine are all of value in controlling abdominal pain. Morphine is to be avoided because of its potential to cause sphincter of Oddi spasm.

Predicting Severity
Whereas classification relates to the present or past severity of acute pancreatitis, prediction is about the future and ultimate severity and outcome of the patient. Accurately predicting acute

Note: Fewer than three positive criteria predict mild, uncomplicated disease, whereas more than six positive criteria predict severe disease with a mortality risk of 50%.

Abbreviations: AST = aspartate transaminase; BUN = blood urea nitrogen; LDH = lactate dehydrogenase; PO₂ = partial pressure of oxygen; WBC = white blood cell count.

pancreatitis severity is important in making triage decisions about whether a patient should be transferred to a tertiary hospital or an intensive care unit and in making decisions about fluid therapy and whether an ERCP is indicated, as well as other issues. There is a very long history of attempts to find prognostic or predictive markers that accurately stratify the risk, with the most widely used being the Ranson’s criteria (Table 33-7) or modified Glasgow criteria. Both use clinical and biochemical parameters scored over the first 48 hours of admission. When there are three or more positive criteria, the disease is considered “predicted severe.” There are many other approaches to predicting severity. At 24 hours after admission an APACHE II score of 8 or more or a serum C-reactive protein level of >150 mg/dL has a similar accuracy in predicting severity as Ranson’s criteria. The more recently proposed Bedside Index for Severity of Acute Pancreatitis (BISAP) is calculated from blood urea nitrogen (> 25 mg/dL), impaired mental status (GCS <15), presence of systemic inflammatory response syndrome, age >60 years, and pleural effusion. Although it has the advantage of simplicity and can be performed within the first 24 hours of admission, it performed no better than other predictors. The presence of SIRS also has prognostic significance. There remains some controversy as to how important obesity is as a risk factor for severe and critical acute pancreatitis. Another approach has been taken in seeking to predict those with the “harmless acute pancreatitis score” using three factors that can be determined on admission: absence of rebound tenderness or guarding, normal hematocrit, and normal serum creatinine. The accuracy of this approach appears to be over 90% and triages most patients away from intensive care.

Unfortunately, these and many other single and combined predictors of severity have an accuracy of around 70%. This means that there is misclassification error of 30% that limits the value in predicting the severity of acute pancreatitis in individual patients. In the absence of any new biomarkers of pancreatitis severity, making better use of existing predictors through sequencing tests, combining tests, or using artificial neural network methodologies has shown some promise. Scoring systems should augment clinical judgment, but not replace it. Over the first 2 to 3 days the clinician must be alert to patients with an elevated BUN or creatinine and/or persistent SIRS after adequate fluid resuscitation because these patients are at risk of developing severe acute pancreatitis.

Classification of Severity

Accurately classifying or staging acute pancreatitis severity is important for clinical decision-making, communication, and enrolment into trials. The wide spectrum of pancreatitis severity was not captured in the previous binary classifications (mild or severe). The key determinants of severity are local complications (absent, sterile, or infected) and systemic complications (absent, transient organ failure, persistent organ failure). Two classification systems have recently been proposed: the three grades (mild, moderately severe, and severe) of the Revised Atlanta Criteria (RAC) and the four categories (mild, moderate, severe, critical) of the Determinants Based Classification (DBC) (Table 33-8). The DBC

</table>
was developed on the principle of casual inference, derived by meta-analysis, and refined by an international multidisciplinary process, and both classifications have been independently validated, which suggests that they are broadly equivalent. More recently a prospective multicenter study has modified the DBC to address the ongoing issue that patients considered to have severe acute pancreatitis represent several subgroups with different morbidity, mortality, and intervention profiles (Table 33-9).

The classification of patient severity is helpful in tracking the clinical trajectory of a patient, and it can be applied on a daily or more frequent basis. It can also be used in retrospect for audit purposes.

### Determining Etiology

The history of alcohol ingestion must be ascertained and preferably confirmed with blood ethanol levels. Gallstones should be investigated by ultrasonography. A gallstone etiology is more likely in females over the age of 50 with an elevation of alkaline phosphatase (>300 iu/L), alanine transferase (>100 iu/L), and amylase (>4000 iu/L). In the absence of gallstones and alcohol, a systematic approach to the identification of another factor will include taking a history of drugs, trauma, ERCP, infection, and measuring serum triglycerides, calcium, and others (see Table 33-4).

### Fluid Resuscitation

Fluid therapy to restore and maintain circulating blood volume is the most important intervention in the early management of acute pancreatitis. However, a recent systematic review has shown that the evidence base for fluid therapy is scant, and most recommendations are based on expert opinion. It is not known which fluid to give, how aggressively to administer it, or what goal to use to guide and monitor the response to it. While there are proponents for vigorous fluid therapy (5–10 mL per kilogram per hour), especially in the first 24 hours, and for specific resuscitation goals, it is probably best to resuscitate with a balanced crystalloid and aim to restore normal blood volume, blood pressure, and urine output. In one study, lactated Ringer’s solution was superior to normal saline in reducing the systemic inflammatory response. Caution needs to be exercised in those with cardiac and renal disease and in the elderly, where the risks of over-resuscitation are greater.

### Nutritional Support

In contrast to analgesia and fluid therapy, there is a sound evidence base for nutritional support in acute pancreatitis. It is no longer acceptable to “rest the pancreas” by avoiding enteral nutrition, now the mainstay of nutritional support. Parenteral nutrition is now known to be more expensive, riskier, and not more effective than enteral nutrition and should only be offered if the patient’s calculated nutritional requirements cannot be achieved by the enteral route. Early initiation of enteral nutrition (within the first 24 hours of admission) is not superior to delaying an oral diet until 72 hours. If this is not tolerated over 48 to 72 hours, then nasogastric tube feedings can be started and increased in step-wise fashion over 2 to 3 days. The tube can be advanced to the jejunum, by endoscopy or fluoroscopy, if there is evidence of feeding intolerance. A delay in commencing enteral nutrition may contribute to the development of intestinal ileus and feeding intolerance, but aggressive early enteral feeding, particularly before adequate resuscitation, may put the patient at risk of nonocclusive mesenteric ischemia. There is no evidence to support the use of elemental or immune-enhancing formulas over standard polymeric formulas. In predicted mild acute pancreatitis the recommencement of oral fluids and then food was delayed until resolution of abdominal pain and normalization of serum levels of amylase, but it appears safe to allow patients to resume intake ad libitum (i.e., patient-controlled nutrition). If after 3 to 5 days there is evidence of feeding intolerance, tube feeding should be commenced.

### Cross-Sectional Imaging

It may be necessary to perform a CT scan to diagnose acute pancreatitis in patients who are severely ill or in those presenting with undifferentiated abdominal pain. But there is no advantage in using CT scanning to predict the severity of acute pancreatitis. The primary purpose of cross-sectional imaging is the diagnosis of local complications; in particular, the development and extent of pancreatic necrosis and the different collections (see Table 33-5). CT scanning is also important to guide the insertion of percutaneous drains, now assuming a greater role in the management of the local complications (discussed later). Magnetic resonance imaging (MRI) is superior to CT scanning in detecting any solid content within collections (Figure 33-13). And when a bleed is suspected, in association with a local complication, an arterial phase CT scan (CTa) is useful in detecting a pseudoaneurysm, active bleeding, and/or hematoma.

### Table 33-9

The Modified Determinant Based Classification (MDBC) (Acevedo) of acute pancreatitis severity compared with the Revised Atlanta Classification (RAC) and Determinants Based Classification (DBC). Note that the DBC has a narrower definition for local complications than RAC, leading to a slightly broader range of mild acute pancreatitis in this table.

...
Therapeutic Endoscopic Retrograde Cholangiopancreatography

Randomized trials have demonstrated that early ERCP (within 24 or 48 hours of admission) reduce complications, but not mortality, in patients with predicted severe gallstone associated acute pancreatitis. While the benefits of this invasive modality are clear (e.g., treatment of cholangitis and release of impacted stone), this can be offset by the risks of increasing the severity of pancreatitis, bleeding, cholangitis, and perforation. More recent evidence has suggested that early ERCP confers no benefit in the absence of concomitant cholangitis, as the offending common duct stone usually passes before ERCP can be performed. This may be evidenced by improvement in the liver function tests over the first 2 to 3 days. If there is persistent cholestasis, an MRCP can be used to detect a common duct stone and can be used as a prerequisite for attempting an ERCP. Persistent cholestasis without cholangitis may require an ERCP but not usually in the acute setting.

Antibiotics

Although the use of broad-spectrum antibiotics to treat established infection in acute pancreatitis is a well-established practice, there has been considerable controversy surrounding the use of prophylactic antibiotics. The overuse of antibiotics has been associated with a documented rise in fungal infections and resistant organisms. Overall, it appears that the most recent and generally better designed studies do not support the use of prophylactic antibiotics to reduce the frequency of pancreatic infectious complications, surgical intervention, and death.

Managing Local Complications

Vigilance is required for the timely and accurate diagnosis of local complications. The decisions regarding how and when to intervene are often difficult. While guided by the information gained by cross-sectional imaging, the decision to intervene is based on the clinical status and trajectory of the patient and the poor response to maximal intensive care support. This means close monitoring of the patient by serial examination, supplemented by regular measurement of inflammatory markers (e.g., C-reactive protein) and a pancreatic protocol CT scan if a local complication is suspected and intervention considered warranted. In practice, intervention is delayed in order to allow demarcation and to reduce the risk of bleeding, disseminated infection, and collateral damage to adjacent organs by an intervention (Figure 33-14). Appreciation of this has resulted in a notable trend toward delayed intervention.

Figure 33-13. Corresponding computed tomography (CT) (A) and MR (B) images of a patient with a symptomatic pseudocyst. CT image reveals a well circumscribed homogenous collection (arrows) exerting mass effect on antrum of stomach. The T2-weighted MR image clearly distinguishes necrotic pancreas (black arrows) from fluid (white arrows). (Reproduced with permission from Bollen TL: Imaging of acute pancreatitis: update of the revised Atlanta classification, Radiol Clin North Am. 2012 May;50(3):429-445.)

Figure 33-14. Operative view of infected acute pancreatitis. Peripancreatic infection, characterized by mucopurulent exudate, extends far beyond the boundaries of the pancreas in the retroperitoneum.
intervention, now uncommon before 3 to 4 weeks from the onset of symptoms. An important emerging approach is the increasing use of percutaneous catheter drainage in patients with suspected infected collections. Fine-needle aspiration is now rarely used to confirm infection because the insertion of a needle at the time of planned drainage allows confirmation of the suspected infection. Preemptive drainage with one or more catheters often produces improvement or stabilization of the patient’s overall clinical status. In this way, drainage “buys time” and allows the lesion to become more walled off and safer to treat. Recent data suggests that primary percutaneous catheter drainage may be the only intervention required in a third to a half of patients and that this proportion might increase further if there were a policy of regular catheter exchange, upsizing, and irrigation. A proportion of patients do, however, require further treatment when they fail to respond and there is a wide array of minimally invasive options to choose from. These interventions can be classified on the basis of the method of visualization, route taken to the lesion, and the purpose of the intervention. In practice, the approach taken will depend on local expertise and equipment as well as the location and type of the specific local complication. A large Dutch randomized trial has shown that open surgical techniques should only be considered in those who fail to respond to the step-up approach, that is, prior percutaneous drainage and minimally invasive intervention. The exception is to be found in the rare situation where an abdominal compartment syndrome requires open decompression, but this is usually earlier than the optimal time to intervene for local complications. A recent landmark randomized trial has compared two minimally invasive techniques, endoscopic transgastric drainage, and the videoscope-assisted retroperitoneal debridement through a flank incision (see Figure 33-15). The data shows that the former approach is superior, although the latter has a role when the walled-off necrosis is remote from the stomach or duodenum, as in the left flank.

The management of an acute noninfected pseudocyst is usually conservative, as about half of these will resolve spontaneously. When symptoms of pain or the inability to eat persist or infection occurs, intervention is required. The indications for intervention are therefore no longer based on size and duration alone. Pseudocysts persist because of communication with the main pancreatic duct and/or distal ductal stenosis. Percutaneous drainage should be avoided in this situation because of the risk of external pancreatic fistula. EUS-guided internal drainage into stomach or duodenum or transpapillary stenting is the preferred approach.

Managing Organ Failure

The specific management of multiple organ failure is beyond the scope of this chapter. The early identification of organ dysfunction and failure is important because it is a key determinant of severity and outcome and to facilitate the timely transfer of the patient to an intensive care unit to optimize management, provide organ support and allow more intensive monitoring. The severity of organ failure can be scored (see Table 33-6). The responsiveness of organ failure to resuscitation over the first 48 hours is an important prognostic clue; those that respond have transient organ failure and have a better outlook than those who do not respond and have persistent organ failure. Organ failure that develops later in the disease course is usually

secondary to infection of a local complication and should be managed accordingly (see Figure 33-9).

**Cholecystectomy**

While it is widely accepted that cholecystectomy is essential to prevent recurrent gallstone associated pancreatitis, the question relates to the timing of it. Index cholecystectomy, done in the same admission and prior to discharge, appears safe and can almost always be accomplished laparoscopically. But index cholecystectomy is not suitable for all patients, particularly some who have had local pancreatic complications, which includes a large inflammatory mass that extends into the porta hepatis. These patients may require an interval cholecystectomy after resolution of the inflammatory process. If surgery is required for the management of local complications, then a cholecystectomy is often performed at that time.

**Diabetes**

Recent evidence indicates that prediabetes and diabetes are common after acute pancreatitis and occur in nearly 40% of patients after hospital discharge. The prevalence of newly diagnosed diabetes is much higher after acute pancreatitis (23%) than the prevalence of diabetes in the general population (4-9%). The risk of diabetes increases by at least twofold after 5 years as compared with 12 months. Interestingly, the severity of acute pancreatitis appears to have minimal effect on risk of diabetes. The implication is that patients recovered from an attack of acute pancreatitis may need follow-up and screening for glucose intolerance.

The management of acute pancreatitis remains a formidable challenge (Table 33-10) due to the variety and severity of the many associated complications (Table 33-11), and continues to evolve. Although specific treatments for acute pancreatitis remain elusive, progress has been made in the management of pain, fluid resuscitation, antibiotic prophylaxis, enteral nutrition, therapeutic ERCP, and cholecystectomy. Progress has also been made in the intensive care management of systemic complications and in the development of less invasive interventions for the treatment of local complications, particularly infected pancreatic necrosis.

H. Fat necrosis
1. Intra-abdominal saponification
2. Subcutaneous tissue necrosis

CHRONIC PANCREATITIS

Definition, Incidence, and Prevalence
Chronic pancreatitis is an incurable, chronic inflammatory condition that is multifactorial in its etiology, highly variable in its presentation, and a challenge to treat successfully. Autopsy studies indicate that evidence of chronic inflammation, such as fibrosis, duct ectasia, and acinar atrophy is seen in up to 5% of the population, although these data are difficult to interpret because many of these changes are also present in asymptomatic elderly patients. Population studies suggest a prevalence that ranges from 5 to 40 persons per 100,000 population, with considerable geographic variation. Differences in diagnostic criteria, regional nutrition, alcohol consumption, and medical access account for variations in the frequency of the diagnosis, but the overall incidence of the disease has risen progressively over the past 50 years.

Etiology
There are multiple etiologies of chronic pancreatitis, including genetic mutations, alcohol exposure, duct obstruction due to trauma, gallstones, and tumors, metabolic diseases such as hyperlipidemia and hyperparathyroidism, and auto-immune disease. In addition, nutritional causes include so-called tropical pancreatitis, which has been thought to result from ingestion of certain starches. A significant number of patients have no discernible cause of the disease despite extensive testing, and are said to have “idiopathic” chronic pancreatitis.

Genetic Causes
In 1952, Comfort and Steinberg reported a kindred of “hereditary chronic relapsing pancreatitis” after treating the proband, a 24-year-old woman, at the Mayo Clinic. Subsequently, familial patterns of chronic, nonalcoholic pancreatitis have been described worldwide, and a familiar pattern has emerged. Typically, patients first present in childhood or adolescence with abdominal pain and are found to have chronic calcific pancreatitis on imaging studies. Progressive pancreatic dysfunction is common, and many patients present with symptoms due to pancreatic duct obstruction. The risk of subsequent carcinoma formation is increased, reaching a prevalence, in some series, of 40%, but the age of onset for carcinoma is typically >50 years old. The disorder is characterized by an autosomal dominant pattern of inheritance, with 80% penetrance and variable expression. The incidence is equal in both sexes.

Whitcomb and colleagues, and separately LeBodic and associates, performed gene-linkage analysis and identified a linkage for hereditary pancreatitis to chromosome 7q35. Subsequently, the region was sequenced and revealed eight trypsinogen genes. Mutational analysis revealed a missense mutation resulting in an Arg-to-His substitution at position 122 of the anionic trypsinogen gene, or PRSS1, one of the primary sites for proteolysis of trypsin. This gain-of-function mutation results in an excess production of trypsinogen, which results in persistent and uncontrolled proteolytic activity and autodestruction within the pancreas. The position mutation of PRSS1 and an additional mutation, now known collectively as the R122H and N291 mutations of PRSS1, account for about two-thirds of cases of hereditary pancreatitis. Masson and associates described a gain-of-function mutation in the anionic trypsinogen gene, PRSS2, that is also present in some cases.

Similarly, SPINK1, an inflammation-induced trypsin inhibitor secreted in acinar cells, has been found to have a role in hereditary pancreatitis. SPINK1 specifically inhibits trypsin action by competitively blocking the active site of the enzyme. Witt and colleagues investigated unrelated children with chronic pancreatitis in Germany and found a variety of SPINK1 mutations in 23% of the patients. Several studies have now confirmed an association of loss-of-function SPINK1 mutations with familial and idiopathic forms of chronic pancreatitis, as well as so-called tropical pancreatitis. SPINK1 mutations
are common in the general population as well, and the frequency of these mutations varies in different cohorts of idiopathic chronic pancreatitis, from 6.4% in France to 25.8% in the United States. Thus, hereditary pancreatitis results from one or more mutational defects that incapacitate an auto-protective process that normally prevents proteolysis within the pancreas.

Cystic fibrosis, originally termed cystic fibrosis of the pancreas, results from a variety of mutations of the cystic fibrosis transmembrane receptor (CFTR). The CFTR is present in pancreatic duct cells and controls the amount of chloride and bicarbonate secreted into the normally alkaline pancreatic juice. The CFTR gene contains over 4300 nucleotides, divided into 24 exons, which encode a 1480-amino acid protein. Over 1000 polymorphisms have been reported, and many are common. The CFTR mutation associated with the classic pulmonary disease, F508, is rarely observed in chronic pancreatitis. But other CFTR mutations have been noted to be associated with chronic idiopathic pancreatitis, auto-immune pancreatitis, and pancreas divisum, in which the pulmonary, intestinal, and cutaneous manifestations of the disease are silent.

Many studies have been undertaken to determine whether specific genetic abnormalities are associated with alcoholic chronic pancreatitis and which might confer susceptibility to the disease. In 2012, a landmark study by Whitcomb and associates demonstrated a likely genetic cause of the predisposition to alcohol-induced chronic pancreatitis in men. In a genome-wide association study of more than 2000 patients, these researchers discovered that a common DNA variant on the X chromosome is present in 26% of men without pancreatitis, but jumps to nearly 50% of men diagnosed with alcoholic pancreatitis. The variant involves the claudin 2 (CLDN2) gene, which encodes a tight junction protein normally present in ductal cells. In cases of chronic pancreatitis, the CLDN2 protein is abnormally expressed in acinar cells and may alter the secretory dynamics of enzyme release. The abnormality does not appear to cause pancreatitis, but if pancreatitis occurs for any reason in a person with the CLDN2 variant, it is more likely that the person will develop chronic pancreatitis; the risk is increased even further among alcohol users. Only 10% of women have the X chromosome–linked variant on both X chromosomes, and most women with the CLDN2 variant on one X chromosome appear to be protected from alcoholic chronic pancreatitis by the other X chromosome, if it is normal. Men, with only one X chromosome, have no protection if they inherit a CLDN2 mutation. This helps to explain the high prevalence of alcoholic chronic pancreatitis among men, although the mechanism remains unclear. This study does not demonstrate a genetic cause for all cases of alcohol-related chronic pancreatitis, but it shows that a genetic element contributes to many patients with the disease (Fig. 33-16).

Alcohol
In 1878, Friedreich proposed that “a general chronic interstitial pancreatitis may result from excessive alcoholism (drunkard’s pancreas).” Since that observation, numerous studies have shown that a causal relationship exists between alcohol and chronic pancreatitis, but the prevalence of alcohol as the etiology of the disease in Western countries ranges widely, from 38% to 94% (Fig. 33-17).

There is a linear relationship between exposure to alcohol and the development of chronic pancreatitis. The risk of disease is present in patients with even a low or occasional exposure to alcohol (1 to 20 g/d), perhaps due to the CLDN2 gene mutation described previously, so there is no threshold level of alcohol exposure below which there is no risk of developing chronic pancreatitis. Furthermore, although the risk of disease is dose related and highest in heavy (>150 g/d, or about 11 1 oz shots, or 12 beers per day) drinkers, the prevalence of chronic pancreatitis among confirmed alcohol abusers is only 5% to 15%. However, the duration of alcohol consumption is definitely associated with the development of pancreatic disease. The onset of disease typically occurs between ages 35 to 40 years, after 16 to 20 years of heavy alcohol consumption. Recurrent episodes of acute pancreatitis are typically followed by chronic symptoms after 4 or 5 years.

In their 1946 classic study, Comfort, Gambrill, and Baggenstoss proposed that chronic pancreatitis was the result of multiple episodes of acute inflammation, with residual and
Progressively increasing chronic inflammation.\textsuperscript{117} Subsequently, Kondo and associates showed that other, additional factors were necessary for repeated exposure to alcohol to cause chronic pancreatitis.\textsuperscript{118} Regardless of the requirement for other predisposing or facilitative factors, the concept that multiple episodes (or a prolonged course) of pancreatic injury ultimately leads to chronic disease is widely accepted as the pathophysiologic sequence\textsuperscript{119} (Fig. 33-18).

Although direct alcohol exposure to the pancreatic ductal system, or elevated levels of alcohol in the bloodstream, has been shown to alter the integrity and function of pancreatic ducts and acini directly,\textsuperscript{120} most investigators believe that alcohol metabolites such as acetaldehyde, combined with oxidant injury, result in local parenchymal injury that is preferentially targeted to the pancreas in predisposed individuals. Repeated or severe episodes of toxin-induced injury activate a cascade of cytokines, which, in turn, induces pancreatic stellate cells (PSCs) to produce collagen and cause fibrosis (Fig. 33-19).

Hyperlipidemia

In addition to the risk of acute pancreatitis, hyperlipidemia and hypertriglyceridemia predispose women to chronic pancreatitis when they receive estrogen replacement therapy.\textsuperscript{127} Fasting triglyceride levels <300 mg/dL are below the threshold for this to occur, and the mechanism of estrogen potentiation of hyperlipidemia-induced chronic pancreatitis is unknown. It is assumed that chronic changes occur after repeated subclinical episodes of acute inflammation. Aggressive therapy of hyperlipidemia is therefore important in peri- or postmenopausal patients who are candidates for estrogen therapy.

Classification

A major impediment to a better understanding of the etiology, frequency, and severity of chronic pancreatitis has been the difficulty with which investigators and clinicians have struggled to identify a useful classification system. Multiple classification systems have been proposed. The TIGAR-O scheme categorizes chronic pancreatitis according to risk factors and etiologies, such as (a) toxic-metabolic, (b) idiopathic, (c) genetic, (d) autoimmune, (e) recurrent and severe acute pancreatitis, or (f) obstructive.\textsuperscript{128} A recent classification system based on histopathology as well as etiology was delineated by Singer and Chari.\textsuperscript{129}

Chronic Calcific (Lithogenic) Pancreatitis

This type is the largest subgroup in the classification scheme proposed by Singer and Chari and includes patients with calcific pancreatitis of most etiologies. Although the majority of patients with calcific pancreatitis have a history of alcohol abuse, stone formation and parenchymal calcification can develop in a variety of etiologic subgroups; hereditary pancreatitis and tropical pancreatitis are particularly noteworthy for the formation of stone disease. The clinician should therefore avoid the assumption that calcific pancreatitis confirms the diagnosis of alcohol abuse.

Anti-inflammatory (Later)

Chronic Obstructive Pancreatitis
This refers to chronic inflammatory changes that are caused by the compression or occlusion of the proximal ductal system by tumor, gallstone, posttraumatic scar, or inadequate duct caliber (as in pancreas divisum). Obstruction of the main pancreatic duct by inflammatory (posttraumatic) or neoplastic processes can result in diffuse fibrosis, dilated main and secondary pancreatic ducts, and acinar atrophy. The patient may have little in

Chronic Inflammatory Pancreatitis

Chronic inflammatory pancreatitis is characterized by diffuse fibrosis and a loss of acinar elements with a predominant mononuclear cell infiltration throughout the gland.

A variant of chronic pancreatitis is a nonobstructive, diffusely infiltrative disease associated with fibrosis, a mononuclear cell (lymphocyte, plasma cell, or eosinophil) infiltrate, and an increased titer of one or more autoantibodies. This type, referred to as autoimmune pancreatitis (AIP), is associated with a variety of illnesses with suspected or proven autoimmune etiology, such as Sjögren’s syndrome, rheumatoid arthritis, and type 1 diabetes mellitus. AIP has been characterized as either type I, with accompanying systemic or multiorgan dysfunction, or type II, which is restricted to the pancreas.

Compressive stenosis of the intrapancreatic portion of the common bile duct is frequently seen in both types of AIP, along with symptoms of obstructive jaundice. Increased levels of serum β-globulin or immunoglobulin G4 are also present. Steroid therapy is uniformly successful in ameliorating the disease, including any associated bile duct compression. CFTR mutations that result in dislocation of the transmembrane protein have been found in AIP, and steroid therapy results in a normalization of the CFTR localization and a resumption of normal chloride and bicarbonate secretion. The differential diagnosis includes lymphoma, plasmacytoma (“pseudotumor” of the pancreas) and diffuse infiltrative carcinoma. Although the diagnosis is confirmed on pancreatic biopsy, presumptive treatment with steroids is usually undertaken, especially when clinical and laboratory findings, such as an elevation in IgG4 levels, support the diagnosis. Failure to obtain a cytologic specimen may lead to an unnecessary resectional procedure, and an untreated inflammatory component may cause sclerosis of the extrahepatic or intrahepatic bile ducts, with eventual liver failure.
**Tropical (Nutritional) Pancreatitis**

Chronic pancreatitis is highly prevalent among adolescents and young adults in Indonesia, southern India, and tropical Africa. Abdominal pain develops in adolescence, followed by the development of a brittle form of pancreateogenic diabetes. Parenchymal and intraductal calcifications are seen, and the pancreatic duct stones may be quite large. Many of the patients appear malnourished, some present with extreme emaciation, and a characteristic cyanotic coloration of the lips may be seen. In addition to protein-calorie malnutrition, toxic products of some indigenous foodstuffs have also been thought to contribute to the disease. Because of the geographic concentration of this early-onset form of chronic pancreatitis, it has been termed tropical pancreatitis, although the exact etiology remains unclear.

Clinically, tropical pancreatitis presents much like hereditary pancreatitis, and a familial pattern among cases is not unusual. *SPINK1* mutations have been documented in 20% to 55% of patients with tropical pancreatitis, and *CFTR* mutations have been reported as well. The accelerated deterioration of endocrine and exocrine function, the chronic pain due to obstructive disease, and the recurrence of symptoms despite decompressive procedures characterize the course of disease. As immigrants from the tropical regions increasingly find their way to all parts of the world, an awareness of this severe form of chronic pancreatitis is helpful for those who treat patients with pancreatic disease.

**Asymptomatic Pancreatic Fibrosis**

Pancreatic fibrosis is seen in some asymptomatic elderly patients, in tropical populations, or in asymptomatic alcohol users. There is diffuse perilobular fibrosis and a loss of acinar cell mass, but there is not a main ductular component. In addition, the presence of fibrosis and decreased exocrine function in patients with diabetes has raised the question of whether long-standing diabetes is a cause of chronic pancreatitis. Patients with this entity are usually asymptomatic in terms of typical pancreatic pain, and a recent histopathologic study of patients with typical chronic pancreatitis and “diabetic exocrine pancreatopathy” reveals significant differences in morphology, including a virtual absence of duct distortion or obstruction (Fig. 33-21).

It remains unknown whether this form of chronic inflammation precedes or contributes to the roughly twofold increase in the risk of pancreatic cancer in patients with long-standing diabetes.

**Idiopathic Pancreatitis**

When a definable cause for chronic pancreatitis is lacking, the term idiopathic is used to categorize the illness. Classically, the idiopathic group includes young adults and adolescents who lack a family history of pancreatitis but who may represent individuals with spontaneous gene mutations encoding regulatory proteins in the pancreas. A variable percentage of *SPINK1* and *CFTR* mutations have been described in various studies. In addition, the idiopathic group has included a large number of older patients for whom no obvious cause of recurrent or chronic pancreatitis can be found. However, because the prevalence of biliary calculi increases steadily with age, it is not surprising that, as methods of biliary stone detection have improved, many elderly “idiopathic” pancreatitis patients are found to have biliary tract disease.

An increasing number of mutations of the *SPINK1* and *CFTR* genes have been identified in association with various forms of chronic pancreatitis. However, the role of genetic analysis in the management of these patients remains unclear, as guidelines have yet to be developed to allow physicians to use the data consistently. Although the clinical management of patients who harbor a minor *CFTR* mutation and chronic pancreatitis, for example, is still dictated by the clinical manifestations of the pancreatitis, recent data suggest that the etiology of chronic pancreatitis, rather than the morphology, may determine the response to surgical treatment.

A shortcoming of these clinical classification systems is the lack of histologic criteria of chronic inflammation due to the usual absence of a biopsy specimen. The differentiation of recurrent acute pancreatitis from chronic pancreatitis with exacerbations of pain can be difficult to establish and is not facilitated by the current system. Similarly, cystic fibrosis is known to cause fibrosis and acinar dysfunction but is not included in the classification despite increasing evidence for its possible role in idiopathic chronic pancreatitis. Therefore, further refinements in the classification system for chronic pancreatitis...
are needed to allow a better prediction of its clinical course and a more accurate diagnosis of a likely etiologic agent.

**Pathology**

**Histology.** In early chronic pancreatitis, the histologic changes are unevenly distributed and are characterized by induration, nodular scarring, and lobular regions of fibrosis (Fig. 33-22). As the disease progresses, there is a loss of normal lobulation, with thicker sheets of fibrosis surrounding a reduced acinar cell mass and dilatation of ductular structures (Fig. 33-23). The ductular epithelium is usually atypical and may display features of dysplasia, as evidenced by cuboidal cells with hyperplastic features, accompanied by areas of mononuclear cell infiltrates or patchy areas of necrosis. Cystic changes may be seen, but areas of relatively intact acinar elements and normal-appearing islets persist. In severe chronic pancreatitis, there is considerable replacement of acinar tissue by broad, coalescing areas of fibrosis, and the islet size and number are reduced (Fig. 33-24). Small arteries appear thickened, and neural trunks become prominent.¹⁴⁷

Tropical pancreatitis and hereditary pancreatitis are histologically indistinguishable from chronic alcoholic pancreatitis. In obstructive chronic pancreatitis, calculi are absent, although periacinar fibrosis and dilated ductular structures are prominent. In pancreatic lobular fibrosis seen in elderly subjects, small ducts are dilated, sometimes with small calculi trapped within. Hypertrophy of ductular epithelia is thought to cause this small-duct disease, which is accompanied by perilobular fibrosis.¹⁴⁸

**Fibrosis.** A common feature of all forms of chronic pancreatitis is the perilobular fibrosis that forms surrounding individual acini, then propagates to surround small lobules, and eventually coalesces to replace larger areas of acinar tissue. The pathogenesis of this process involves the activation of pancreatic stellate cells (PSCs) that are found adjacent to acini and small arteries.¹⁴⁹ The extended cytoplasmic processes of PSCs encircle the acini but appear quiescent in the normal gland, where they contain lipid vacuoles and cytoskeletal proteins. In response to pancreatic injury, the PSCs become activated and proliferate (similarly to hepatic stellate cells), lose their lipid vesicles, and transform into myofibroblast-like cells. These cells respond to proliferative factors such as transforming growth factor β, platelet-derived growth factor, and proinflammatory cytokines that synthesize and secrete type I and III collagen and fibronectin. Studies indicate that vitamin A metabolites, similar to those present in quiescent PSCs, can inhibit the collagen production of activated cultured PSCs.¹⁵⁰ This raises the possibility that early intervention may be possible to interrupt or prevent the fibrosis resulting from ongoing activation of PSCs.

The overall pathogenic sequence proposed by Schneider and Whitcomb¹⁵¹ whereby alcohol induces acute pancreatitis and, with ongoing exposure, promotes the development of chronic fibrosis, is summarized in Fig. 33-19. PSCs surrounding the acinus are activated in acute pancreatitis but may be inactivated by anti-inflammatory cytokines and, in the absence of further injury, may revert to a quiescent state. The role of proinflammatory macrophages, cytokines, and PSCs in models of acute and chronic pancreatitis represents an important area of current research.

**Stone Formation.** Pancreatic stones are composed largely of calcium carbonate crystals trapped in a matrix of fibrillar and other material. The fibrillar center of most stones contains no
calcium but rather a mixture of other metals. This suggests that stones form from an initial noncalcified protein precipitate, which serves as a focus for layered calcium carbonate precipitation. The same low molecular weight protein is present in stones and protein plugs and was initially named pancreatic stone protein, or PSP.\textsuperscript{152} PSP was found to be a potent inhibitor of calcium carbonate crystal growth and has subsequently been renamed lithostathine.\textsuperscript{153} Independently, a 15-kDa fibrillar protein isolated from the pancreas was named pancreatic thread protein, and it has been shown to be homologous with lithostathine. Finally, a protein product of the \textit{reg} gene, so named because it is expressed in association with regenerating islets in models of pancreatic injury, was isolated and called \textit{reg} protein and was subsequently found to be homologous with lithostathine.\textsuperscript{154} The PSP/pancreatic thread protein/\textit{reg}/lithostathine gene encodes for a 166-amino acid product that undergoes posttranslational modification to produce isoforms present in pancreatic juice. The protein is expressed in all rodents and mammals, both in the pancreas as well as in brain tissue, where it is found in particularly high concentrations in pyramidal neurons in Alzheimer’s disease and Down syndrome. It is also found in the renal tubules, which is consistent with its biologic action of preventing calcium carbonate precipitation.

Calcium and bicarbonate ions are normally present in pancreatic juice in high concentrations, and the solubility product of calcium carbonate is greatly exceeded under normal conditions. Microcrystals of calcium carbonate can be seen in normal pancreatic juice but are usually clinically silent. Lithostathine is a potent inhibitor of calcium carbonate crystal formation, at a concentration of only 0.1 \(\mu\text{mol/L}\). However, lithostathine concentrations in normal pancreatic juice are in the range of 20 to 25 \(\mu\text{mol/L}\), so a constant suppression of calcium carbonate crystal formation is present in the normal pancreas.

In alcoholics and in patients with alcoholic chronic pancreatitis, lithostathine expression and secretion are dramatically inhibited\textsuperscript{155} (Fig. 33-25). In addition, elevated levels of precipitated lithostathine in the duct fluid in chronic pancreatitis patients suggests that the availability of the protein may be further reduced by the action of increased proteases and other proteins present in the duct fluid of alcoholic patients. Increased pancreatic juice protein levels in alcoholic men are reversible by abstinence from alcohol,\textsuperscript{156} so the availability and effectiveness of lithostathine may be restored in patients with early-stage disease by timely intervention. Nevertheless, calcific stone formation represents an advanced stage of disease, which can further promote injury or symptoms due to mechanical damage to duct epithelium or obstruction of the ductular network.

**Duct Distortion.** Although calcific stone disease is normally a marker for an advanced stage of disease, parenchymal and ductular calcifications do not always correlate with symptoms. Obstructing main duct stones are commonly observed and are thought to be an indication for endoscopic or surgical removal. The ball-valve effect of a stone in a secreting system produces inevitable episodes of duct obstruction, usually accompanied by pain. But some patients with complete duct obstruction have prolonged periods of painlessness. Ductular hypertension has been documented in patients with proximal stenosis of the main pancreatic duct, and prolonged ductular distention after secretin administration is taken as a sign of ductular obstruction.\textsuperscript{157} Although calculus disease and duct enlargement appear together as late stages of chronic pancreatitis, controversy persists over whether they are associated, are independent events, or are causally related.

**Radiology.** Radiologic imaging of chronic pancreatitis assists in four areas: (a) diagnosis, (b) the evaluation of severity of disease, (c) detection of complications, and (d) assistance in determining treatment options.\textsuperscript{158} With the advent of cross-sectional imaging techniques such as CT and MRI, the contour, content, ductal pattern, calcifications, calculi, and cystic disease of the pancreas are all readily discernible. Transabdominal ultrasonography is frequently used as a screening method for patients with abdominal symptoms or trauma, and the extension of ultrasonic imaging to include endoscopic ultrasound (EUS) and laparoscopic US have resulted in the highest-resolution images that are capable of detecting very small (<1 cm) abnormalities in the pancreas. EUS is now frequently used as a preliminary step in the evaluation of patients with pancreatic disease, and magnetic resonance cholangiopancreatography (MRCP) is increasingly being used to select patients who are candidates for the most invasive imaging method, ERCP. The staging of disease is important in the care of patients, and a combination of imaging methods is usually used (Table 33-12).

Ultrasonography is frequently used as an initial imaging method in patients with abdominal symptoms, and changes consistent with pancreatic duct dilatation, intraductal filling defects, cystic changes, and a heterogeneous texture are seen in chronic pancreatitis (Fig. 33-26). The sensitivity of transabdominal ultrasonography ranges from 48\% to 96\%, and it is operator dependent.\textsuperscript{159} However, the contour, texture, and ductal pattern are usually quite discernible, and it is a reliable method for periodic reexamination to determine the efficacy of treatment.

EUS has heavily impacted the evaluation and management of patients with chronic pancreatitis. Although it is more operator dependent than transabdominal ultrasonography, EUS provides not only imaging capability but also adds the capacity to obtain cytologic and chemical samples of tissue and fluid aspirated with linear array monitoring (Fig. 33-27). EUS images obtained through a high-frequency (7.5- to 12.5-mHz) transducer are able to evaluate subtle changes in 2- to 3-mm

Structures within the pancreas and can detect indolent neoplasms in the setting of chronic inflammation. Small intraductal lesions, intraductal mucous cystic lesions, and sub ductular abnormalities are recognizable by EUS (Table 33-13). This allows ERCP to be reserved for these patients who require therapeutic maneuvers, or for the evaluation of more complex problems. EUS is comparable to ERCP in the detection of advanced changes in chronic pancreatitis and may be more sensitive than ERCP in the detection of mild disease.160

CT scanning has affected the diagnosis of pancreatic disease more broadly than any other method. With the advent of faster helical CT scanning and CT angiography, visualization of the nature, extent, location, and relative relationships of pancreatic structures and lesions is possible with great clarity. Duct dilatation, calculous disease, cystic changes, inflammatory events, and anomalies are all detectable with a resolution of 3 to 4 mm (Fig. 33-28). CT scanning has a false-negative rate of <10% for chronic pancreatitis, but early or mild chronic disease may go undetected by CT imaging. The earliest changes are dilatation of secondary ducts and heterogeneous parenchymal changes, which are detectable by EUS and ERCP. Another drawback of CT scanning is its lower sensitivity for detecting small neoplasms, which are seen with increased frequency in chronic pancreatitis and may be invisible to all modalities except EUS.

An MRI, in both the cross-sectional mode and the coronally oriented heavily weighted T2 or high spin ratio imaging structures within the pancreas and can detect indolent neoplasms in the setting of chronic inflammation. Small intraductal lesions, intraductal mucous cystic lesions, and sub ductular abnormalities are recognizable by EUS (Table 33-13). This allows ERCP to be reserved for these patients who require therapeutic maneuvers, or for the evaluation of more complex problems. EUS is comparable to ERCP in the detection of advanced changes in chronic pancreatitis and may be more sensitive than ERCP in the detection of mild disease.160

(MRCP) that can disclose fluid-filled ducts and cystic lesions, has added greatly to the imaging options for chronic pancreatitis (Fig. 33-29). The resolution of cross-sectional MRI scanning is now approaching that of CT scanning, although the availability of MRI scanners and the complexity of the images produced have limited their large-scale use for routine imaging of the pancreas. MRCP has been shown to be an effective screening technique for disclosing ductal abnormalities that correlate closely with the contrast-filled ducts imaged by ERCP. The advantages of MRCP include its noninvasive methodology and its ability to image obstructed ducts that are not opacified by ERCP injection. It is therefore a useful screening study to detect duct abnormalities and to confirm the need for interventional procedures. Oral, IV, and intraductal contrast are unnecessary for MRCP, and its lack of ionizing radiation makes this the safest method to image the ductal system in high-risk patients.

For the diagnosis and staging of chronic pancreatitis, ERCP is considered to be the gold standard. It also serves as a vehicle that enables other diagnostic and therapeutic maneuvers, such as biopsy or brushing for cytology, or the use of stents to relieve obstruction or drain a pseudocyst (Fig. 33-30).
Unfortunately, ERCP also carries a risk of procedure-induced pancreatitis that occurs in approximately 5% of patients.\textsuperscript{161} Patients at increased risk include those with sphincter of Oddi dysfunction and those with a previous history of post-ERCP pancreatitis. Post-ERCP pancreatitis occurs after uncomplicated procedures, as well as after those that require prolonged manipulation. Severe pancreatitis and deaths have occurred after ERCP. It should be reserved for patients in whom the diagnosis is unclear despite the use of other imaging methods, or in whom a diagnostic or therapeutic maneuver is specifically indicated.

**Presentation, Natural History, and Complications**

**Presenting Signs and Symptoms.** Pain is the most common symptom of chronic pancreatitis. It is usually midepigastric in location but may localize or involve either the left or right upper quadrant of the abdomen. Occasionally, it is perceived in the lower midabdomen but is frequently described as penetrating through to the back (Fig. 33-31). The pain is typically steady and boring, but not colicky. It persists for hours or days and may be chronic with exacerbations caused by eating or drinking alcohol. Chronic alcoholics also describe a steady, constant pain that is temporarily relieved by alcohol, followed by a more severe recurrence hours later.

Patients with chronic pancreatic pain typically flex their abdomen and either sit or lie with their hips flexed, or lie on their side in a fetal position. Unlike ureteral stone pain or biliary colic, the pain causes the patient to be still. Nausea or vomiting may accompany the pain, but anorexia is the most common associated symptom.

Pain from chronic pancreatitis has been ascribed to multiple etiologies. Ductal hypertension, due to strictures or stones, may predispose to pain that is initiated or exacerbated by eating. Chronic pain without exacerbation may be related to parenchymal disease or retroperitoneal inflammation with persistent neural involvement. Acute exacerbations of pain in the setting of chronic pain may be due to acute increases in duct pressure or recurrent episodes of acute inflammation in the setting of chronic parenchymal disease. Nealon and Matin have described these various pain syndromes as being predictive of the response to various surgical procedures.\textsuperscript{162} Pain that is found in association with ductal hypertension is most readily relieved by pancreatic duct decompression, through endoscopic stenting or surgical decompression.

The surgical relief of pain due to obstructive pancreatopathy may be dependent on the degree of underlying fibrosis and the etiology of the disease rather than the presence of ductal obstruction, per se, according to a recent studies from Johns Hopkins. Cooper et al studied 35 patients with chronic pain associated with evidence of duct obstruction who were treated with local resection of the pancreatic head and longitudinal pancreaticojejunostomy (LR-LPJ), or Frey procedure.\textsuperscript{163} The degree of pain resolution after surgery was compared to the degree of underlying parenchymal fibrosis. After a follow-up that averaged 22 months, patients with more than 80% fibrosis had 100% pain relief, whereas only 60% patients with less than 10% fibrosis experienced substantial or complete pain relief. Subsequently, this group studied 60 patients who had undergone either the Frey procedure or the Whipple procedure for refractory pain due to chronic pancreatitis.\textsuperscript{164} In addition to histopathologic findings, they also analyzed the etiology of the disease. Of patients with “toxic” etiologies of acquired disease (i.e., a history of alcohol or tobacco abuse), 89% experienced prolonged pain relief, whereas only 39% of those with hereditary or idiopathic disease achieved this result. Further, these results were independent of the degree of pancreatic fibrosis. These findings suggest that the etiology of the disease may be the most important predictor of the benefit of a resectional or hybrid procedure, and that patients with idiopathic or hereditary disease might be considered for an alternative approach, such as total pancreatectomy with islet autotransplantation (see following section).

The pain of chronic pancreatitis may decrease or disappear completely over a period of years, as symptoms of exocrine and endocrine deficiency become apparent.\textsuperscript{164} This is referred to as burned out pancreatitis and correlates with the progression of disease from a mild or moderate stage to severe destruction of the pancreas. Although this evolution of painful to nonpainful disease is sometimes used as a justification to avoid intervention in painful chronic pancreatitis, noninterventional approaches to the treatment of chronic pancreatitis are inevitably accompanied by the development of narcotic addiction, inability to work, and the sequelae of chronic illness.

Although increased ductal pressure, and therefore parenchymal pressure, has been thought to be the cause of pain in chronic obstructive pancreatitis, the role of chronic inflammation per se, and the development of actual nerve damage in the diseased gland, are also thought to contribute to pain.\textsuperscript{165} Chronic inflammation results in the infiltration of tissue by macrophages, which secrete prostaglandins and other nociceptive agents that cause chronic stimulation of afferent neural fibers. Inflammatory damage to the perineural layers surrounding the unmyelinated pancreatic nerves and a focal infiltration of inflammatory cells around nerves suggest that neural fibers are a target for the cellular response to inflammation in the pancreas.\textsuperscript{166}

Strategies to relieve pain are therefore based on three approaches: (a) reducing secretion and/or decompress the secretory compartment, (b) resecting the focus of chronic inflammatory change, or (c) interrupting the transmission of afferent neural impulses through neural ablative procedures. A trial of antisecretory therapy or endoscopic duct drainage may select those patients who will benefit preferentially from a decompressive procedure.

---

**Figure 33-31.** Pain location in chronic pancreatitis. (Reproduced with permission from Greenfield LJ, Mulholland MW, Oldham KT, et al: Surgery, Scientific Principles and Practice, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2001.)
Patients with chronic pain due to chronic pancreatitis are often treated for years with escalating doses of narcotics, which imposes the additional problem of opioid dependency on this population. Further, it is now apparent that the pain pattern of many patients may be described as being either “visceral pain,” caused by inflammation in and around the pancreas, or “central sensitization of pain,” which is a syndrome of increased pain perception and sensitivity caused by the prolonged presence of pain\(^\text{167}\) (Fig. 33-32). Recent studies have suggested a method to differentiate these pain processes and further suggest that drugs that decrease or ameliorate the central sensitization of pain, such as pregabalin and tramadol, may be especially useful in chronic pancreatitis patients.\(^\text{168}\) These methods of differential diagnosis of pain syndromes now appear to offer the means by which it is possible to further identify and predict which patients will benefit from a surgical approach to chronic pancreatitis.\(^\text{169}\)

**Malabsorption and Weight Loss.** When pancreatic exocrine capacity falls below 10% of normal, diarrhea and steatorrhea develop\(^\text{170}\) (Fig. 33-33). Patients describe a bulky, foul-smelling, loose (but not watery) stool that may be pale in color and float on the surface of toilet water. Frequently, patients will describe a greasy or oily appearance to the stool, or may describe an “oil slick” on the water’s surface. In severe steatorrhea, an orange,
oily stool is often reported. As exocrine deficiency increases, symptoms of steatorrhea are often accompanied by weight loss. Patients may describe a good appetite despite weight loss or diminished food intake due to abdominal pain.

In severe symptomatic chronic pancreatitis, anorexia or nausea may occur with or separate from abdominal pain. The combination of decreased food intake and malabsorption of nutrients usually results in chronic weight loss. As a result, many patients with severe chronic pancreatitis are below ideal body weight.

Lipase deficiency tends to manifest itself before trypsin deficiency, so the presence of steatorrhea may be the first functional sign of pancreatic insufficiency. As pancreatic exocrine function deteriorates further, the secretion of bicarbonate into the duodenum is reduced, which causes duodenal acidification and further impairs nutrient absorption. Pancreatic exocrine insufficiency is frequently asymptomatic, however, and pancreatic exocrine function is difficult to measure, so a diagnosis of chronic pancreatitis is sufficient to justify a trial of pancreatic enzyme supplements. Each meal should be followed by 90,000 United States Pharmacopeia units of lipase, and the metabolic and symptomatic status of the patients should be followed.

Pancreatogenic Diabetes. The islets comprise only 2% of the mass of the pancreas, but they are preferentially conserved when pancreatic inflammation occurs. In chronic pancreatitis, acinar tissue loss and replacement by fibrosis is greater than the degree of loss of islet tissue. Islets are typically smaller than normal and may be isolated from their surrounding vascular network by the fibrosis. With progressive destruction of the gland, endocrine insufficiency commonly occurs. Frank diabetes is seen initially in about 20% of patients with chronic pancreatitis, and impaired glucose metabolism can be detected in up to 70% of patients. In a study of 500 patients with predominantly alcoholic chronic pancreatitis, diabetes developed in 83% within 25 years of the clinical onset of chronic pancreatitis, and more than half of the diabetic patients required insulin treatment. Ketoacidosis and diabetic nephropathy are relatively uncommon in pancreatogenic diabetes (see Table 33-3), but retinopathy and neuropathy are seen to occur with a similar frequency as in type 1 and type 2 diabetes.

Pancreatogenic diabetes is most common in cases of chronic pancreatitis, and it is often seen after surgical resection for benign or malignant disease (Fig. 33-34). Distal pancreatectomy and Whipple procedures have a higher incidence of diabetes than do drainage procedures, and the severity of diabetes is usually worse after subtotal or total pancreatectomy. Pancreatogenic, or type 3c diabetes (T3cDM), is seen in cystic fibrosis, in association with pancreatic cancer, and in cases of severe hemochromatosis.

The etiology and pathophysiology of pancreatogenic diabetes is distinct from that of either autoimmune (type 1) or obesity-related (type 2) diabetes. In type 3c diabetes, the loss of functioning pancreatic tissue by disease or surgical removal results in a global deficiency of all three glucoregulatory islet cell hormones: insulin, glucagon, and PP. In addition, there is a paradoxical combination of enhanced peripheral sensitivity to insulin and decreased hepatic sensitivity to insulin. As a result, insulin therapy is frequently difficult; patients are hyperglycemic when insulin replacement is insufficient (due to unsuppressed hepatic glucose production) or hypoglycemic when insulin replacement is barely excessive (due to enhanced peripheral insulin sensitivity and a deficiency of pancreatic glucagon secretion to counteract the hypoglycemia). This form of diabetes is referred to as brittle diabetes and requires special attention.

PP deficiency correlates with the severity of chronic pancreatitis, and impairments in the hepatic action of insulin are reversed in PP-deficient chronic pancreatitis patients by administration of PP. In addition, a study of type 1 and type 3c diabetic patients treated with insulin pump therapy revealed that the addition of a continuous subcutaneous infusion of PP reduced the insulin requirements needed for glycemic control. Studies are currently underway to identify a clinically suitable PP analog or PP receptor agonist.

Laboratory Studies. The diagnosis of chronic pancreatitis depends on the clinical presentation, a limited number of indirect measurements that correlate with pancreatic function, and selected imaging studies (Table 33-14). The direct measurement of pancreatic enzymes (e.g., lipase and amylase) by blood test is highly sensitive and fairly specific in acute pancreatitis but is seldom helpful in the diagnosis of chronic pancreatitis. The pancreatic endocrine product that correlates most strongly with chronic pancreatitis is the PP response to a test meal (Fig. 33-35). Severe chronic pancreatitis is associated with a blunted or absent PP response to feeding but, as with many other tests, a normal PP response does not rule out the presence of early disease.

Tests for chronic pancreatitis

I. Measurement of pancreatic products in blood
   A. Enzymes
   B. Pancreatic polypeptide

II. Measurement of pancreatic exocrine secretion
   A. Direct measurements
      1. Enzymes
      2. Bicarbonate
   B. Indirect measurement
      1. Bentiromide test
      2. Schilling test
      3. Fecal fat, chymotrypsin, or elastase concentration
      4. [14C]-olein absorption

III. Imaging techniques
   A. Plain film radiography of abdomen
   B. Ultrasonography
   C. Computed tomography
   D. Endoscopic retrograde cholangiopancreatography
   E. Magnetic resonance cholangiopancreatography
   F. Endoscopic ultrasonography

The measurement of pancreatic exocrine secretion requires aspiration of pancreatic juice from the duodenum after nutrient (Lundh test meal) or hormonal (CCK or secretin) stimulation. Direct aspiration of pancreatic juice by endoscopic cannulation of the duct is performed in some centers, but it is not risk free, comfortable for the patient, or more sensitive than luminal intubation methods.

Indirect tests of pancreatic exocrine function are based on the measurement of metabolites of compounds that are altered (“digested”) by pancreatic exocrine products and can be quantified by serum or urine measurements. A commonly used indirect test is the bentiromide test, in which pancreatic polypeptide (PP) response to a test meal.

Figure 33-35. Pancreatic polypeptide (PP) response to a test meal. Immunoreactive PP (IR-PP) responses in control subjects (NL, n = 6) and patients with severe chronic pancreatitis (CP) accompanied by PP deficiency (CP, n = 5) are shown. A test meal was administered at 0 minutes. Means ± standard error of the mean are shown. (Reproduced with permission from Brunicardi FC, Chaiken RL, Ryan AS, et al. Pancreatic polypeptide administration improves abnormal glucose metabolism in patients with chronic pancreatitis, J Clin Endocrinol Metab. 1996 Oct;81(10):3566-3572.)

EUS findings may be inconclusive in mild or “minimal change” pancreatitis, however, and improved criteria for an EUS-based diagnosis are still a work in progress. Most importantly, EUS is highly reliable in ruling out pancreatic carcinoma when CT findings are normal or equivocal.

Prognosis and Natural History. The prognosis for patients with chronic pancreatitis is dependent on the etiology of the disease, the development of complications, and on the age and socioeconomic status of the patient. The influence of treatment is less evident in long-term studies, although the general absence of randomized, prospective trials clouds the issue of whether specific forms of therapy alter the long-term outlook for patients with the disease.

Several studies have demonstrated that, although symptoms of pain decrease over time in about half of the patients, this decline is also accompanied by a progression of exocrine and endocrine insufficiency. In general, the likelihood of eventual pain relief is dependent upon the stage of disease at diagnosis, and the persistence of alcohol use in patients with alcoholic chronic pancreatitis. Miyake and colleagues found that pain relief was achieved in 60% of alcoholic patients who successfully discontinued drinking, but in only 26% who did not.

The long-term survival of patients with chronic pancreatitis is less than for patients without pancreatitis. In an international multicenter study of >2000 patients, Lowenfels and colleagues found that the 10- and 20-year survival rates for patients with chronic pancreatitis were 70% and 45%, respectively, compared to 93% and 65% for patients without pancreatitis. The mortality risk was found to be 1.6-fold higher in patients who continued to abuse alcohol, compared to those who did not. Continued alcohol abuse has a similar effect on the response to surgical treatment (Fig. 33-36), and results in a twofold increase in mortality over a 10- to 14-year follow-up period.

In addition to progressive endocrine and exocrine dysfunction, and the risk of the specific complications outlined here and in Table 33-16, the other significant long-term risk for the patient with chronic pancreatitis is the development of pancreatic carcinoma. There is a progressive, cumulative increased risk of carcinoma development in patients with chronic pancreatitis, which continues throughout the subsequent lifetime of the patient (Fig. 33-37). The incidence of carcinoma in patients with chronic pancreatitis ranges from 1.5% to 6%, which is at least 10-fold greater than that of patients of similar age seen in a hospital setting. In patients with chronic pancreatitis accompanied by diabetes, the risk of carcinoma has been found to be increased 12- to 33-fold compared to healthy, comparably aged controls. In patients with advanced chronic pancreatitis referred for surgical therapy, indolent, undiagnosed carcinoma can be seen in as many as 10% of patients.

The development of carcinoma in the setting of chronic pancreatitis is no doubt related to the dysregulation of cellular proliferation and tissue repair processes in the setting of chronic inflammation, as is seen throughout the alimentary tract and elsewhere. In the setting of chronic pancreatitis, carcinoma development can be especially cryptic, and the diagnosis of early-stage tumors is particularly difficult. Awareness of this risk justifies close surveillance for cancer in patients with chronic pancreatitis. Periodic measurement of tumor markers such as CA19-9, and periodic imaging of the pancreas with CT scan and EUS seem logical in order to detect the development

of carcinoma in the patient with chronic pancreatitis, although no evidence exists to indicate that this alters the outcome of patients who develop pancreatic cancer. Surgical procedures, particularly drainage procedures performed for presumed chronic pancreatitis, should always include biopsy of the tissue to exclude the diagnosis of malignancy.

**Complications**

**Pseudocyst.** A chronic collection of pancreatic fluid surrounded by a nonepithelialized wall of granulation tissue and fibrosis is referred to as a pseudocyst. Pseudocysts occur in up to 10% of patients with acute pancreatitis, and in 20% to 38% of patients with chronic pancreatitis, and thus, they comprise the most common complication of chronic pancreatitis. The identification and treatment of pseudocysts requires definition of the various forms of pancreatic fluid collections that occur (Table 33-17). In chronic pancreatitis, a pancreatic duct leak with extravasation of pancreatic juice results in a peripancreatic fluid collection (PPFC). Over a period of 3 to 4 weeks, the PPFC is sealed by an inflammatory reaction that leads to development of a wall of acute granulation tissue without much fibrosis. This is referred to as an acute pseudocyst. Acute pseudocysts may resolve spontaneously in up to 50% of cases, over a course of 6 weeks or longer. Pseudocysts >6 cm resolve less frequently than smaller ones but may regress over a period of weeks to months. Pseudocysts are multiple in 17% of patients, or they may be multiloculated. They may occur intrapancreatically or extend beyond the region of the pancreas into other cavities or compartments (Fig. 33-38).

Pseudocysts may become secondarily infected, in which case they become abscesses. They can compress or obstruct adjacent organs or structures, leading to superior mesenteric-portal vein thrombosis or splenic vein thrombosis. They can erode into visceral arteries and cause intracystic hemorrhage or pseudoaneurysms (Fig. 33-39). They also can perforate and cause peritonitis or intraperitoneal bleeding.

### Table 33-17

**Definitions of pancreatic fluid collections**

<table>
<thead>
<tr>
<th>TERM</th>
<th>DEFINITION</th>
</tr>
</thead>
<tbody>
<tr>
<td>Peripancreatic fluid collection</td>
<td>A collection of enzyme-rich pancreatic juice that occurs early in the course of acute pancreatitis, or that forms after a pancreatic duct leak; located in or near the pancreas; it lacks a well-organized wall of granulation or fibrous tissue</td>
</tr>
<tr>
<td>Early pancreatic (sterile) necrosis</td>
<td>A focal or diffuse area of nonviable pancreatic parenchyma, typically occupying &gt;30% of the gland and containing liquefied debris and fluid</td>
</tr>
<tr>
<td>Late pancreatic (sterile) necrosis</td>
<td>An organized collection of sterile necrotic debris and fluid with a well-defined margin or wall within the normal domain of the pancreas</td>
</tr>
<tr>
<td>Acute pseudocyst</td>
<td>A collection of pancreatic juice enclosed within a perimeter of early granulation tissue, usually as a consequence of acute pancreatitis that has occurred within the preceding 3–4 wk</td>
</tr>
<tr>
<td>Chronic pseudocyst</td>
<td>A collection of pancreatic fluid surrounded by a wall of normal granulation and fibrous tissue, usually persisting for &gt;6 wk</td>
</tr>
<tr>
<td>Pancreatic abscess</td>
<td>Any of the above in which gross purulence (pus) is present, with bacterial or fungal organisms documented to be present</td>
</tr>
</tbody>
</table>

Pseudocysts usually cause symptoms of pain, fullness, or early satiety. Asymptomatic pseudocysts can be managed expectantly and may resolve spontaneously or persist without complication. Symptomatic or enlarging pseudocysts require treatment, and any presumed pseudocyst without a documented antecedent episode of acute pancreatitis requires investigation to determine the etiology.
A pseudocyst can erode into an adjacent artery, which results in contained hemorrhage otherwise known as a pseudoaneurysm. A contrast-injected computed tomographic scan reveals active bleeding (area marked B) into a pseudocyst (arrows) as a result of this process. (Reproduced with permission from Balthazar EJ: CT diagnosis and staging of acute pancreatitis, Radiol Clin North Am. 1989 Jan;27(1):19-37.)

The timing and method of treatment requires careful consideration. Pitfalls in the management of pseudocysts result from the incorrect (presumptive) diagnosis of a cystic neoplasm masquerading as a pseudocyst, a failure to appreciate the solid or debris-filled contents of a pseudocyst that appears to be fluid filled on CT scan, and a failure to document true adherence with an adjacent portion of the stomach before attempting transgastric internal drainage.

If the pseudocyst has failed to resolve with conservative therapy and symptoms persist, internal drainage is usually preferred to external drainage to avoid the complication of a pancreaticocutaneous fistula. Pseudocysts communicate with the pancreatic ductal system in up to 80% of cases, so external drainage creates a pathway for pancreatic duct leakage to and through the catheter exit site. Internal drainage may be performed with either endoscopic methods (transgastric or transduodenal puncture and multiple stent placements, with or without a nasocystic irrigation catheter), or surgical methods (a true cystoenterostomy, biopsy of cyst wall, and evacuation of all debris and contents). Surgical options include a cystogastrostomy (Fig. 33-40), a Roux-en-Y cystojejunostomy, or a cystoduodenostomy. Cystojejunostomy is the most versatile method, and it can be applied to pseudocysts that penetrate into the transverse mesocolon, the paracolic gutters, or the lesser sac. Cystogastrostomy can be performed endoscopically (Fig. 33-41), laparoscopically, or by a combined laparoscopic-endoscopic method.

Because pseudocysts often communicate with the pancreatic ductal system, two newer approaches to pseudocyst management are based on main duct drainage, rather than pseudocyst drainage per se. Transpapillary stents inserted at the time of the lesion, including a cystic neoplasm. Although pseudocysts comprise roughly two-thirds of all pancreatic cystic lesions, they resemble cystadenomas and cystadenocarcinoma radiographically. An incidentally discovered cystic lesion should be examined by EUS and aspirated to determine whether it is a true pancreatic cystic neoplasm or a pseudocyst.

Endoscopic ultrasound (EUS)-guided transgastric puncture of pancreatic pseudocyst. A. Transgastric stents placed across fused posterior wall of stomach and anterior wall of pseudocyst. (Reproduced with permission from Chauhan SS, Forsmark CE. Evidence-based treatment of pancreatic pseudocysts, Gastroenterology. 2013 Sep;145(3):511.)
large-bore catheters or multiple stents and an aggressive approach to management for success to be achieved. Failure of nonsurgical therapy, with subsequent salvage procedures to remove infected debris and establish complete drainage, is associated with increased risks for complications and death.\textsuperscript{211,212}

The most experienced therapeutic endoscopists report a complication rate of 17% to 19% for the treatment of sterile pseudocysts, and deaths as a result of endoscopic therapy have occurred.\textsuperscript{212} Therefore, the use of endoscopic methods to treat sterile or infected pancreatic necrosis has a higher complication rate and is limited to specialized centers.

Resection of a pseudocyst is sometimes indicated for cysts located in the pancreatic tail or when a midpancreatic duct disruption has resulted in a distally located pseudocyst. Distal pancreatectomy for removal of a pseudocyst, with or without splenectomy, can be a challenging procedure in the setting of prior pancreatitis. An internal drainage procedure of the communicating duct or of the pseudocyst itself should be considered when distal resection is being contemplated.

**Pancreatic Ascites.** When a disrupted pancreatic duct leads to pancreatic fluid extravasation that does not become sequestered as a pseudocyst, but drains freely into the peritoneal cavity, pancreatic ascites occurs. Occasionally, the pancreatic fluid tracks superiorly into the thorax, and a pancreatic pleural effusion occurs. Referred to as \textit{internal pancreatic fistulae}, both complications are seen more often in patients with chronic pancreatitis rather than after acute pancreatitis. Pancreatic ascites and pleural effusion occur together in 14% of patients, and 18% have a pancreatic pleural effusion alone.\textsuperscript{213}

Patients demonstrate the general demographics of chronic pancreatitis and usually present with a subacute or recent history of progressive abdominal swelling despite weight loss. Pain and nausea are rarely present. The abdominal CT scan discloses ascites and the presence of chronic pancreatitis or a partially collapsed pseudocyst (Fig. 33-43). Paracentesis or thoracentesis reveals noninfected fluid with a protein level >25 g/L and a markedly elevated amylase level. Serum amylase may also be elevated, presumably from reabsorption across the parietal membrane. Serum albumin may be low, and patients may have

coexisting liver disease. Paracentesis is therefore critical to differentiate pancreatic from hepatic ascites.

ERCP is most helpful to delineate the location of the pancreatic duct leak and to elucidate the underlying pancreatic ductal anatomy. Pancreatic duct stenting may be considered at the time of ERCP, but if nonsurgical therapy is undertaken and then abandoned, repeat imaging of the pancreatic duct is appropriate to guide surgical treatment.

Antisecretory therapy with the somatostatin analogue octreotide acetate, together with bowel rest and parenteral nutrition, is successful in more than half of patients. Reappraisal of serosal surfaces to facilitate closure of the leak is considered a part of therapy, and this is accomplished by complete paracentesis. For pleural effusions, a period of chest tube drainage may facilitate closure of the internal fistula. Surgical therapy is reserved for those who fail to respond to medical treatment. If the leak originates from the central region of the pancreas, a Roux-en-Y pancreaticojejunostomy is performed to the site of duct leakage (Fig. 33-44). If the leak is in the tail, a distal pancreatectomy may be considered, or an internal drainage procedure can be performed. The results of surgical treatment are usually favorable if the ductal anatomy has been carefully delineated preoperatively.

Pancreatic-Enteric Fistula. The erosion of a pancreatic pseudocyst into an adjacent hollow viscus can result in a pancreatic-enteric fistula. The most common site of communication is the transverse colon or splenic flexure. The fistula usually presents with evidence of GI or colonic bleeding and sepsis. If the fistula communicates with the stomach or duodenum, it may close spontaneously or persist as a pancreatic-enteric fistula. When the fistula involves the colon, operative correction is usually required.

**Figure 33-44.** Internal drainage for leaking pancreatic duct. A Roux-en-Y pancreaticojejunostomy is performed at the site of duct rupture to accomplish internal drainage of the pancreatic duct leak. (Reproduced with permission from Beger HG: The Pancreas. London: Blackwell-Science; 1998.)

**Head-of-pancreas Mass.** In up to 30% of patients with advanced chronic pancreatitis, an inflammatory mass develops in the head of the pancreas. The clinical presentation includes severe pain and frequently includes stenosis of the distal common bile duct, duodenal stenosis, compression of the portal vein, and stenosis of the proximal main pancreatic duct (Table 33-18). Mutations and polymorphisms of *p53* have been found in these patients, and a focus of ductular carcinoma was found in 3.7% of patients with pancreatic head enlargement in one series. It was concluded that an accelerated transformation from hyperplasia to dysplasia exists in patients with pancreatic head enlargement, although the etiology for this process remains unclear.

**Splenomegaly**. Vascular complications of chronic pancreatitis are fortunately infrequent because they are difficult to treat successfully. Portal vein compression and occlusion can occur as a consequence of an inflammatory mass in the head of the pancreas, and splenic vein thrombosis occurs in association with chronic pancreatitis in 1% to 8% of cases. Variceal formation can occur as a consequence of either portal or splenic venous occlusion, and splenic vein thrombosis with gastric variceal formation is referred to as left-sided or sinistral portal hypertension. Although bleeding complications are infrequent, the mortality risk of bleeding is >20%. When gastroesophageal varices are caused by splenic vein thrombosis, the addition of splenectomy to prevent variceal hemorrhage is prudent when surgery is otherwise indicated to correct other problems.

**Treatment**

**Medical Therapy.** The medical treatment of chronic or recurrent pain in chronic pancreatitis requires the use of analgesics, a cessation of alcohol use, oral enzyme therapy, and the selective use of antisecretory therapy. Interventional procedures to block visceral afferent nerve conduction or to treat obstructions of the main pancreatic duct are also an adjunct to medical treatment.

**Analgesia.** Oral analgesics are prescribed as needed, alone or with analgesia-enhancing agents such as gabapentin. Adequate pain control usually requires the use of narcotics, but these should be titrated to achieve pain relief with the lowest effective dose. Opioid addiction is common, and the use of long-acting analgesics by transdermal patch together with oral agents for pain exacerbations slightly reduces the sedative effects of high-dose oral narcotics.
It is essential for patients to abstain from alcohol. In addition to removing the causative agent, alcohol abstinence results in pain reduction or relief in 60% to 75% of patients with chronic pancreatitis. Despite this benefit, roughly half of alcoholic chronic pancreatitis patients continue to abuse alcohol.

**Enzyme Therapy.** Pancreatic enzyme administration serves to reverse the effects of pancreatic exocrine insufficiency. Adequate pancreatic enzyme replacement reverses the exocrine insufficiency seen in most patients, and it prevents secondary complications such as metabolic bone disease due to inadequate absorption of the fat-soluble vitamins A, D, E, and K. In addition, pancreatic enzyme replacement may reduce or alleviate the pain experienced by patients. The choice of enzyme supplement and the dose should be selected based on whether malabsorption or pain (or both) are the indications for therapy (Table 33-19). Conventional (nonenteric-coated) enzyme preparations are partially degraded by gastric acid but are available within the duodenal and jejunal regions to bind to CCK-releasing peptide and downregulate the release of CCK. This theoretically reduces the enteric signal for pancreatic exocrine secretion, which reduces the pressure within a partially or completely obstructed pancreatic duct. Enteric-coated preparations result in little to no pain relief, presumably due to their reduced bioavailability in the proximal gut. Due to the loss of pancreatic enzymes by acid hydrolysis and proteolysis, relatively large doses are required to achieve effective levels of enzyme within the proximal small bowel. Enteric-coated preparations are protected from acid degradation but are presumably not released in the critical proximal gut in sufficient quantity to inhibit the stimulus for endogenous pancreatic enzyme secretion. Nonalcoholic patients may experience more effective pain relief than alcoholic patients, but it is recommended that all patients with chronic pancreatitis pain begin a trial of nonenteric-coated enzyme supplements together with an acid-suppressive medication for 1 month. If pain relief is achieved, therapy is continued. If enzyme therapy fails, further investigation of the pancreatic ductal system by ERCP guides the therapy based on specific anatomical findings (Fig. 33-45).

**Antisecretory Therapy.** Somatostatin administration has been shown to inhibit pancreatic exocrine secretion and CCK release. The somatostatin analogue octreotide acetate has therefore been investigated for pain relief in patients with chronic pancreatitis. In a double-blind, prospective, randomized 4-week trial, 65% of patients who received 200 μg of octreotide acetate subcutaneously three times daily reported pain relief, compared with 35% of placebo-treated subjects. Patients who had the best results were patients with chronic abdominal pain, suggestive of obstructive pancreatopathy. However, in another trial that used a 3-day duration of treatment, no significant pain relief was observed. Anecdotal reports suggest that severe pain exacerbations in chronic pancreatitis can benefit from a combination of octreotide therapy and TPN, and a pilot study of the effectiveness of the sustained-release form of octreotide suggested that it was as effective as three-times-per-day administration of the short-acting form of the drug.

**Neurolytic Therapy.** Celiac plexus neurolysis with alcohol injection has been an effective form of analgesic treatment in patients with pancreatic carcinoma. However, the use of radiologically or endoscopically guided celiac plexus blockade in chronic pancreatitis has been disappointing. Due to the risk of alcohol injury and the need for repeated injections, celiac plexus blockade in chronic pancreatitis has used short-acting analgesics or other drugs rather than 50% alcohol. A trial of EUS-guided celiac plexus blockade revealed successful pain relief in 55% of patients, but the benefit lasted beyond 6 months in only 10% of patients. The procedure therefore appears safe, but the effect is short lived in those patients who obtain pain relief.

**Endoscopic Management.** The techniques of endoscopic treatment of pancreatic duct obstruction, stone disease, pseudocyst formation, pancreatic duct leak, and for the diagnosis and management of associated pancreatic tumors have expanded greatly over the past 20 years. Newer endoscopes with expanded therapeutic capabilities have been introduced, and the role of EUS-guided needle and catheter insertion has expanded the ability of the therapeutic endoscopist in the diagnosis and treatment of chronic pancreatitis and its complications.

Pancreatic duct stenting is used for treatment of proximal pancreatic duct stenosis, decompression of a pancreatic duct leak, and for drainage of pancreatic pseudocysts that can be catheterized through the main pancreatic duct. Pancreatic duct stents can induce an inflammatory response within the

Make a correct diagnosis
• Appropriate history
• Corroborating imaging tests
  • MRI/MRCP
  • EUS
  • CT
• Functional tests if imaging tests equivocal
  • Tube-based secretin test
  • Endoscopic-based secretin test
• Assess for alternative diseases and complications and treat if present
  • Pancreatic cancer or IPMN
  • Pseudocyst
  • Bile duct obstruction
  • Duodenal obstruction

Medical therapy
• Measure pain severity, character, and impact on QOL
• Refer for formal structured smoking and alcohol cessation programs
• Counsel on good nutrition and initiate supplementation with vitamin D and calcium
  • Baseline bone mineral density testing
• Provide information on local and national support groups
• Initiate analgesics (starting with Tramadol)
  • Increase dose and potency slowly as required
• Initiate adjunctive agents in those with persistent pain or requiring higher dosages or potency of narcotics
  • Pregabalin, Gabapentin
  • SSRI
  • SSNRI
  • Tricyclic antidepressants
• Assess for evidence of coexistent exocrine or endocrine insufficiency and treat if present
  • Fecal elastase or serum trypsin
  • HbA1C or GTT
• Initiate steroids if autoimmune pancreatitis

Figure 33-45. Management algorithm for chronic pancreatitis. duct, so prolonged stenting is usually avoided. Patients with sphincter of Oddi dyskinesia are at high risk for developing post-ERCP pancreatitis after biliary sphincterotomy, and the prophylactic placement of a pancreatic duct stent or the administration of rectal indomethacin reduces the amylase level and development of pancreatitis after biliary sphincterotomy.\textsuperscript{33,228} Pancreatic duct leaks are seen in 37\% of patients with acute pancreatitis, and pancreatic duct stenting appears to facilitate the resolution of the leak.\textsuperscript{229} Similarly, pancreatic duct stenting has been used to treat postsurgical pancreatic duct leaks and posttraumatic leaks.\textsuperscript{229-231}

Pancreas divisum (see Fig. 33-3) is thought to cause pain and chronic pancreatitis due to functional or mechanical obstruction of the dorsal duct draining exclusively, or predominantly, through the lesser papilla. A study from Marseille reported good long-term results in 24 patients after minor papilla sphincterotomy and dorsal duct stenting.\textsuperscript{232} The number of patients with chronic pain decreased from 83\% before stenting to 29\% after stenting, but pancreatitis or recurrent papillary stenosis occurred in 38\%. Patients that responded best were those with intermittent pain, and this subset may be preferentially treated with endoscopic therapy. Patients with recurrent pain and a dilated dorsal duct may be candidates for internal drainage of the obstructed duct with either an extended Puestow procedure or a Frey procedure (see later in this section).

Idiopathic pancreatitis patients have been treated with endoscopic stenting, pancreatic duct sphincterotomy, and endoscopic stone removal with good results. In a prospective randomized trial, 53\% of idiopathic recurrent pancreatitis patients in the control group experienced continued episodes of pancreatitis, although only 11\% of the treated patients had continued symptoms.\textsuperscript{233}

Extracorporeal shock wave lithotripsy (ESWL) has been used for pancreatic duct stones, together with endoscopic stenting and stone removal.\textsuperscript{234} A single ESWL session was used in 35 patients with pancreatic duct stones, together with 86 ERCP sessions to complete the stone removal process. After 2.4 years, 80\% of patients had significant relief of symptoms (Fig. 33-46). Also, endoscopic intraductal lithotripsy can now be performed in some specialized centers. However, due to the tendency for recurrent stone formation, the use of ESWL or endoscopic lithotripsy for long-term management of calcific pancreatitis remains uncertain.

**Surgical Therapy**

**Indications and History** The traditional approach to surgical treatment of chronic pancreatitis and its complications has maintained that surgery should be considered only when the medical therapy of symptoms has failed. Nealon and Thompson published a landmark study in 1993, however, that showed that the progression of chronic obstructive pancreatitis could be delayed or prevented by pancreatic duct decompression.\textsuperscript{235} No other therapy has been shown to prevent the progression of chronic pancreatitis, and this study demonstrated the role of surgery in the early management of the disease (Table 33-20). Small-duct disease or “minimal change chronic pancreatitis” are causes for uncertainty over the choice of operation, however. Major resections have a high complication rate, both early and late, in chronic alcoholic pancreatitis, and lesser procedures often result in symptomatic recurrence. Therefore, the choice of operation and the timing of surgery are based on each patient’s pancreatic anatomy, the likelihood (or lack thereof) that further

Eighty-three patients with chronic pancreatitis were evaluated by exocrine, endocrine, nutritional, and endoscopic retrograde cholangiopancreatography studies, and all had mild to moderate disease and dilated pancreatic ducts. A Puestow-type duct decompression procedure was performed in 47 patients, and all subjects were restaged by the same methods 24 months later.

medical and endoscopic therapy will halt the symptoms of the disease, and the chance that a good result will be obtained with the lowest risk of morbidity and mortality. Finally, preparation for surgery should include restoration of protein-caloric homeostasis, abstinence from alcohol and tobacco, and a detailed review of the risks and likely outcomes to establish a bond of trust and commitment between the patient and the surgeon.

Historically, the surgery for chronic pancreatitis before the second half of the 20th century was a true demonstration of trial and error. Obtaining good surgical outcomes before the availability of CT scans and ERCP was either the result of serendipity or due to the skill and creativity of the surgeon. In 1911, Link described an operation he devised on the spot, when a laparotomy in a young woman with abdominal pain revealed a fluctuant, obstructed pancreatic duct. After performing a dochotomy and evacuating multiple stones, he inserted a rubber tube, and exteriorized the pancreatostomy just above her navel. He later described the operation as having been a success for the next 30 years of the patient’s life, during which the patient managed the care of the drainage tube without apparent problems.

With the demonstration in 1942 by Priestley that total pancreatectomy was technically feasible, and the report in 1946 by Whipple that proximal pancreatic resection was beneficial in (three) patients with chronic pancreatitis, the option of surgical resection as treatment for chronic pancreatitis was established. By the mid 1950s, however, growing disappointment with the high risk of resection and the lack of long-term benefit overshadowed the surgical treatment of chronic pancreatitis. The choice of resection vs. drainage was largely based on surgeon preference until the 1970s, when the widespread adoption of ERCP and CT scans provided the ability to preoperatively diagnose obstructive and sclerotic disease, and this resulted in the rational selection of operative procedures. During this period, the major drawbacks to surgical therapy remained the recurrence of symptoms despite surgery, the corresponding development of an inflammatory (or malignant) mass in the undrained pancreatic head (Fig. 33-47), or the high morbidity and mortality of major resectional procedures that predisposed patients to a cascade of metabolic problems.

**Sphincteroplasty** The sphincter of Oddi and the pancreatic duct sphincter serve as gatekeepers for the passage of pancreatic juice into the duodenum (Fig. 33-48). Stenosis of either sphincter (sclerosing papillitis), due to scarring from pancreatitis or from the passage of gallstones, may result in obstruction of the pancreatic duct and chronic pain. As gallstone pancreatitis became a popular diagnosis in the 1940s and 1950s, attention was focused on the ampullary region as a possible cause of chronic symptoms, and surgical sphincteroplasty was advocated. Although endoscopic techniques are now used routinely to perform sphincterotomy of either the common bile duct or pancreatic duct, a true (permanent)
sphincteroplasty can only be performed surgically. Transduodenal sphincteroplasty with incision of the septum between the pancreatic duct and common bile duct may offer significant relief for the rare patient with a focal obstruction and inflammation isolated to this region (Fig. 33-49).

**Drainage Procedures** After the early reports of success with pancreatostomy for the relief of symptoms of chronic pancreatitis, Cattell described pancreaticojejunostomy for relief of pain in unresectable pancreatic carcinoma. Shortly thereafter, Duval and, separately, Zollinger and associates described the caudal Roux-en-Y pancreaticojejunostomy for the treatment of chronic pancreatitis in 1954 (Fig. 33-50). The so-called Duval procedure was used for decades by some surgeons, but it almost invariably failed due to restenosis and segmental obstruction of the pancreas due to progressive scarring. In 1958, Puestow and Gillesby described these segmental narrowings and dilatations of the ductal system as a “chain of lakes,” and proposed a longitudinal decompression of the body and tail of the pancreas into a Roux limb of jejunum (Fig. 33-51). Four of Puestow and Gillesby’s 21 initial cases were side-to-side anastomoses, and 2 years after their report, Partington and Rochelle described a much simpler version of the longitudinal, or side-to-side Roux-en-Y pancreaticojejunostomy that became universally known as the Puestow procedure (Fig. 33-52).

Successful pain relief after the Puestow-type decompression procedure has been reported in 75% to 85% of patients for the first few years after surgery, but pain recurs in >20% of patients after 5 years due to progressive disease even in patients who are abstinent from alcohol.

With the advent of therapeutic endoscopy and techniques for transluminal stone removal and lithotripsy, multiple series have reported the successful endoscopic treatment of pancreatic duct calculi, although the long-term outcomes of these efforts has been uneven. Endoscopic removal of pancreatic duct stones is usually coupled to prolonged pancreatic duct stenting,
Figure 33-52. Longitudinal dochotomy in obstructing calcific pancreatitis. A longitudinal pancreatotomy typically discloses segmental stenosis of the pancreatic duct and the presence of intraductal calculi in a patient with chronic calcific pancreatitis (A). Following mobilization of a Roux limb of jejunum, a longitudinal pancreaticojejunostomy is performed to permit extensive drainage of the pancreatic duct system (B). This technique, described by Partington and Rochelle, is the typical method used for the Puestow procedure.

which carries the risk of further inflammation.252,253 Despite the risk of perioperative complications, the surgical management of pancreatic duct stones and stenosis has been shown to be superior to endoscopic treatment in randomized clinical trials in which the long, side-to-side technique of pancreaticojejunostomy is used.254-256

Resectional Procedures

Distal Pancreatectomy For patients with focal inflammatory changes localized to the body and tail, or in whom no significant ductal dilatation exists, the technique of partial (40–80%) distal pancreatectomy has been advocated (Fig. 33-53). Although distal pancreatectomy is less morbid than more extensive resectional procedures, the operation leaves untreated a major portion of the gland, and is therefore associated with a significant risk of symptomatic recurrence. It has been a more popular operation in British centers, where its success seems to be greater, perhaps due to the lower incidence of alcoholic chronic pancreatitis.257 However, long-term outcomes reveal good pain relief in only 60% of patients, with completion pancreatectomy required for pain relief in 13% of patients.

Laparoscopic distal pancreatectomy has been shown to be feasible for the removal of focal lesions of the distal pancreas,258 but it is more difficult in the setting of chronic pancreatitis.

Ninety-Five Percent Distal Pancreatectomy In 1965, Fry and Child proposed the more radical 95% distal pancreatectomy, which was intended for patients with sclerotic (small duct) disease and which attempted to avoid the morbidity of total pancreatectomy by preserving the rim of pancreas in the pancreaticoduodenal groove, along with its associated blood vessels and distal common bile duct.241 The operation was found to be associated with pain relief in 60% to 77% of patients long term, but it is accompanied by a high risk of brittle diabetes, hypoglycemic coma, and malnutrition. Although the operation was the first attempt to resect the pancreatic head while preserving the duodenum and distal bile duct, the extensive degree of metabolic complications led to its failure as viable treatment for the symptoms of pancreatic sclerosis.

Proximal Pancreatectomy In 1946, Whipple reported a series of five patients treated with either pancreaticoduodenectomy or total pancreatectomy for symptomatic chronic pancreatitis, with one operative death.240 Subsequently, proximal pancreatectomy or pancreaticoduodenectomy, with or without pylorus preservation (Fig. 33-54), has been widely used for the treatment of chronic pancreatitis.259 In the three largest modern (circa 2000) series of the treatment of chronic pancreatitis by the Whipple

Figure 33-53. Distal (spleen-sparing) pancreatectomy. A distal pancreatectomy for chronic pancreatitis is usually performed with en bloc splenectomy, using either an open or laparoscopic technique. In the presence of minimal inflammation, a spleen-sparing version can be performed, as shown here.
procedure, pain relief 4 to 6 years after operation was found in 71% to 89% of patients. However, mortality ranged from 1.5% to 3%, and major complications occurred in 25% to 38% of patients at the Johns Hopkins Hospital,260 the Mayo Clinic,261 and the Massachusetts General Hospital.262 In follow-up, 25% to 48% of patients developed diabetes, and about the same percentage required exocrine therapy. Advocates of the Whipple procedure as treatment for chronic pancreatitis suggest that the high rate of symptomatic relief outweighs the metabolic consequences and the mortality risk of the procedure, but increasingly this approach is being reserved for those patients with suspected occult malignancy.

Total Pancreatectomy Priestley and associates first described successful total pancreatectomy in 1944 in a patient with hyperinsulinism.239 and two of Whipple’s original five cases of chronic pancreatitis reported in 1946 were treated with total pancreatectomy.240 Subsequently, surgeons who used total pancreatectomy found that the operation produces no better pain relief for their patients than pancreaticoduodenectomy (about 80–85%). Moreover, the metabolic consequences of total pancreatectomy in the absence of islet cell transplantation can be profound and life-threatening. The patients have a “brittle” form of diabetes in which avoidance of hyper- and hypoglycemia is problematic.263 In addition, lethal episodes of hypoglycemia are common in severe apancreatic diabetes. These are due to hypoglycemic unresponsiveness, due to the absence of pancreatic glucagon, and to hypoglycemia unawareness, despite an ongoing need to treat with exogenous insulin.277 In a series of >100 patients treated with total pancreatectomy, Gall and colleagues showed that half of all the late deaths after this operation were due to (iatrogenic) hypoglycemia.264 Despite newer forms of insulin, insulin delivery systems, and continuous blood glucose monitoring systems, severe pancreateogenic diabetes remains an adverse outcome, as complete prevention of the physiologic consequences of total pancreatectomy remains an unfulfilled goal. Even with the growing acceptance of islet auto-transplantation as an adjunct to the procedure (see later in this section), total pancreatectomy itself is now used only rarely for the treatment of refractory chronic pancreatitis.

Hybrid Procedures In 1980, Beger and associates described the Duodenum-preserving Pancreatic Head Resection or DPPHR265 (Fig. 33-55), and they published long-term results with DPPHR for the treatment of chronic pancreatitis in 1985266 and again in 1999.267 In 388 patients who were followed for an average of 6 years after DPPHR, pain relief was reportedly maintained in 91%, mortality was <1%, and diabetes developed in 21%, with 11% demonstrating a reversal of their preoperative diabetic status. These authors also compared the DPPHR procedure with the pylorus-sparing Whipple procedure in a randomized trial of 40 patients with chronic pancreatitis.268 The mortality was reportedly zero in both groups, and the morbidity was also comparable. Pain relief (over 6 months) was seen in 94% of DPPHR patients, but in only 67% of Whipple patients. Furthermore, the insulin secretory capacity and glucose tolerance were noted to deteriorate in the Whipple group, but they actually improved in the DPPHR patients.

The DPPHR requires the careful dissection of the gastroduodenal artery and the creation of two anastomoses (Fig. 33-56), and it carries a similar complication risk as the Whipple procedure due to the risk of pancreatic leakage and intra-abdominal fluid collections.

In 1987, Frey and Smith described the local resection of the pancreatic head with longitudinal pancreaticojunostomy (LR-LPJ), which included excavation of the pancreatic head, including the ductal structures in continuity with a long ductotomy of the dorsal duct269 (Fig. 33-57). The Frey procedure provides thorough decompression of the pancreatic head as well as the body and tail of the gland, and a long-term follow-up suggested that improved outcomes are associated with this more extensive decompressive procedure. Frey and Amikura reported their results in 50 patients followed for >7 years, and they found complete or substantial pain relief in 87% of patients. There was no operative mortality, but 22% of patients developed postoperative complications.270

Figure 33-54. The pancreaticoduodenectomy (Whipple procedure) can be performed either with the standard technique, which includes distal gastrectomy (A), or with preservation of the pylorus (B). The pylorus-sparing version of the procedure is used most commonly. (Reproduced from Wu GY, Aziz K, Whalen GF: An Internist’s Illustrated Guide to Gastrointestinal Surgery. Totowa: Humana Press; 2003.)
Figure 33-55. The duodenum-preserving pancreatic head resection described by Beger and colleagues. A. The completed resection after transection of the pancreatic neck, and subtotal removal of the pancreatic head, with preservation of the distal common bile duct and duodenum. B. Completion of the reconstruction with anastomosis to the distal pancreas and to the proximal pancreatic rim by the same Roux limb of jejunum. (Reproduced with permission from Bell RH, Rikkers LF, Mulholland M: Digestive Tract Surgery: A Text and Atlas. Philadelphia, PA: Lippincott Williams & Wilkins; 1996.)

Key steps in the performance of the LR-LPJ include preservation of the pancreatic neck as well as the capsule of the posterior pancreatic head. In the pancreaticoduodenectomy and the DPPHR, the pancreatic neck is freed up from the portal and superior mesenteric vein confluence and divided. In the LR-LPJ, the neck of the pancreas is preserved intact as are the body and tail of the pancreas. Not having to divide the pancreatic neck, as in the pancreaticoduodenectomy or DPPHR, reduces the risk of the operation because it avoids intraoperative problems with the venous structures lying posterior to the gland. To reduce the risk of penetrating the posterior capsule of the head, Frey recommended in his 1994 report that the posterior limit of resection be the back wall of the opened duct of Wirsung and duct to the uncinate (Fig. 33-58).

Subsequent to Frey’s own modification of the technique, other surgeons have described modifications of the extent or technique of the LR-LPJ. Andersen and Topazian advocated performing the LR-LPJ as it was originally described, in which the entirety of the ducts are excised from the head (Fig. 33-59), and described the use of the ultrasonic aspirator and dissector for this purpose. This device permits precise removal of the ducts and adjacent tissue with good visualization and without complications. There is little pancreatic tissue behind these ducts, and the pancreatic capsule is continuously palpated as the dissection proceeds to ensure a safe margin of resection. The intrapancreatic portion of the common bile duct is usually exposed, and avoiding injury to it is enhanced by the ultrasonic aspirator. The majority of the parenchyma of the uncinate process is spared, and the excavation of the pancreatic head is made contiguous with a generous dochotomy of the dorsal duct. Whether merely unroofing as opposed to removal of the proximal ducts contributes to better pain relief is not known and awaits a randomized trial to compare the two versions of the LR-LPJ. Izbicki and colleagues at the University of Hamburg also recommend a more extensive excavation of the pancreatic head, and they use a technique that they refer to as the Hamburg modification of the LR-LPJ. This wider excavation of the pancreatic head is created in continuity with the dorsal dochotomy, and it is followed by a single, side-to-side pancreaticojejunostomy.

In 2001, Ho and Frey subsequently described merely excavating the core of the pancreatic head and draining the excava-

Figure 33-56. Intraoperative view of the Beger procedure. The gastroduodenal artery is encircled by a vessel loop. Just below, the intrapancreatic portion of the common bile duct is exposed as it courses toward the ampulla. A rim of well-vascularized pancreatic tissue remains in the duodenal C-loop. Preservation of the posterior branch of the gastroduodenal artery is essential to preserve viability of these structures.
Figure 33-57. Frey procedure. The local resection of the pancreatic head with longitudinal pancreaticojejunostomy (LR-LPJ) provides complete decompression of the entire pancreatic ductal system. Reconstruction is performed with a side-to-side Roux-en-Y pancreaticojejunostomy. (Reproduced with permission from Bell RH, Rikkers LF, Mulholland M: Digestive Tract Surgery: A Text and Atlas. Philadelphia, PA: Lippincott Williams & Wilkins; 1996.)

Figure 33-58. Operative view of excavated head of the pancreas during the Frey procedure. The main pancreatic duct is opened widely down to the level of the ampulla, and the head of the pancreas is excavated in a conical fashion so as to allow complete decompression of the chronically obstructed and inflamed pancreatic ducts. (Reproduced with permission from Aspelund G et al. Improved outcomes for benign disease with limited pancreatic head resection, J Gastrointest Surg. 2005 Mar;9(3):400-409.)

Figure 33-59. Complete excavation of the pancreatic head and distal pancreatic dochotomy. A true excavation and removal of the proximal ductal system is combined with a distal pancreatic dochotomy. Reconstruction is performed with a single side-to-side Roux-en-Y pancreaticojejunostomy. (Reproduced with permission from Andersen DK, Topazian MD. Pancreatic head excavation: a variation on the theme of duodenum-preserving pancreatic head resection, Arch Surg. 2004 Apr;139(4):375-379.)
Farkas and colleagues described a similar excavation of the central portion of the pancreatic head without any effort to include the duct of the body in the lateral pancreaticojejunostomy, and they reported excellent results with what they termed an organ-preserving pancreatic head resection (OPPHR) in a randomized comparison to the pylorus-preserving pancreaticoduodenectomy (PPPD).

This approach was advocated by Gloor and associates in Bern as an alternative to the DPPHR procedure in patients with portal hypertension and was described as the Berne modification of the DPPHR (Fig. 33-62). Köninger and colleagues in Heidelberg subsequently published a randomized, controlled trial of the “Berne” version of the excavation method compared to the “classic” Beger procedure. Operative times and length of stay were shorter in the group undergoing excavation of the pancreatic head, while long-term outcomes and quality-of-life scores were identical over 2 years postoperatively.

The common element of these variations on the theme of LR-LPJ remains the excavation or “coring out” of the central portion of the pancreatic head. It remains uncertain, however, whether and to what degree the dochotomy needs to be extended into the body and tail. The logical conclusion of all of these efforts is that the head of the pancreas is the nidus of the chronic inflammatory process in chronic pancreatitis and that removal of the central portion of the head of the gland is the key to the successful resolution of pain in the long term.

Complications Initial and long-term results of the LR-LPJ demonstrate pain relief that is equivalent to that of pancreaticoduodenectomy and the DPPHR. The observed mortality rate has been virtually zero, and therefore, less than with the Whipple procedure. Major complications were less with the LR-LPJ (16%) than with pancreaticoduodenectomy (40%) or DPPHR (25%) in one single-site series, and the incidence of new postoperative diabetes after LR-LPJ was 8% with an average follow-up of 3 years.

Comparisons of the Three Operative Procedures: Pancreaticoduodenectomy (Whipple procedure), DPPHR (Beger procedure), and LR-LPJ (Frey procedure). There has been considerable interest to apply evidence-based methods to the study of the three operations currently advocated for the treatment of chronic pancreatitis. The best studies, or level 1 data by the Strength of Recommendation Taxonomy, are prospective, randomized controlled trials comparing two or more operations from a single or multi-institutional study. Retrospective, cohort-based studies are regarded as level 2 data by the Strength of Recommendation Taxonomy criteria.

To date, ten published level 1 studies and three level 2 studies have examined various comparisons between these three operations. In the level 1 study of Klempp and colleagues and that of Buchler et al, DPPHR patients had a shorter hospital stay, greater weight gain, less postoperative diabetes, and exocrine dysfunction than standard Whipple patients over a 3- to 5-year follow-up. Pain control was similar between the two procedures. Similar results were observed in a
of new diabetes (8%) for both DPPHR and LR-LPJ compared to
the Whipple procedure (25%), but no significant differences in
outcomes or pain relief between DPPHR and LR-LPJ.\textsuperscript{199} Finally,
level 2 data support the efficacy of both DPPHR and LR-LPJ in
patients with dilated as well as nondilated ducts.\textsuperscript{286,289,289}

Long-term exocrine and/or endocrine insufficiency in
chronic pancreatitis patients treated surgically is a product of the
surgical intervention as well as the progression of the underlying
disease. Although the short-term (3-year) incidence of new diabe-
tes after operation appears less with the LR-LPJ and DPPHR than
with the PPPD, the late incidence of diabetes appears similar in all
groups. After an average of 7 years of follow-up after LR-LPJ or
PPPd, survival, pain relief, and pancreatic function were similar
in both groups. The rate of diabetes was slightly lower after LR-
LPJ (61\%) than after PPPD (65\%), but these had both more than
doubled from their preoperative status.\textsuperscript{275-281} Therefore, although
the limited pancreatic procedures of DPPHR and LR-LPJ have
a lower initial rate of endocrine dysfunction, the long-term risk
of diabetes is more related to the progression of the underlying
disease than to the effects of operation.

The level 1 studies confirm that the duodenum preserving
options are associated with a lower immediate morbidity and
mortality and therefore, in the absence of a mass or concerns
about cancer, are better options than a Whipple procedure for
chronic pancreatitis. The choice of LR-LPJ, DPPHR, or OPPHR
depends largely on surgeon experience, and the LR-LPJ is most
common in the United States.

**Total Pancreatectomy With Islet Auto-Transplantation** Islet
cell transplantation for the treatment of diabetes is an attractive
adjunct to pancreatic surgery in the treatment of benign pancre-
atic disease. Despite the difficulties in recovering islets from a
chronically inflamed gland, Najarian and associates demonstrated
the utility of autotransplantation of islets in patients with chronic
pancreatitis in 1980.\textsuperscript{281} Subsequently, through refinements in
the methods of harvesting and gland preservation, and through
standardization of the methods by which islets are infused into
the portal venous circuit for intrahepatic engraftment, the suc-
cess of total pancreatectomy combined with islet autotransplant-
lation has steadily increased to achieve insulin independence in
the majority of patients treated in recent series.\textsuperscript{282,283} Although
2 to 3 million islets are required for successful engraftment in
an allogeneic recipient, the auto-transplant recipient can usually
achieve long-term, insulin-independent status after engraftment
of only 300,000 to 400,000 islets (about one-third to one-half of
the number of islets in the normal pancreas).\textsuperscript{284}

The ability to recover a sufficient quantity of islets from
a sclerotic gland is dependent on the degree of fibrotic dis-
ease present, so the selection of patients as candidates for
autologous islet transplantation is important. The impressive
improvement in quality of life measures and pain relief seen
after total pancreatectomy with islet auto-transplantation (TP-
IAT) indicate that it is a highly successful form of therapy for
some patients (Fig. 33-63).\textsuperscript{295} The outcomes of TP-IAT are sig-
nificantly better in pediatric patients than in adults, largely due
to the prevalence of hereditary and idiopathic causes of chronic
pancreatitis in pediatric patients.\textsuperscript{296} These studies suggest that
further definition is needed regarding criteria for considering
TP-IAT vs. hybrid or resectional procedures for patients with
persistent symptoms. With the emerging evidence that hybrid
procedures seem to offer better outcomes in patients with toxic
etiologies of chronic pancreatitis, and that TP-IAT appears to

---

**Figure 33-62.** The Berne modification of the local resection of the
pancreatic head with longitudinal pancreaticojejunostomy.
preferentially benefit patients with hereditary and idiopathic forms of the disease, the importance of the careful definition of the etiology of chronic pancreatitis, including genetic testing, is steadily increasing.

**PANCREATIC NEOPLASMS**

**Neoplasms of the Endocrine Pancreas**

Neoplasms of the endocrine pancreas are relatively uncommon but do occur with enough frequency (five cases per million population) that most surgeons will encounter them in an urban practice. The cells of the endocrine pancreas, or islet cells, originate from neural crest cells, also referred to as amine precursor uptake and decarboxylation cells. Multiple endocrine neoplasia (MEN) syndromes occur when these cells cause tumors in multiple sites. The MEN1 syndrome involves pituitary tumors, parathyroid hyperplasia, and pancreatic neoplasms. Although most pancreatic endocrine tumors are nonfunctional, some are functional, secreting peptide products that produce interesting clinical presentations. Neoplasms of the endocrine pancreas that are not associated with excess hormone levels and a recognizable clinical syndrome are considered nonfunctional. Special immunohistochemical stains allow pathologists to confirm the peptide products being produced within the cells of a pancreatic endocrine tumor. However, the histologic characteristics of these neoplasms do not predict their clinical behavior, and malignancy is usually determined by the presence of local invasion and lymph node or hepatic metastases. Unfortunately, most pancreatic endocrine tumors are malignant, but the course of the disease is far more favorable than that seen with pancreatic exocrine cancer. The key to diagnosing these rare tumors is recognition of the classic clinical syndrome; confirmation is achieved by measuring serum levels of the elevated hormone. Localization of the tumor can be a challenging step, but once accomplished, the surgery is relatively straightforward. The goals of surgery range from complete resection, often accomplished with insulinomas, to controlling symptoms with debulking procedures. Unresectable disease in the liver is often addressed with chemoembolization.

As with pancreatic exocrine tumors, the initial diagnostic imaging test of choice for pancreatic endocrine tumors is a multidetector CT scan with four phases of contrast and fine cuts through the pancreas and liver. Neuroendocrine tumors of the pancreas often enhance with contrast. EUS can be superior to CT in localizing these tumors, which can produce dramatic symptoms despite their small (<1 cm) size. In contrast to pancreatic exocrine tumors, many of the endocrine tumors have somatostatin receptors (SSTRs) that allow them to be detected by a radiolabeled octreotide scan. A radioactive somatostatin analogue is injected intravenously, followed by whole-body radionuclide scanning (Fig. 33-64). The success of this modality in localizing tumors and detecting metastases has decreased the use of older techniques such as angiography and selective venous sampling.

**Insulinoma**

Insulinomas are the most common functional pancreatic endocrine neoplasms and present with a typical clinical
syndrome known as Whipple’s triad. The triad consists of symptomatic fasting hypoglycemia, a documented serum glucose level <50 mg/dL, and relief of symptoms with the administration of glucose. Patients can present with a profound syncopal episode or less severe symptoms that are averted by frequent eating. Common symptoms include palpitations, trembling, diaphoresis, confusion or obtundation, and seizure, and family members may report that the patient has undergone personality change.

Routine laboratory studies will uncover a low blood sugar, the cause of all of these symptoms. Serum insulin levels are elevated. C-peptide levels should also be elevated and rule out the unusual case of surreptitious administration of insulin or oral hypoglycemic agents because excess endogenous insulin production leads to excess C-peptide. The diagnosis can be clinched with a monitored fast in which blood is sampled every 4 to 6 hours for glucose and insulin levels until the patient becomes symptomatic. However, this can be dangerous and must be done with close supervision.

Insulinomas are usually localized with CT scanning and EUS. Technical advances in EUS have led to preoperative identification of >90% of insulinomas. Visceral angiography with venous sampling is rarely required to accurately localize the tumor. Insulinomas are evenly distributed throughout the head, body, and tail of the pancreas. Unlike most endocrine pancreatic tumors, the majority (90%) of insulinomas are benign and solitary, and only 10% are malignant. They are typically cured by simple enucleation. However, tumors located close to the main pancreatic duct and large (>2 cm) tumors may require a distal pancreatectomy or pancreaticoduodenectomy. Intraoperative US is useful to determine the tumor’s relation to the main pancreatic duct and guides intraoperative decision making. Approximately 90% of insulinomas are sporadic, and 10% are associated with the MEN1 syndrome. Insulinomas associated with the MEN1 syndrome are more likely to be multifocal and have a higher rate of recurrence.

**Noninsulinoma Hyperinsulinemia Hypoglycemia Syndrome**

A syndrome of noninsulinoma pancreaticogenous hypoglycemia was described by Service et al in 1999. The syndrome is associated with beta-cell hypertrophy, islet hyperplasia and increased beta-cell mass. When these findings are accompanied by ectopic islet tissue, multilobulated islets, and ductuloinsular complexes, the definition of nesideoblastosis is met. Nesideoblastosis accompanied by hyperinsulinism was previously considered a disease of neonates, where subtotal or total pancreatectomy was required to correct potentially fatal neonatal hyperinsulinism. However, dozens of cases of nesideoblastosis associated with hyperinsulinism have now been reported in patients 2 to 5 years after Roux-en-Y gastric bypass for obesity. Many of these patients have undergone partial or total pancreatectomy to prevent potentially fatal hypoglycemia. The illness in former bariatric surgery patients appears to result from an idiosyncratically-prolonged hypersecretion of the incretin hormones GIP and GLP-1 after the gastric bypass. GLP-1 is a potent stimulant of the expression of the transcription factor PDX-1, which normally regulates beta-cell development and growth. The correct treatment of this condition to prevent episodes of hypoglycemia is conversion of the gastric bypass to a form of bariatric procedure that restores normal intestinal flow of nutrients, such as the gastric sleeve, or the addition of a restriction element such as an adjustable gastric band. Pancreatic resection without conversion of the Roux-en-Y gastric bypass is not appropriate because this allows the abnormal enteroinsular relationship to continue and hyperinsulinemia persists or recurs after partial pancreatectomy.

**Gastrinoma**

Zollinger-Ellison syndrome (ZES) is caused by a gastrinoma, an endocrine tumor that secretes gastrin, leading to acid hypersecretion and peptic ulceration. Many patients with ZES present with abdominal pain, peptic ulcer disease, and severe esophagitis. However, in the era of effective antacid therapy, the presentation can be less dramatic. Although most of the ulcers are solitary, multiple ulcers in atypical locations that fail to respond to antacids should raise suspicion for ZES and prompt a work-up. At the time of diagnosis, 21% of patients with gastrinoma have diarrhea.

The diagnosis of ZES is made by measuring the serum gastrin level. It is important that patients stop taking proton pump inhibitors for this test. In most patients with gastrinomas, the level is >1000 pg/mL. Gastrin levels can be elevated under conditions other than ZES. Common causes of hypergastrinemia include pernicious anemia, treatment with proton pump inhibitors, renal failure, G-cell hyperplasia, atrophic gastritis, retained or excluded antrum, and gastric outlet obstruction. In equivocal cases, when the gastrin level is not markedly elevated, a secretin stimulation test is helpful.

**Figure 33-64.** Radioactive octreotide scan demonstrating pancreatic endocrine tumor in the body of the pancreas (arrow).
SPECIFIC CONSIDERATIONS

PART II

In 70% to 90% of patients, the primary gastrinoma is found in Passaro’s triangle, an area defined by a triangle with points located at the junction of the cystic duct and common bile duct, the second and third portion of the duodenum, and the neck and body of the pancreas (Fig. 33-65). However, because gastrinomas can be found almost anywhere, whole-body imaging is required. The test of choice is SSTR (octreotide) scintigraphy in combination with CT. The octreotide scan is more sensitive than CT, locating about 85% of gastrinomas and detecting tumors <1 cm. With the octreotide scan, the need for tedious and technically demanding selective angiography and measurement of gastrin gradients has declined. EUS is another modality that assists in the preoperative localization of gastrinomas. It is particularly helpful in localizing tumors in the pancreatic head or duodenal wall, where gastrinomas are usually <1 cm in size. A combination of octreotide scan and EUS detects >90% of gastrinomas.

It is important to rule out MEN1 syndrome by checking serum calcium levels before surgery because resection of the gastrinoma(s) in these patients rarely results in normalization of serum gastrin concentrations or a prolongation of survival. Only one-fourth of gastrinomas occur in association with the MEN1 syndrome. One-half of patients with gastrinomas will have solitary tumors while the remainder will have multiple gastrinomas. Multiple tumors are more common in patients with MEN1 syndrome. Aggressive surgical treatment is justified in patients with sporadic gastrinomas. If patients have MEN1 syndrome, the parathyroid hyperplasia is addressed with total parathyroidectomy and implantation of parathyroid tissue in the forearm.

Approximately 50% of gastrinomas metastasize to lymph nodes of the liver and are therefore considered malignant. Patients who meet criteria for operability should undergo exploration for possible removal of the tumor. Although the tumors are submucosal, a full-thickness excision of the duodenal wall is performed if a duodenal gastrinoma is found. All lymph nodes in Passaro’s triangle are excised for pathologic analysis. If the gastrinoma is found in the pancreas and does not involve the main pancreatic duct, it is enucleated. Pancreatic resection is justified for solitary gastrinomas with no metastases. A highly selective vagotomy can be performed if unresectable disease is identified or if the gastrinoma cannot be localized. This may reduce the amount of expensive proton pump inhibitors required. In cases in which hepatic metastases are identified, resection is justified if the primary gastrinoma is controlled and the metastases can be safely and completely removed. Debubling or incomplete removal of multiple hepatic metastases is probably not helpful, especially in the setting of MEN1. The application of new modalities such as radiofrequency ablation seems reasonable, but data to support this approach are limited. Postoperatively, patients are followed with fasting serum gastrin levels, secretin stimulation tests, octreotide scans, and CT scans. In patients found to have inoperable disease, chemotherapy with streptozocin, doxorubicin, and 5-fluorouracil (5-FU) is used. Other approaches such as somatostatin analogues, interferon, and chemoembolization also have been used in gastrinoma with some success.

Unfortunately, a biochemical cure is achieved in only about one-third of the patients operated on for ZES. Despite the lack of success, long-term survival rates are good, even in patients with liver metastases. The 15-year survival rate for patients without liver metastases is about 80%, while the 5-year survival rate for patients with liver metastases is 20% to 50%. Pancreatic tumors are usually larger than tumors arising in the duodenum, and more often they have lymph node metastases. In gastrinomas, liver metastases decrease survival rates, but lymph node metastases do not. The best results are seen after complete excision of small sporadic tumors originating in the duodenum. Large tumors associated with liver metastases, located outside of Passaro’s triangle, have the worst prognosis.

Vasoactive Intestinal Peptide-Secreting Tumor

In 1958, Verner and Morrison first described the syndrome associated with a pancreatic neoplasm secreting VIP. The classic clinical syndrome associated with this pancreatic endocrine neoplasm consists of severe intermittent watery diarrhea leading to dehydration, and weakness from fluid and electrolyte losses. Large amounts of potassium are lost in the stool. The vasoactive intestinal peptide-secreting tumor (VIPoma) syndrome is also called WDHA syndrome due to the presence of watery diarrhea, hypokalemia, and achlorhydria. The massive (5 L/d) and episodic nature of the diarrhea associated with the appropriate electrolyte abnormalities should raise suspicion of the diagnosis. Serum VIP levels must be measured on multiple occasions because the excess secretion of VIP is episodic and single measurements might be normal and misleading. A CT scan localizes most VIPomas, although as with all islet cell tumors, EUS is the most sensitive imaging method. Electrolyte and fluid balance is sometimes difficult to correct preoperatively and must be pursued aggressively. Somatostatin analogues are helpful in controlling the diarrhea and allowing replacement of fluid and electrolytes. VIPomas are more commonly located in the distal pancreas and most have spread outside the pancreas. Palliative debulking operations can sometimes improve symptoms for a period, along with somatostatin analogues. Hepatic artery embolization also has been reported as a potentially beneficial treatment.

Glucagonoma

Diabetes in association with dermatitis should raise the suspicion of a glucagonoma. The diabetes usually is mild. The classic necrolytic migratory erythema manifests as cyclic migrations of lesions with spreading margins and healing centers typically on
the lower abdomen, perineum, perioral area, and feet. Patients also complain of an enlarged, sensitive tongue. The diagnosis is confirmed by measuring serum glucagon levels, which are usually >500 pg/mL. Glucagon is a catabolic hormone, and most patients present with malnutrition. The rash associated with glucagonoma is thought to be caused by low levels of amino acids. Preoperative treatment usually includes control of the diabetes, parenteral nutrition, and octreotide. Like VIPomas, glucagonomas are more often in the body and tail of the pancreas and tend to be large tumors with metastases. Again, debulking operations are recommended in good operative candidates to relieve symptoms.

**Somatostatinoma**

Because somatostatin inhibits pancreatic and biliary secretions, patients with a somatostatinoma present with gallstones due to bile stasis, diabetes due to inhibition of insulin secretion, and steatorrhea due to inhibition of pancreatic exocrine secretion and bile secretion. Most somatostatinomas originate in the proximal pancreas or the pancreatoduodenal groove, with the ampulla and peripancreatic area as the most common site (60%). The most common presentations are abdominal pain (25%), jaundice (25%), and cholelithiasis (19%). This rare type of pancreatic endocrine tumor is diagnosed by confirming elevated serum somatostatin levels, which are usually >10 ng/mL. Although most reported cases of somatostatinoma involve metastatic disease, an attempt at complete excision of the tumor and cholecystectomy is warranted in fit patients.

**Nonfunctioning Pancreatic Endocrine Tumors**

Although some pancreatic endocrine neoplasms secrete one or more hormones and are associated with interesting characteristic clinical syndromes, most are not associated with elevated serum hormone levels that cause symptoms. Pancreatic endocrine tumors are considered functional if they are associated with a clinical syndrome and nonfunctioning if not associated with clinical symptoms. The majority of pancreatic endocrine tumors (PET), also called pancreatic neuroendocrine tumors (pNET), are malignant because they have the potential for uncontrolled growth and metastasis. Immunohistochemical markers such as synaptophysin, chromogranin A (CgA), and neuron-specific enolase can be helpful in the diagnosis, but the gross histology is not a reliable predictor of biologic behavior. CgA is used by some as a serum marker to monitor patients for disease recurrence or response to treatment, but the test performs poorly for this purpose. Patients often present similar to patients with pancreatic adenocarcinoma with vague pain or weight loss, but pNETs are increasingly discovered incidentally when imaging is performed for another reason. The tumor frequently enhances with arterial contrast (Fig. 33-66). Sometimes a cystic component is seen due to central necrosis. Octreoscan (somatostatin receptor scintigraphy) can be helpful to stage the disease. Surgical resection is typically recommended in fit patients in the absence of metastatic disease. For patients with tumors in the body and tail of the pancreas, this typically includes splenectomy. Enucleation and splenic preservation, although tempting in small tumors, fails to remove regional lymph nodes.

With advances in imaging, small indolent pNETs are being discovered with increasing frequency, and some surgeons are considering observation in these cases. There are several arguments in favor of observation of small (<2 cm) nonfunctional pNETs, particularly in MEN-1 patients. Pancreatic resection has significant morbidity and mortality. In the setting of MEN-1, resection is rarely curative, and most patients require reoperation. Also, the survival of these patients, even with metastatic disease, is generally excellent at least compared to pancreatic ductal adenocarcinoma. However, the 5-year survival with metastatic pNET is only 16% and radical surgery with curative intent is the standard of care, particularly in sporadic cases that are fit surgical candidates where the primary tumor can be completely excised.

Adjuvant treatment after resection is withheld in the absence of radiographically demonstrable metastatic disease even if CgA levels remain elevated. Although these tumors have a slow growth pattern compared to pancreatic ductal adenocarcinoma, many patients with pNETs will die of their disease even after an apparent complete resection, making surveillance after complete resection important. CT scan and or octreotide scan is recommended annually for 5 years after resection.

![Figure 33-66](image-url) Pancreatic neuroendocrine tumor (PNET) demonstrating enhancement during arterial phase of computed tomography scan. Pancreatic head PNET seen in (**left**) sagital, (**middle**) coronal, and (**right**) lateral views of the abdomen.
Incomplete resection (debulking) for locally advanced or metastatic pNETs of the pancreas is controversial because of the favorable survival duration of patients without surgery. However, in carefully selected fit patients with a pNET in the head of the pancreas and minimal disease in the liver, a pancreaticoduodenectomy with wedge resection of the liver metastasis might be appropriate because this avoids the morbidity of gastrointestinal hemorrhage and biliary and gastric outlet obstruction before death from the metastatic disease. The role of cytoreductive surgery in metastatic pNET is controversial, but consensus guidelines agree that aggressive resection of the primary tumor, regional lymph nodes, and liver/distant metastases should be pursued if greater than 90% of the tumor burden can be resected, which is the case in only about 10% of patients with metastatic disease.

Treatment of metastatic pancreatic neuroendocrine cancer requires a multidisciplinary approach often including a combination of cytoreductive surgery when appropriate, directed therapy for the treatment of liver metastases when possible, and systemic medical therapy. Local ablative therapies include radiofrequency ablation (RFA), cryotherapy, microwave coagulation, and ethanol injection, although RFA is the most popular and widely studied. These therapies can be performed percutaneously or during surgery via laparotomy or laparoscopy, can be repeated, and have been shown to complement resection of the primary tumor and amenable liver metastases; making palliative surgery possible for patients that would otherwise not meet criteria. This approach often improves symptoms and 5-year survival is improved to 48%.306

Transarterial chemoembolization (TACE) can be employed as palliative therapy in patients with liver metastases not amenable to surgical resection and/or ablation. It relies on the principle that metastatic tumor cells derive the majority of their oxygen supply from the hepatic artery as opposed to hepatocytes, which receive oxygen primarily from the portal vein. Performed via angiography, embolization may be performed alone (bland embolization) or in combination with chemotherapeutic agents (chemoembolization). Radioembolization, the selective distribution of radioactive yttrium-90 microspheres into the peritumoral vasculature via branches of the hepatic artery, is another alternative.

Somatostatin analogs can inhibit release of hormones from functional pNETs and reduce diarrhea in patients with VIPomas, glucagonomas, and somatostatinomas, and it can also help the rash of glucagonomas. Somatostatin analogs such as octreotide (Sandostatin LAR Depot), lanreotide (Somatuline Depot), and a new analog pasireotide (Sifnifor LAR) are also used to slow the growth of some functional and nonfunctional pNETs. Disease seen on an octreotide scan can somatostatin receptors and would be expected to respond. Patients with unresectable disease are often treated with somatostatin analogs first before targeted therapy and cytotoxic chemotherapy are utilized because the side effects are minimal.

Some targeted drugs can be helpful in treating advanced pNETs that progress despite somatostatin analogs. Sunitinib (Sutent) attacks new blood vessel growth and other targets that help cancer cells grow. Everolimus (Afinitor) works by blocking a cell protein known as mammalian target of rapamycin (mTOR) and the VEGF pathway, which normally helps cells grow and divide. These targeted agents induce stabilization much more frequently than response, but they tend to carry fewer side effects than traditional cytotoxic chemotherapy. Cytotoxic chemotherapy for pNETs is usually reserved for large tumors or quickly growing tumors that are causing symptoms, or tumors that progressed despite somatostatin analogs and targeted therapy. Platinum-based chemotherapy does, however, remain the standard of care for high-grade (poorly differentiated) pNET, yielding high response rates but typically short-lived benefit. The newer cytotoxic combination of capecitabine and temozolomide has shown activity in well-differentiated pNET.306

Neoplasms of the Exocrine Pancreas

Epidemiology and Risk Factors. It is estimated that in 2017, 53,670 Americans will be diagnosed with pancreatic cancer and 43,090 will die from the disease. Overall, pancreatic cancer has the worst prognosis of all malignancies with a 5-year survival rate of only 7.2%.307 The incidence of pancreatic cancer continues to increase, perhaps related to the increased incidence of risk factors such as obesity and diabetes, and as a result, it is predicted that pancreatic cancer will become the leading cause of cancer deaths in the United States by 2050. Pancreatic cancer recently surpassed breast cancer and is now the third leading cause of cancer death behind lung and colorectal cancer. Despite its ubiquity, this disease is extremely difficult to treat, and its exact cause is unknown. However, epidemiologic studies linking various environmental and host factors provide some clues. Recent discoveries using modern molecular biologic techniques have also improved our understanding of the causes of pancreatic cancer. The etiology of pancreatic cancer likely involves a complex interaction of genetic and environmental factors. These factors will become more fully understood as DNA sequencing is used to screen populations at risk for developing pancreatic cancer.

Pancreatic cancer is more common in older adults with most patients being 75 to 84 years old. Pancreatic cancer is more common in African Americans and slightly more common in men than women. The risk of developing pancreatic cancer is two to three times higher if a parent or sibling had the disease. Another risk factor that is consistently linked to pancreatic cancer is cigarette smoking. Smoking increases the risk of developing pancreatic cancer by at least twofold due to the carcinogens in cigarette smoke.308 Coffee and alcohol consumption have been investigated as possible risk factors, but the data are inconsistent. As in other GI cancers, diets high in fat and low in fiber, fruits, and vegetables are thought to be associated with an increased risk of pancreatic cancer.

Diabetes has been known to be associated with pancreatic cancer for many years. In fact, glucose intolerance is present in 80% of patients with pancreatic cancer, and approximately 20% have overt diabetes, a much greater incidence than would be expected to occur by chance. Preexisting type 2 diabetes increases the risk for development of pancreatic cancer by about twofold.309 The new onset of diabetes also can be an early manifestation of otherwise occult pancreatic cancer. Thus, the new onset of diabetes, or a sudden increase in insulin requirement in an older adult patient with preexisting diabetes, should provoke concern for the presence of pancreatic cancer.

Recent epidemiologic studies have confirmed the fact that patients with chronic pancreatitis, especially familial pancreatitis, have an increased risk of developing pancreatic cancer.124,196-198 Large, retrospective cohort studies of patients with pancreatitis have revealed up to a 20-fold increase in risk for pancreatic cancer. This increased risk seems to be independent of the type of pancreatitis, a finding consistent with the fact that most studies have shown little effect of alcohol ingestion per se.
on the risk of pancreatic carcinoma. The mechanisms involved in carcinogenesis in patients with preexisting pancreatitis are unknown. However, the mutated K-ras oncogene, which is present in most cases of pancreatic cancer, has been detected in the ductal epithelium of some patients with chronic pancreatitis.

**Genetics of Pancreatic Cancer.** Pancreatic carcinogenesis probably involves multiple mutations that are inherited and acquired throughout aging. The K-ras oncogene is currently thought to be the most commonly mutated gene in pancreatic cancer, with approximately 90% of tumors having a mutation. This prevalent mutation is present in precursor lesions and is therefore thought to occur early and be essential to pancreatic cancer development. K-ras mutations can be detected in DNA from serum, stool, pancreatic juice, and tissue aspirates of patients with pancreatic cancer, suggesting that the presence of this mutation or others may provide the basis for diagnostic testing in select individuals. The HER2/neu oncogene, homologous to the epidermal growth factor receptor (EGFr), is overexpressed in pancreatic cancers. This receptor is involved in signal transduction pathways that lead to cellular proliferation. Multiple tumor-suppressor genes are deleted and/or mutated in pancreatic cancer, including p53, p16, and DPC4 (Smad 4), and in a minority of cases, BRCA2. Most pancreatic cancers have three or more of the aforementioned mutations.

The genetic landscape of pancreatic adenocarcinoma has recently been investigated using exome capture technology combined with the SOLiD or Illumina next generation sequencing platforms and copy number analysis. Detailed analysis of 99 tumors reaffirmed the importance of the already known mutations such as KRAS, TP53, CDKN2A, SMAD4, MLL3, TGFB2, ARID1A, and SF3B1 in pancreatic cancer and identified eight novel significantly mutated genes involved in chromatin modification (EPC1 and ARID2), DNA damage repair (ATM) and other mechanisms (ZIM2, MAP2K4, NALCN, SLC16A4, and MAGEA6). Pathway-based analysis of recurrently altered genes also revealed the involvement of axon-guidance genes, particularly SLIT/ROBO signaling, in pancreatic carcinogenesis. Rapid and sensitive sequencing techniques will hopefully lead to better diagnostic and therapeutic approaches for pancreatic cancer.

It is estimated that up to 10% of pancreatic cancers occur as a result of an inherited genetic predisposition. A family history of pancreatic cancer in a first-degree relative increases the risk of pancreatic cancer by about twofold. Rare familial cancer syndromes that are associated with an increased risk of pancreatic cancer include BRCA2, the familial atypical multiple mole–melanoma syndrome, hereditary pancreatitis, familial adenomatous polyposis (FAP), and ataxia-telangiectasia.

**Pathology.** Pancreatic cancer probably arises through a stepwise progression of cellular changes, just as colon cancer progresses by stages from hyperplastic polyp to invasive cancer. Systematic histologic evaluation of areas surrounding pancreatic cancers has revealed the presence of precursor lesions that have been named pancreatic intraepithelial neoplasia (Fig. 33-67). Three stages of pancreatic intraepithelial neoplasia have been defined. These lesions demonstrate the same oncogene mutations and loss of tumor-suppressor genes found in invasive cancers, the frequency of these abnormalities increasing with progressive cellular atypia and architectural disarray. The ability to detect these precursor lesions in humans at a stage where the cancer can still be prevented or cured is an important goal of current pancreatic cancer research.

About two-thirds of pancreatic adenocarcinomas arise within the head or uncinate process of the pancreas; 15% are in the body, and 10% are in the tail, with the remaining tumors demonstrating diffuse involvement of the gland. Tumors in the pancreatic body and tail are generally larger at the time of diagnosis, and therefore, less commonly resectable. Tumors in the head of the pancreas are typically diagnosed earlier because they cause obstructive jaundice. Ampullary carcinomas, carcinomas of the distal bile duct, and periampullary duodenal adenocarcinomas present in a similar fashion to pancreatic head cancer but have a slightly better prognosis, probably because early obstruction of the bile duct and jaundice leads to the diagnosis.

In addition to ductal adenocarcinoma, which makes up about 75% of nonendocrine cancers of the pancreas, there are a variety of less common types of pancreatic cancer. Adenosquamous carcinoma is a variant that has both glandular and squamous differentiation. The biologic behavior of this lesion is unfortunately no better than the typical ductal adenocarcinoma. Acinar cell carcinoma is an uncommon type of pancreatic cancer that usually presents as a large tumor, often 10 cm in diameter or more, but the prognosis of patients with these tumors may be better than with ductal cancer.

**Diagnosis and Staging.** Exact pathologic staging of pancreatic cancer is important because it allows accurate quantitative assessment of results and comparisons between institutions. The tumor-node-metastasis (TNM) staging of pancreatic cancer was updated by the American Joint Committee on Cancer in 2017 (AJCC) (Table 33-21).

The important changes in the staging include more stratification for tumor size and stratification for number of lymph nodes involved. In the new system, tumors ≤2 cm remain as T1 lesions but are subcategorized as T1a (≤0.5 cm), T1b (>0.5–<1 cm), and T1c (1–2 cm). Tumors that are >2–<4 cm are categorized as T2, and tumors >4 cm are categorized as T3. Tumors that involve the celiac axis, superior mesenteric artery, and/or common hepatic artery are still categorized as T4 regardless of size. Metastasis in one to three regional lymph nodes is considered N1 disease, and involvement of ≥4 regional lymph nodes is N2. Patients without nodal involvement (N0) are stages IA, IB, and IIA based on tumor size (T1–T3, respectively). Patients with one to three regional lymph nodes involved (N2) are stage IIB regardless of tumor size. All patients with N2 disease without distant metastases are considered stage III regardless of tumor size. Patients with vascular involvement (T4) are stage III regardless of nodal involvement, and patients with distant metastases are, of course, stage IV.

Ten percent of pancreas cancer cases are diagnosed while the cancer is still confined to the primary site (localized stage); 29% are diagnosed after the cancer has spread to regional lymph nodes or directly beyond the primary site; 52% are diagnosed after the cancer has already metastasized (distant stage); and for the remaining 9%, the staging information was unknown. The corresponding 5-year relative survival rates were 31.5% for localized, 11.5% for regional, 2.7% for distant, and 5.1% for unstaged. The overall 5-year relative survival rate for patients with pancreatic cancer for 2007 to 2013 from Surveillance, Epidemiology, and End Results (SEER) was 8.2%.
The most critical deficit in the ability to treat pancreatic cancer effectively is the lack of tools for early diagnosis. The pancreas is situated deep within the abdomen, and the early symptoms of pancreatic cancer often are too vague to raise suspicion of the disease. Ultimately, the majority of patients present with pain and jaundice. On physical examination, weight loss is evident and the skin is icteric; a distended gallbladder is palpable in about one-fourth of patients. More fortunate patients have tumors situated such that biliary obstruction and jaundice occur early and prompt diagnostic tests. Unfortunately, however, the vast majority of patients are not diagnosed until weight loss has occurred—a sign of advanced disease.

Although it is often taught that carcinoma of the pancreas presents with painless jaundice (to help distinguish it from choledocholithiasis), this aphorism is not accurate. Most patients do experience pain as part of the symptom complex of pancreatic cancer, and it is often the first symptom. Therefore, awareness of the way pancreatic pain is perceived may help clinicians suspect pancreatic cancer. The pain associated with pancreatic cancer is usually perceived in the epigastrium but can occur in any
The current diagnostic and staging test of choice for pancreatic cancer is a multidetector, dynamic, contrast-enhanced CT scan, and the techniques for obtaining high-quality images are constantly improving (Fig. 33-68). The accuracy of CT scanning for predicting unresectable disease is about 90% to 95%. In contrast, CT scanning is less accurate in predicting resectable disease. CT scanning will miss small liver metastases, and predicting arterial involvement is sometimes difficult. CT findings that indicate a tumor is unresectable include involvement of ≥180° of the celiac axis, hepatic or superior mesenteric artery, enlarged lymph nodes outside the boundaries of resection, ascites, and distant metastases (e.g., liver). Invasion of the superior mesenteric vein or portal vein is not in itself a contraindication to resection as long as the veins are patent. Tumors are considered “borderline resectable” if there is abutment of ≤180 degrees of the circumference of the SMA, celiac axis, or hepatic artery or if there is a short segment of vein occlusion. Also, patients with CT findings suspicious for metastatic disease, like 1 mm liver lesions too small to characterize or biopsy, are considered “borderline resectable” as are patients with multiple comorbidities or marginal performance status. There is growing consensus that neoadjuvant treatment should be considered in all patients with any radiographic evidence of extension to adjacent vascular structures.

Currently, multidetector CT is probably the single most versatile and cost-effective tool for the diagnosis and staging of pancreatic cancer. Abdominal MRI provides essentially the same information as CT scanning. Positron emission tomography scanning in locally advanced lesions may help rule out distant metastases. EUS can be used to detect small pancreatic masses that could be missed by CT scanning and is commonly used when there is a high suspicion for pancreatic cancer but no mass is identified by the CT scan. EUS has the added advantage of providing the opportunity for transluminal biopsy of pancreatic masses, although a tissue diagnosis before pancreaticoduodenectomy is not required. However, in specific patients a histologic diagnosis may be necessary such as for those in a
neoadjuvant clinical trial or before chemotherapy in advanced tumors. EUS is a sensitive test for portal/superior mesenteric vein invasion, although it is somewhat less effective at detecting superior mesenteric artery invasion. When all of the current staging modalities are used, their accuracy in predicting resectability has improved.

As imaging continuously improves and high-quality imaging is always obtained before surgery, the chance of bringing a patient to the operating room with the intent of a curative resection and finding upon exploration that the patient has unresectable disease is becoming increasingly uncommon.

In an attempt to avoid such futile laparotomies, preliminary laparoscopy has been advocated for patients with disease felt to be resectable by CT imaging (Fig. 33-69). Diagnostic laparoscopy with the use of US is reported to improve the accuracy of predicting resectability to about 98%. The technique involves more than simple visualization with the scope and requires the placement of multiple ports and manipulation of the tissues. A general exploration of the peritoneal surfaces is carried out. The ligament of Treitz and the base of the transverse mesocolon are examined for tumor. The gastrocolic ligament is incised, and the lesser sac is examined. The ultrasound probe is used to examine the liver, porta hepatis and the portal vein, the celiac axis, and the superior mesenteric artery.

The percentage of patients in whom a positive laparoscopy helps avoid a nontherapeutic laparotomy varies from 10% to 30% in carcinoma of the head of the pancreas, but it may be as high as 50% in patients with tumors in the body and tail of the gland. Resection for pancreatic cancer is being approached laparoscopically, particularly for tumors in the body and tail of the pancreas thus eliminating the need for any separate staging laparoscopy procedure. Also, as the quality of CT scanning has improved, the value of routine diagnostic laparoscopy has decreased. The morbidity of diagnostic laparoscopy is less than that of laparotomy, and the procedure can be performed on an outpatient basis. Patients who are found to have unresectable disease recover more rapidly from a laparoscopy than a laparotomy and can receive palliative chemotherapy and radiation sooner. The potential immunosuppressive effects of a major surgical procedure also are avoided, as well as the negative psychologic impact of a major painful operation with little benefit.

Biliary obstruction can be relieved with an endoscopic approach in almost all cases. When large (10F) plastic stents are used, most patients do not require replacement for about 3 months. Metallic wall stents last about 5 months on average and usually fail only with tumor ingrowth. Keeping in mind that patients with unresectable pancreatic cancer usually live <1 year, the requirement for numerous stent changes is unlikely.

Diagnostic laparoscopy is possibly best applied to patients with pancreatic cancer on a selective basis. Diagnostic laparoscopy will have a higher yield in patients with large tumors (T3,
>4 cm), tumors located in the body or tail, patients with equivocal findings of metastasis on CT scan, and patients with other indications of advanced disease such as marked weight loss or markedly elevated CA19-9 (>1000 U/mL).

An algorithm for the diagnosis, staging, and treatment of pancreatic cancer is shown in Fig. 33-70. In practice, many of these patients are selected for neoadjuvant chemotherapy and then undergo restaging CT and staging laparoscopy prior to surgery.

**Palliative Surgery and Endoscopy.** Most patients with pancreatic cancer (85–90%) have disease that clearly precludes surgical resection. For these patients, appropriate and effective palliative treatment is critical to the quality of their remaining life. Because of the poor prognosis of the disease, it is not appropriate to use invasive, toxic, and expensive regimens in patients with extremely advanced disease and poor performance status. When patients do desire antineoplastic therapy, it is important to encourage them to enroll in clinical trials so that therapeutic advances can be made. In general, there are three clinical problems in advanced pancreatic cancer that require palliation: pain, jaundice, and duodenal obstruction. The mainstay of pain control is oral narcotics. Sustained-release preparations of morphine sulfate are frequently used. Invasion of retroperitoneal nerve trunks accounts for the severe pain experienced by patients with advanced pancreatic cancer. A celiac plexus nerve block can control pain effectively for a period of months, although the procedure sometimes needs to be repeated.

Jaundice is present in the majority of patients with pancreatic cancer, and the most troublesome aspect for the patient is the accompanying pruritus. Biliary obstruction may also lead to cholangitis, coagulopathy, digestive symptoms, and hepato cellular failure. In the past, surgeons traditionally performed a biliary and enteric bypass when unresectable disease was found at laparotomy. This is an increasingly uncommon situation for the surgeon because locally advanced unresectable disease is now detected by high-quality preoperative imaging. Metastatic disease is also more reliably predicted by preoperative imaging and, in select cases, staging laparoscopy.

In current practice, jaundice is usually palliated by an endoscopic biliary stent, often prior to surgical referral. Duodenal obstruction is usually a late event in pancreatic cancer and occurs in only about 20% of patients. Endoscopic metallic duodenal stents are an option, but the patient’s poor prognosis, the cost, and the fact that duodenal stents often do not result in ideal palliation has to be considered. The results of three RCTs examining endoscopic metallic stenting for malignant gastric outlet obstruction demonstrated that major and minor complications were comparable to gastrojejunoscopy but time to tolerating oral intake and hospital stay was shorter. Robot-assisted laparoscopic biliary-enteric bypass is now available at many centers. Although this should result in similar palliation as an open bypass and may be associated with more rapid recovery, the potential complications, the patient’s life expectancy, and cost of this procedure must be considered. As many patients today already have a bile duct stent in place by the time of referral to a surgeon, it is not clear that operative biliary bypass is required. In patients with extensive metastases, an alternative short-term palliative option to consider in patients with gastric outlet obstruction is a percutaneous endoscopic gastrostomy tube or gastrojejunal feeding tube that allows decompression of the stomach and feeding into the jejunum.

If an operative bypass is performed, choledochojejunostomy is the preferred approach. Although an easy procedure to perform, choledochoiodudenostomy is felt to be unwise because of the proximity of the duodenum to tumor. Some have discouraged the use of the gallbladder for biliary bypass; however, it...
is suitable as long as the cystic duct clearly enters the common duct well above the tumor. The jejunum is brought anterior to the colon, if possible, rather than retrocolic, where the tumor potentially would invade the bowel sooner. Some surgeons use a loop of jejunum with a jejunojejunostomy to divert the enteric stream away from the biliary-enteric anastomosis. Others use a Roux-en-Y limb with the gastrojejunalostomy located 50 cm downstream from the hepaticojejunostomy (Fig. 33-71). Potential advantages of the defunctionalized Roux-en-Y limb include the ease with which it will reach up to the hepatic hilum, probable decreased risk of cholangitis, and easier management of biliary anastomotic leaks. If a gastrojejunostomy is performed, it should be placed dependently and posterior along the greater curvature to improve gastric emptying, and a vagotomy should not be performed. Endoscopic stents are definitely not as durable as a surgical bypass. Recurrent obstruction and cholangitis is more common with stents and results in inferior palliation. However, the endoscopic approach is associated with considerably less initial morbidity and mortality than surgical bypass. Expandable metallic wall stents have superior patency and provide better palliation than plastic stents (Fig. 33-72).

If an initial diagnostic laparoscopy reveals a contraindication to the Whipple procedure, such as liver metastases, it is not appropriate to perform a laparotomy simply to create a biliary bypass. In such a patient, it is better to place an endoscopic stent. In contrast, in the uncommon scenario where a laparotomy has already been performed as part of the assessment of resectability and the Whipple procedure is not possible, a surgical bypass is usually performed. However, if the patient has a functioning endoscopic stent already in place, it may be reasonable to forego surgical bypass.

**Chemotherapy and Radiation for Locally Advanced/Metastatic Disease.** Patients with locally advanced unresectable disease are treated with chemotherapy and possibly radiation, and patients with stage IV metastatic disease are treated with systemic chemotherapy. The role of RT in unresectable, locoregionally advanced pancreas cancer remains controversial. RT may slow the progression of local disease and possibly alleviate or prevent symptoms including pain, biliary obstruction, bleeding, and bowel obstruction. However, the likelihood of micrometastatic distant disease is high, treatment is not expected to be curative, and radiation can result in toxicity. Stereotactic body radiotherapy (SBRT) has been used to limit toxicity by targeting high-dose short-course radiation to enhance local response prior to surgery. In a phase 2 multi-institutional trial evaluating gemcitabine and SBRT in patients with locally advanced unresectable pancreatic cancer, 10% of patients with locally advanced disease who would not have been candidates for initial surgery were deemed to have resectable tumors following therapy, and 8% ultimately underwent R0 and node-negative resection. A number of chemotherapy regimens are available for pancreatic cancer, but the results are not impressive. Gemcitabine (Gemzar) was approved by the U.S. Food and Drug Administration (FDA) for use in pancreatic cancer in 1996. In patients with unresectable pancreatic cancer, gemcitabine results in symptomatic

Figure 33-72. Expandable metallic biliary stent. After ERCP cannulation of the distal bile duct (left) the stent is advanced over the cannula and placed across the obstruction in the distal bile duct (right).
improvement, improved pain control and performance status, and weight gain. However, survival is improved by only 1 to 2 months. Prior to gemcitabine, 5-fluorouracil (5-FU) was used as the standard treatment for unresectable pancreatic cancer. Both of these drugs are still used today. 5-FU or capecitabine (Xeloda), a similar but orally administered drug, are frequently used as a radiosensitizer during radiation therapy. Single-agent gemcitabine is still commonly used in patients with a poor performance status.

Erlotinib (Tarceva) was approved in 2005 based on very minimal improvement in overall survival in combination with gemcitabine. The study showed that erlotinib in combination with gemcitabine results in a statistically significant improvement in overall survival in patients with advanced pancreatic cancer in the first-line setting. Although the absolute benefit in overall survival was modest with a median survival difference between the two arms of only 2 weeks.

FOLFIRINOX, a combination of three chemotherapy drugs (5-FU/leucovorin, irinotecan, and oxaliplatin) is now commonly used as first-line treatment for metastatic pancreatic adenocarcinoma in patients with a relatively good performance status. In 2010, a Phase 3 clinical trial showed positive results for patients treated with FOLFIRINOX. The objective response rate was improved from 9% to 32%, and median overall survival of patients with metastatic pancreatic cancer improved from 7 to 11 months, but the improvement was associated with increased toxicity, so patient selection is important. Patients treated with FOLFIRINOX may experience more severe side effects than those treated with gemcitabine alone, so this combination is usually reserved for patients with a good performance status.

In 2013, another combination therapy was approved as first-line treatment for metastatic pancreatic adenocarcinoma. Albumin-bound paclitaxel (Abraxane) was approved to be used in combination with gemcitabine (Gemzar). The median overall survival was improved to 8.5 months in the nabpaclitaxel–gemcitabine group as compared with 6.7 months in the gemcitabine group. Progression-free survival and the response rate were also improved. Rates of peripheral neuropathy and myelosuppression were increased, but this regimen is less toxic than FOLFIRINOX.

In 2015, Irinotecan (ONIVYDE), in combination with 5-FU (fluorouracil) and leucovorin, was approved for treatment of metastatic pancreatic adenocarcinoma that has progressed following treatment with a gemcitabine based therapy. The median overall survival in patients assigned to nanoliposomal irinotecan plus fluorouracil and folinic acid was 6.1 months vs. 4.2 months with fluorouracil and folinic acid. Common side effects for this second-line therapy were neutropenia, diarrhea, vomiting, and fatigue.

These results may warrant treatment in patients who understand the benefits and risks. However, the lack of significant survival advantage should encourage physicians to refer motivated patients for experimental protocols because it is only through continued clinical research that more meaningful treatments for pancreatic cancer will be developed.

Ablation for Locally Advanced Unresectable Disease. Persistent arterial vascular encasement after neoadjuvant therapy contraindicates resection. Irreversible electroporation utilizes delivery of high-voltage millisecond electrical pulses resulting in permanent disruption of the cellular membranes and subsequent apoptosis. This process leads to cell death, but does not injure the extracellular matrix, thus allowing cellular tumor ablation while preserving structural components of tissues. Collagen-based structures such as vessels or the pancreatic duct are not disrupted. Furthermore, because IRE is not based on thermal damage of cancer cells, the heat-sink phenomenon is not a concern, and even lesions abutting large vessels can be ablated with radical intent. Irreversible electroporation using the Nanoknife is reported to enable treatment of pancreatic tumors abutting vascular structures without compromise of the vessels or concern for the heat sink effect of nearby blood flow. Martin has created a registry and accumulated multi-institutional data on 200 patients with locally advanced pancreatic cancer showing OS of 28.3 months for patients with borderline resectable pancreatic cancer and 23.2 months in patients with unresectable pancreatic cancer. Those numbers compare favorably with the survival of patients treated with chemoradiation alone, which is 13 months in historical controls. This modality is new, but these early reports indicate it may be safe in combination with chemotherapy and are of particular interest because of the potential to downstage and offer surgery to patients initially diagnosed with locally advanced unresectable disease. It is also important to understand that a significant learning curve exists to achieve safety and optimization of the technique. Proper patient selection, technical ability with intraoperative ultrasound to allow precise IRE electrode bracketing, and standardization of the IRE energy delivery is important. Randomized prospective trials are needed before adoption of this technique can be expanded.

Surgical Resection: Pancreaticoduodenectomy. In a patient with appropriate clinical and/or imaging indications of pancreatic cancer, a tissue diagnosis before performing a pancreaticoduodenectomy is not essential. Although percutaneous CT-guided biopsy is usually safe, complications such as hemorrhage, pancreatitis, fistula, and abscess can occur. Tumor seeding along the subcutaneous tract of the needle is uncommon. Likewise, FNA under EUS guidance is safe and well tolerated. The problem with preoperative or even intraoperative biopsy is that many pancreatic cancers are not very cellular and contain a significant amount of fibrous tissue, so a biopsy may be misinterpreted as showing chronic pancreatitis if it does not contain malignant glandular cells. In the face of clinical and radiologic preoperative indications of pancreatic cancer, a negative biopsy should not preclude resection. In patients who are not candidates for resection because of metastatic disease, biopsy for a tissue diagnosis becomes important because these patients may be candidates for palliative chemotherapy trials. It is especially important to make an aggressive attempt at tissue diagnosis before surgery in patients whose clinical presentation and imaging studies are more suggestive of alternative diagnoses such as pancreatic lymphoma or pancreatic islet cell tumors. These patients might avoid surgery altogether in the case of lymphoma or warrant an aggressive approach in the case of islet cell carcinoma.

Pancreatectoduodenectomy can be performed through a midline incision from xiphoid to umbilicus or through a bilateral subcostal incision. The initial portion of the procedure is an assessment of resectability. The liver and visceral and parietal peritoneal surfaces are thoroughly assessed. The gastrohepatic omentum is opened, and the celiac axis area is examined for enlarged lymph nodes. The base of the transverse mesocolon is examined for tumor involvement.

The ascending and hepatic flexure of the colon are mobilized off the duodenum and head of the pancreas and reflected medially. A Kocher maneuver is performed by dissecting behind
the head of the pancreas. The superior mesenteric vein is identified early in the case and dissected up toward the inferior border of the neck of the pancreas. The gastroepiploic vein and artery are ligated to prevent any traction injury. Often, the middle colic vein and right gastroepiploic vein share a common trunk before entering into the superior mesenteric vein. Knowledge of this anatomy helps reduce injury to the veins and unnecessary blood loss. The relation of the tumor to the superior mesenteric vein and artery cannot be accurately assessed by palpation at this point and is not completely determined until later in the operation when the neck of the pancreas is divided and the surgeon is committed to resection. Mesenteric vascular involvement is best determined by a high quality preoperative CT scan.

It is important to assess for an aberrant right hepatic artery, which is present in 20% of patients. The aberrant artery commonly arises from the superior mesenteric artery posterior to the pancreas and ascends parallel and adjacent to the superior mesenteric and portal veins. The presence of an aberrant right hepatic artery should be apparent on the preoperative CT scan and can be identified intraoperatively by palpation on the back side of the hepatoduodenal ligament, where a prominent pulse will be felt posterior and to the right of the portal vein.

The porta hepatis is examined. Enlarged or firm lymph nodes that can be swept down toward the head of the pancreas with the specimen do not preclude resection. If the assessment phase reveals no contraindications to the Whipple procedure (Table 33-22), the resection phase commences.

If the pylorus is to be preserved, the stomach and proximal duodenum are mobilized off the pancreas, preserving the gastroepiploic vessels down to the pylorus. The proximal hepatic artery is identified usually by removing a lymph node that commonly lies just anterior to the artery. The hepatic artery is dissected and traced toward the porta hepatis. The gastroduodenal branch of the hepatic artery is identified. A test clamping is performed to ensure that a strong pulse remains in the proper hepatic artery before division of the gastroduodenal artery. In cases of celiac occlusion, flow comes from the superior mesenteric artery and retrograde through the gastroduodenal artery to the proper hepatic artery. Ligation of the gastroduodenal in this case would be equivalent to hepatic artery ligation. A bypass to the hepatic artery would be required. Once the test clamping is negative and the gastroduodenal artery is divided, the hepatic artery is retracted medially, and the common bile duct is retracted laterally to reveal the anterior surface of the portal vein behind them. Dissection is performed only on the anterior surface of the vein. If there is no tumor involvement, the neck of the pancreas will separate from the vein easily. A large, blunt-tipped clamp is a safe instrument to use for this dissection. The tunnel under the neck of the pancreas can then be completed mostly under direct vision from inferior and superior.

The gallbladder is then mobilized from the liver, the cystic duct and artery are ligated, and the gallbladder is removed. The common hepatic duct is circumferentially dissected. Either the duodenum is divided 2 cm distal to the pylorus, which defines the procedure as a pylorus-preserving pancreaticoduodenectomy, or PPPD) or the antrum is divided, as classically described by Whipple. The jejunum is divided beyond the ligament of Treitz, and the mesentery is ligated until the jejunum can be delivered posterior to the superior mesenteric vessels from left to right.

The common hepatic duct is then divided usually just above the entrance of the cystic duct, and the bile duct is dissected down to the superior margin of the duodenum. Inferior traction on the distal bile duct opens the plane to make visible the anterior portion of the portal vein. The pancreatic neck is divided anterior to the portal vein (Fig. 33-73). The use of cautery is avoided in the area of the pancreatic duct. The pancreatic head and uncinate process then are dissected off of the right lateral aspect of the superior mesenteric vein, ligating the fragile branches draining the head and uncinate process into the portal vein (Fig. 33-74). The uncinate process is then dissected off of the posterior and lateral aspect of the superior mesenteric artery. This can be the most tedious portion of the operation.

Minimally Invasive Pancreatectomy. Laparoscopic distal pancreatectomy has been proven to be safe and is appropriate for essentially all indications for pancreatectomy. This approach is associated with decreased blood loss and quicker recovery. Centrally located lesions near the splenoportal confluence must be approached laparoscopically with caution. Robotic technology may make dissection and control of major vessels in this area easier and perhaps safer. Interest in laparoscopic pancreatectoduodenectomy is increasing throughout the United States with some early adopters reporting excellent outcomes comparable to the open procedure. Early results indicate this technique is feasible, but considerable expertise is required in both open pancreatic resection as well as advanced laparoscopic techniques to achieve these outcomes. Whether the advantages seen in other areas of minimally invasive surgery apply to the Whipple procedure is an area of current investigation.

Variations and Controversies. The preservation of the pylorus has several theoretical advantages, including prevention of reflux of pancreaticobiliary secretions into the stomach, decreased incidence of marginal ulceration, normal gastric acid secretion and hormone release, and improved gastric function. Patients with pylorus-preserving resections have appeared to regain weight better than historic controls in some studies. Return of gastric emptying in the immediate postoperative period may take longer after the pylorus-preserving operation, and it is controversial whether there is any significant improvement in long-term quality of life with pyloric preservation.

Techniques for the pancreaticojejunostomy include end-to-side or end-to-end and duct-to-mucosa sutures or invagination (Fig. 33-75). Pancreaticogastrostomy has also been investigated. Some surgeons use stents, glue to seal the anastomosis, or octreotide to decrease pancreatic secretions. No matter what combination of these techniques is used, the clinically significant pancreatic leakage rate is always about 10%. Therefore, the choice of techniques depends more on the surgeon’s personal experience.

Traditionally, most surgeons place drains around the pancreatic and biliary anastomoses because disruption of the pancreaticojejunostomy cannot be avoided in one out of 10 patients.
This complication can lead to the development of an upper abdominal abscess or can present as an external pancreatic fistula. Usually, a pure pancreatic leak is controlled by the drains and will eventually seal spontaneously. Combined pancreatic and biliary leaks are cause for concern because bile will activate the pancreatic enzymes. In its most virulent form, disruption leads to necrotizing retroperitoneal infection, which can erode major arteries and veins of the upper abdomen, including the exposed portal vein and its branches or the stump of the gastroduodenal artery. Impending catastrophe is often preceded by a small herald bleed from the drain site. Depending on the clinical situation, such an event is an indication to perform an angiogram or return the patient to the operating room to widely drain the pancreaticojejunostomy and to repair the involved blood vessel. Open packing may be necessary to control diffuse necrosis and infection. Some studies have questioned the practice of routine drain placement after pancreatectomy with reliance on postoperative percutaneous drainage when leaks occur. However, a randomized, controlled, multicenter trial showed that patients who develop a leak after pancreaticoduodenectomy are

Figure 33-75. Techniques for pancreaticojejunostomy. **A** to **D**, Duct-to-mucosa, end-to-side. **E**, Intraoperative photographs of end-to-side pancreaticojejunostomy. **F** to **J**, End-to-end invagination. **K** to **O**, End-to-side invagination.
at a substantially increased risk of mortality if a drain was not placed at the time of resection.\textsuperscript{337} In contrast, the outcome does not seem to be as dramatically affected by drain placement in the setting of distal pancreatectomy.\textsuperscript{338} In the absence of a fistula, drains should be removed early in the postoperative period, preferably by postoperative day 5.\textsuperscript{339}

Many patients with pancreatic cancer are malnourished preoperatively and suffer from gastroparesis in the immediate postoperative period. Routine placement of a feeding jejunostomy tube and gastrostomy tube has become less common, and most surgeons use these tubes selectively. Gastrostomy tubes may decrease the length of stay in patients who might

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure33-75}
\caption{(Continued)}
\end{figure}
be predicted to have severe gastroparesis. Jejunostomy tubes are certainly not benign and can result in leaks and intestinal obstruction. However, parenteral nutrition is also associated with serious complications such as line sepsis, loss of gut mucosal integrity, and hepatic dysfunction. Enteric tubes should be considered in patients at risk such as malnourished patients who have received neoadjuvant chemotherapy.

Because of the high incidence of direct retroperitoneal invasion and regional lymph node metastasis at the time of surgery, trails of more extended resections including extension of the pancreatic resection to the middle body of the pancreas, segmental resection of the portal vein, if necessary, resection of retroperitoneal tissue along the right perinephric area, and lymphadenectomy to the region of the celiac plexus were examined. In the hands of experienced surgeons, these techniques are associated with greater blood loss but no increase in mortality. However, improved survival has not been demonstrated. Total pancreatectomy has also been considered in the past. Although pancreatic leaks are eliminated, major morbidity from brittle diabetes and exocrine insufficiency outweigh any theoretical benefit.

Pancreatic cancer can recur locally after pancreaticoduodenectomy. Intraoperative radiotherapy (IORT) delivers radiation to the operative bed at the time of resection. Radiation to
surrounding normal areas is minimized, but the radiation is delivered all in one setting, rather than in fractionated doses over time. Favorable results were recently reported among a series of patients with locally advanced unresectable or borderline-resectable PDAC who received intensive neoadjuvant treatment followed by exploratory laparotomy and IORT.340

Complications of Pancreaticoduodenectomy. The operative mortality rate for pancreaticoduodenectomy has decreased to <5% in high-volume centers (where individual surgeons perform more than 15 cases per year), suggesting that patients in rural areas would benefit from referral to large urban centers.341-342 The most common causes of death are sepsis, hemorrhage, and cardiovascular events. Postoperative complications are unfortunately still very common and include delayed gastric emptying, pancreatic fistula, and hemorrhage.

Delayed gastric emptying is common after pancreaticoduodenectomy and is treated conservatively as long as complete gastric outlet obstruction is ruled out by a contrast study. In the acute phase, intravenous erythromycin may help, but the problem usually improves with time.

Considerable attention has been focused on the prevention of pancreatic leak after pancreas resection. Modifications of the anastomotic technique (end-to-side or end-to-end, duct-to-mucosa, or invaginated), the use of jejunum or the stomach for drainage, the use of pancreatic duct stents, the use of octreotide, and various sealants have all been evaluated.

Long-acting synthetic analogues of somatostatin have been evaluated as a pharmacologic therapy to reduce pancreatic secretion and the rate of pancreatic fistula after pancreatic resection. Some European studies supported benefit particularly in selected higher risk patients, while previous North American trials concluded there was no benefit.343-349 A recent single-center, randomized trial with pasireotide (a newer analog) suggested potential benefit.350

Many technical modifications to the classic pancreaticoduodenectomy have been described. However, numerous technical variations to the pancreaticoenteric anastomosis have not clearly demonstrated an objective method to consistently decrease the rate of clinically significant postoperative pancreatic fistula, which in most series is about 10%. Yeo compared the incidence of pancreatic fistula in patients who had a pancreaticoduodenectomy with reconstruction via a pancreaticogastrostomy or pancreaticojejunostomy.351 There was no significant difference between the two techniques in the incidence of pancreatic fistula. A recent meta-analysis summarized the results of 16 trials comparing pancreaticogastrostomy to pancreaticojejunostomy. All of the observational clinical studies reported superiority of pancreaticogastrostomy over pancreaticojejunostomy, most likely influenced by publication bias. In contrast, all randomized prospective trials failed to show advantage of a particular technique, suggesting both techniques provide equally good results.352

Other options to consider when performing the pancreatic anastomosis are the duct-to-mucosa vs. the invagination techniques. Some surgeons choose the technique at the time of operation, depending on the size of the pancreatic duct and the texture of pancreas favoring invagination when the duct is small and the pancreatic texture is soft.353 Other surgeons use the same technique every time. The duct-to-mucosa anastomosis results in a low pancreatic fistula rate, particularly in patients with a large pancreatic duct and a fibrotic pancreas.354

Use of a pancreatic duct stent across the anastomosis has been suggested as a means of preventing a pancreatic leak and as an aid in technical precision. Both internal stenting as well as external stenting have been practiced. A recent Cochrane analysis of eight randomized, controlled trials failed to identify any convincing evidence of benefit with internal or external pancreatic duct stents.355 Some previous studies indicated that stents might be harmful. A recent multicenter randomized trial comparing external to internal pancreatic duct stents during pancreaticoduodenectomy showed a lower rate of pancreatic fistula with internal stents, so this controversy is likely to continue.356

Reconstruction with an isolated Roux-en-Y pancreaticoenteric anastomosis has been suggested as a method to decrease postoperative pancreatic leak.357-358 The logic behind this technical modification is that the use of separate Roux-en-Y limbs for biliary and pancreatic secretions may protect the pancreatic anastomosis from activated pancreatic enzymes. However, data is limited, and this is not a common practice.

Avoiding the pancreatic anastomosis altogether by ductal ligation or occlusion has also been evaluated as a potential technique to reduce the rate of postoperative pancreatic fistula.359-360 Ductal occlusion with neoprene or prolamine, which are nonresorbable glues, has been abandoned due to pancreatic atrophy and loss of exocrine function. Duct occlusion in pancreaticojejunostomy significantly increases the risk of endocrine insufficiency without a decrease in the postoperative complication rate. To avoid long-term loss of function, absorbable glues, such as fibrin glue, have been evaluated to limit the action of pancreatic enzymes until the anastomosis is healed. Fibrin glue has been used for both duct occlusion and has also been applied to the surface of the pancreatic stump and anastomotic site without clear improvement in pancreatic fistula rate. The effect of BioGlue applied to the anastomotic surface after the Whipple procedure and pancreatic stump after distal pancreatectomy was evaluated in a retrospective cohort study. There were no statistically significant differences in the incidence or severity grades of postoperative pancreatic fistulas.361 A randomized prospective trial of application of fibrin glue to the surface of the pancreaticojejunostomy in high-risk patients did not reduce the incidence of pancreatic fistula or total complications after pancreaticoduodenectomy.362

If not combined with a biliary leak, pancreatic fistula, although serious, can usually be managed conservatively. In about 95% of cases, reoperation is not indicated, and prolonged drainage, using drains placed in the original operation or percutaneously after resection, results in spontaneous closure of the fistula.363

Hemorrhage can occur either intraoperatively or postoperatively. Intraoperative hemorrhage typically occurs during the dissection of the portal vein. A major laceration of the portal vein can occur at a point in the operation at which the portal vein is not yet exposed. Temporary control of hemorrhage is generally possible in this situation by compressing the portal vein and superior mesenteric vein against the tumor with the surgeon’s left hand behind the head of the pancreas. An experienced assistant is needed to divide the neck of the pancreas to the left of the portal vein and achieve proximal and distal control. Sometimes, the vein can be sutured closed with minimal narrowing. Other times, a segmental resection and interposition graft (internal jugular vein) may be needed.

Postoperative hemorrhage can occur from inadequate ligation of any one of numerous blood vessels during the procedure.
Hemorrhage can also occur due to digestion of retroperitoneal blood vessels due to a combined biliary-pancreatic leak. Uncommonly, a stress ulcer, or later, a marginal ulcer, can result in GI hemorrhage. Typically, a vagotomy is not performed when pancreaticoduodenectomy is performed for pancreatic cancer, but patients are placed on proton pump inhibitors.

**Outcome and Value of Pancreaticoduodenectomy for Cancer.** Survival figures indicate that perhaps few patients are cured indefinitely of pancreatic cancer with pancreaticoduodenectomy. This has led to a nihilistic view toward patients with this disease which has further contributed to poor outcomes. Using the National Cancer Data Base (1995–2004), Bilimoria reported on 9559 patients with early stage potentially resectable tumors (pretreatment clinical Stage I: T1N0M0 and T2N0M0).364 Multivariate models were employed to identify factors predicting failure to undergo surgery and assess the impact of pancreatectomy on survival. This study identified a striking underuse of pancreatectomy in the United States. Of clinical stage I patients, 71.4% (6823/9559) did not undergo surgery; 6.4% (616/9559) were excluded due to comorbidities; 4.2% (403/9559) refused surgery; 9.1% (869/9559) were excluded due to age; and 38.2% (3644/9559) with potentially resectable cancers were not offered surgery. Patients were less likely to undergo surgery if they were older than 65 years, were black, were on Medicare or Medicaid, had pancreatic head lesions, earned lower annual incomes, or had less education. Patients were less likely to receive surgery at low-volume and community centers. Patients who were not offered surgery had worse survival than patients who underwent resection. Overall survival from PDAC would significantly increase if more patients with stage I tumors were identified and offered surgery at high-volume centers (Fig. 33-76).

Although pancreaticoduodenectomy may be performed with the hope of the rare cure in mind, the operation more importantly provides better palliation than any other treatment, and it is the only modality that offers any meaningful improvement in survival. If the procedure is performed without major complications, many months of palliation are usually achieved. However, it is the surgeon’s duty to make sure patients and their families have a realistic understanding of the true goals of pancreaticoduodenectomy in the setting of pancreatic cancer.

**Adjuvant Chemotherapy and Radiation.** Small studies in the 1980s suggested that adjuvant chemotherapy with 5-FU combined with radiation improves survival by about 9 months after pancreatic resection for pancreatic adenocarcinoma.365 Subsequent, noncontrolled studies have reinforced that concept; however, the data have been criticized due to the low number of patients and low dose of radiation therapy that was given. In addition, gemcitabine has replaced 5-FU as standard therapy in pancreatic cancer but is thought to be too toxic when given with radiotherapy without dose reduction. A recent large European multicenter trial concluded that there was no value to chemoradiotherapy, although the study suggested the possibility that chemotherapy alone might have survival benefit.366 Randomized trials have failed to resolve the debate regarding the role of adjuvant radiation therapy in resectable pancreas cancer. A reasonable consideration in a disease with high rates of distant metastases is to begin with adjuvant chemotherapy, followed by radiation therapy in patients who do not progress, particularly in patients where there may be increased concern about local recurrence such as in patients with close margins.

Remarkable results in adjuvant therapy were reported by the Virginia Mason Clinic with combination 5-FU, cisplatinum, interferon-α, and external beam radiation.367 Although the toxicity was high (42% hospitalized for GI toxicity), the promising results prompted larger confirmatory studies. Unfortunately, one such study was stopped due to toxicity, and this protocol has not been widely adopted. More recent results with FOLFIRINOX in the setting of metastatic disease have encouraged clinical trials using this regimen in the adjuvant setting, which are currently underway (ClinicalTrials.gov identifier: NCT02172976). Nevertheless, pending further study, it is typical in the United States for patients with acceptable functional status to receive some form of adjuvant chemotherapy and sometimes chemoradiotherapy after surgery.

**Neoadjuvant Treatment.** There are several potential advantages to the use of chemotherapy or chemoradiation before an attempt at surgical resection. For example, it avoids the risk that adjuvant treatment is delayed by complications of surgery. Neoadjuvant treatment also may decrease the tumor burden at operation, increasing the rate of resectability and killing some tumor cells before they can be spread intraoperatively. Another potential advantage is that it allows patients with occult metastatic disease to avoid the morbidity of pancreatic resection. As many as 20% of patients treated with neoadjuvant chemoradiation develop metastatic disease detected by restaging CT and do not go on to surgery. This approach may separate patients into a subset likely to benefit from resection and a subset in whom surgery would be unlikely to provide clinical benefit. Preoperative chemoradiation has been shown not to increase the perioperative morbidity or mortality of pancreaticoduodenectomy. It may even decrease the incidence of pancreatic fistula. Prospective randomized trials investigating this concept are ongoing but are difficult to complete due to the high number of patients who fail to complete or receive a full course of either therapy. Studies have shown that neoadjuvant therapy is associated with a lower rate of lymph node positivity and improved survival is achieved among the patients who do not develop disease progression during neoadjuvant therapy and go on to resection. Neoadjuvant therapy should be considered an acceptable alternative to surgery first followed by adjuvant therapy for resectable pancreatic cancer. Patients should be encouraged to consider available
clinical trials of neoadjuvant therapy for resectable pancreatic cancer. Unfortunately, a recent trial attempting to randomize patients with resectable pancreatic cancer to neoadjuvant versus adjuvant therapy failed to demonstrate an advantage for the neoadjuvant approach. However, the study was inconclusive because it was stopped after 73 of a planned 254 patients due to slow accrual, with only 66 eligible for analysis. Other trials are ongoing. The NEOPA trial (ClinicalTrials.gov identifier: NCT01900327) is a prospectively randomized phase 3 trial of patients receiving neoadjuvant chemoradiation followed by curative surgery vs. primary surgery followed by adjuvant therapy with a primary endpoint of 3-year overall survival.

Most pancreatic surgeons agree that neoadjuvant chemotherapy, and perhaps chemoradiotherapy, should be offered to patients with locally advanced but resectable disease (vein involvement) and to patients with “borderline resectable disease” (abutment of ≤180 degrees of the circumference of the SMA, celiac axis, or hepatic artery or if there is a short segment of vein occlusion, CT findings suspicious for metastatic disease, like 1 mm liver lesions too small to characterize or biopsy, and patients with multiple comorbidities or marginal performance status). This strategy acknowledges the fact that these patients are at high risk of early distant recurrence and/or R1 resection with early local recurrence. Neoadjuvant treatment helps select the right patients for surgery and may reduce the incidence of a margin positive resection.

Postoperative Surveillance. Recurrence after successful resection usually manifests as hepatic metastases. Adjuvant chemotherapy with or without radiation is usually administered for 6 months. During this time period, patients are monitored with frequent physical examinations and laboratory tests, including CA19-9. CT scans are typically ordered every 3 months in the first 2 years after resection or when a rising CA19-9 or new symptoms suggest recurrence. Surgical therapy for recurrent disease is usually reserved only for select patients with limited disease who remain reasonable operative candidates who develop symptomatic gastric outlet or bowel obstruction.

Ampullary and Periampullary Cancer. Ampullary cancers need to be distinguished from periampullary cancers. The ampulla is the junction of the biliary and pancreatic ducts within the duodenum. Periampullary cancer includes tumors arising from the distal bile duct, duodenal mucosa, or pancreas just adjacent to the ampulla, and the ampulla can be overgrown by cancers that arise from these adjacent areas, making it impossible to determine the true site of origin. Clinically, the term periampullary cancer is, therefore, a nonspecific term used to refer to a variety of tumors arising at the intersection of these four sites. The term ampullary cancer is more specific and is reserved for tumors that arise at the ampulla. Based on their location, ampullary cancers are usually detected relatively early due to the appearance of jaundice and have a more favorable prognosis. The ampulla of Vater is lined by an epithelial layer that transitions from pancreatic and biliary ductal epithelium to duodenal mucosal epithelium. Ampullary adenocarcinomas can therefore have an intestinal and/or pancreaticobiliary histologic morphology, with the former having a better prognosis. Patients with ampullary cancer have a 10-year survival of about 35%, which is a much better prognosis than patients with pancreatic adenocarcinoma. The difference in survival is not entirely explained by an earlier presentation and lower incidence of lymph node metastases. There are biologic, particularly molecular, differences between ampullary and pancreatic adenocarcinoma of the pancreas.

Intestinal type ampullary cancers have a lower incidence of EGFr and mutant p53 overexpression, and fewer activating K-ras mutations. These tumors are more likely to have genetic changes similar to colon cancer such as microsatellite instability and adenomatous polyposis coli mutations.

Management of Periampullary Adenomas. Benign tumors such as ampullary adenomas can also originate at the ampulla. The accuracy of endoscopic biopsy in distinguishing ampullary cancer from benign adenoma is poor, with false-negative rates from 25% to 56% even if sphincterotomy precedes the biopsy. However, benign villous adenomas of the ampullary region can be excised locally. This technique is applicable only for small tumors (approximately 2 cm or less) with no evidence of malignancy upon biopsy. EUS may help to accurately determine if there is invasion into the duodenal wall. In the absence of invasion, adenomas may be amenable to an endoscopic or transduodenal excision. A longitudinal duodenotomy is made and the tumor is excised with a 2- to 3-mm margin of normal duodenal mucosa. In some centers, small periampullary adenomas can also be removed endoscopically. A preoperative diagnosis of cancer is a contraindication to transduodenal excision, and pancreaticoduodenectomy should be performed. Likewise, if final pathologic examination of a locally excised tumor reveals invasive cancer, the patient should be returned to the operating room for a pancreaticoduodenectomy. An important subset of patients are those with FAP who develop periampullary or duodenal adenomas. These lesions have a high incidence of harboring carcinoma and frequently recur unless the mucosa at risk is resected. A standard (not pylorus-sparing) Whipple is the procedure of choice in FAP patients with periampullary lesions.

Cystic Neoplasms of the Pancreas. A cystic neoplasm needs to be considered when a patient presents with a fluid-containing pancreatic lesion. Asymptomatic cystic neoplasms of the pancreas may be more frequent than previously recognized and are being identified with increasing frequency as the use of abdominal CT scanning and MRI has increased. Pancreatic cysts are now thought to be present in about 9% of the population age 80 and older. When symptoms are clearly attributable to a pancreatic cyst, resection is indicated in patients who are fit candidates for surgery. However, management of asymptomatic pancreatic cysts is nuanced and can trigger significant anxiety for patients and their surgeons. Invasive surveillance and aggressive surgical intervention can cause harm, decrease quality of life, and increase costs. While the overall risk that an incidental pancreatic cyst is malignant is very low (about 1 in 10,000), the risks of surgery are very significant with a 2% to 5% mortality and 30% to 40% morbidity. However, some of these neoplasms slowly undergo malignant transformation and thus represent an opportunity for surgical cure, which is uncommon after transformation to invasive pancreatic adenocarcinoma. The dilemma for the surgeon is to identify the minority of cysts that pose a significant risk and provide individual patients with an accurate assessment of their unique risk-benefit ratio of resection vs. surveillance.

Surveillance programs are of questionable value in patients who are not candidates for surgery due to age and or multiple comorbidities and limited life expectancy. Surgeons also need to clearly explain to the patient the risks and benefits of surveillance itself. MRI is the preferred surveillance imaging modality.
over computed tomography because MRI does not expose the patient to radiation and better demonstrates the structural relationship between the pancreatic duct and associated cyst. Also, MRI is less invasive than EUS. EUS is therefore reserved for further evaluation of higher risk cysts. Another problem to confront is when to stop surveillance in a cyst that has been stable during observation. Some clinicians stop following after 5 years but data is lacking to guide this decision. In addition, patients who have undergone resection of a pancreatic cystic neoplasm with high grade dysplasia may warrant continued surveillance after surgery particularly when there is a possible field effect such as in IPMN or concern that all of the disease has not been resected. Individualized decision-making and multidisciplinary input is ideal.372

**Pseudocysts.** The most common cystic lesion of the pancreas is the pseudocyst, which, of course, has no epithelial lining and is a nonneoplastic complication of pancreatitis or pancreatic duct injury. As discussed in “Complications of Chronic Pancreatitis,” the diagnosis is usually straightforward from the clinical history. Although not usually necessary, analysis of pseudocyst fluid would reveal a high amylase content. The danger comes in mistaking a cystic pancreatic neoplasm for a pseudocyst and incorrectly draining a cystic neoplasm into the GI tract rather than resecting the neoplasm. For this reason, biopsy of the pseudocyst wall is a requirement in the management of pancreatic pseudocysts.

**Cystadenoma.** Serous cystadenomas are essentially considered benign tumors without malignant potential. Serous cystadenocarcinoma has been reported very rarely (<1%). Therefore, malignant potential should not be used as an argument for surgical resection, and the majority of these lesions can be safely observed in the absence of symptoms due to mass effect or rapid growth. The average rate of growth is about 0.5 cm per year. About 50% of cystadenomas are asymptomatic and detected as an incidental finding. Most symptomatic patients have mild upper abdominal pain, epigastric fullness, or moderate weight loss. Occasionally, cystadenomas can grow to a size capable of producing jaundice or GI obstruction due to mass effect (Fig. 33-77). For symptomatic patients with serous cystadenoma, surgical resection is indicated. For lesions in the tail, splenectomy is not necessary, given the benign nature of the tumor. In appropriate candidates, a laparoscopic approach to distal pancreatectomy with or without splenic preservation can be considered. These cysts are frequently found in older women in which pancreatic resection for a benign neoplasm should be avoided in the absence of significant symptoms. All regions of the pancreas are affected, with half in the head/uncinate process, and half in the neck, body, or tail of the pancreas. They have a spongy appearance, and multiple small cysts (microcystic) are more common than larger cysts (macrocystic or oligocystic). These lesions contain thin serous fluid that does not stain positive for mucin and is low in CEA (<200 ng/mL). Typical imaging characteristics include a well-circumscribed cystic mass, small septations, fluid close to water density, and sometimes, a central scar with calcification. If a conservative management is adopted, it is important to be sure of the diagnosis. EUS-FNA should yield nonviscous fluid with low CEA and amylase levels, and if cells are obtained, which is rare, they are cuboidal and have a clear cytoplasm.

**Mucinous Cystadenoma and Cystadenocarcinoma.** Mucinous cystic neoplasms (MCNs) encompass a spectrum ranging from benign but potentially malignant to carcinoma with a very aggressive behavior (Table 33-23). There is often heterogeneity within the lesions with benign and malignant-appearing regions, making it impossible to exclude malignancy with biopsy. MCNs are commonly seen in perimenopausal women, and about two-thirds are located in the body or tail of the pancreas. Like cystadenomas, most MCNs are now incidental findings identified during imaging performed for other reasons. When symptoms are present, they are usually nonspecific and include upper abdominal discomfort or pain, early satiety, and weight loss. On imaging studies, the cysts have thick walls and do not communicate with the main pancreatic duct (Fig. 33-78). There may be nodules or calcifications within the wall of the cyst. The cysts are lined by tall columnar epithelium that fills the cyst with viscous mucin. The submucosal layer consists of a highly cellular stroma of spindle cells with elongated nuclei similar to the “ovarian stroma,” which is a key pathologic feature distinguishing these lesions. Elevated CEA levels in the fluid (≥200 ng/mL) are consistent with mucinous lesions and may suggest malignant transformation.373 Solid areas may contain atypical cells or invasive cancer, and extensive sampling of the specimen is necessary to accurately predict prognosis.

Figure 33-77. Mucinous cystic neoplasm in tail of pancreas.
Resection is the treatment of choice for most mucin-producing cystic tumors. Malignancy cannot be ruled out without removal and extensive sampling of the entire tumor. Malignancy has been reported in 6% to 36% of MCNs. Current thinking is that all of these tumors will eventually evolve into cancer if left untreated. However, for individual patients, the surgeon is often faced with a difficult decision. The risk of pancreas surgery in an older patient with multiple comorbidities and a relatively short life expectancy regardless of their pancreatic cyst is frequently weighed against the potential future risk that the cyst, particularly a small cyst, will transform into an incurable invasive cancer.

The utility of detailed DNA analysis of pancreatic cyst fluid to diagnose mucinous and malignant cysts has been evaluated in the PANDA study. The study concluded that cyst fluid K-ras mutation was helpful in the diagnosis of mucinous cysts with 96% specificity. Components of DNA analysis detecting malignant cysts included allelic loss amplitude over 82% and high DNA amount. The criteria of high amplitude K-ras mutation followed by allelic loss showed maximum specificity (96%) for malignancy. However, this test lacks sensitivity. In clinical practice, the surgeon must take all of these complementary factors into consideration when determining the malignant potential of a pancreatic cystic neoplasm.

Because most MCNs are located in the body and tail of the pancreas, distal pancreatectomy is the most common treatment. For small lesions, it may be appropriate to preserve the spleen, but splenectomy ensures removal of the lymph node basin that can potentially be involved. It is very important not to rupture the cyst during resection, and the tumor should be removed intact, not morselized. Therefore, a laparoscopic approach may not be appropriate for larger lesions. Completely resected MCNs without atypia are usually cured especially if small (<3 cm). Even patients with moderate dysplasia or carcinoma in situ are usually cured by complete resection. Noninvasive MCNs require no surveillance after resection. For MCNs with an associated invasive carcinoma, prognosis depends on the extent of the invasive component, tumor stage, and resectability. The 2-year survival rate and 5-year survival rate of patients with
Intraductal Papillary Mucinous Neoplasm. Intraductal papillary mucinous neoplasms (IPMNs) usually occur within the head of the pancreas and arise within the pancreatic ducts. The ductal epithelium forms a papillary projection into the duct, and mucin production causes intraluminal cystic dilation of the pancreatic ducts (Fig. 33-79). Imaging studies demonstrate diffuse dilation of the pancreatic duct, and the pancreatic parenchyma is often atrophic due to chronic duct obstruction. However, classic features of chronic pancreatitis, such as calcification and a beaded appearance of the duct, are not present. At ERCP, mucin can be seen extruding from the ampulla of Vater, a so-called fish-eye lesion that is virtually diagnostic of IPMN (Fig. 33-80). Initial reports suggested a male predominance, but more recent series indicate an equal distribution. Patients are usually in their seventh to eighth decade of life and present with abdominal pain or recurrent pancreatitis, thought to be caused by obstruction of the pancreatic duct by thick mucin. Some patients (5–10%) have steatorrhea, diabetes, and weight loss secondary to pancreatic insufficiency.

Some IPMNs primarily involve the main pancreatic duct, while others involve the branch ducts. The mean frequency of malignancy in main duct IPMN (MD-IPMN) is 62% (Fig. 33-81). Considering this high incidence of malignant lesions and the low 5-year survival rates (31–54%), international consensus guidelines recommend resection for all surgically fit patients with MD-IPMN.\textsuperscript{372} If the margin is positive for high-grade dysplasia, additional resection should be attempted to obtain at least moderate-grade dysplasia at the surgical margin.

The surgical management of IPMNs is complicated by the fact that the lesion itself is small and preoperative imaging studies show a dilated pancreatic duct but not necessarily the mass. Mucus can dilate the duct proximal and distal to the lesion. Furthermore, these lesions can spread microscopically along the duct, and there can be skip areas of normal duct between the diseased portions. Therefore, thorough preoperative imaging including EUS, MRCP, or ERCP, and sometimes pancreatic ductoscopy, which can also be repeated intraoperatively, is useful (see Fig. 33-80). The surgeon needs to be prepared to extend the resection, if necessary, based on intraoperative findings and frozen section of the margin. Extending the resection to the point of total pancreatectomy is controversial due to the morbidity of this operation. Like MCNs, the IPMNs require careful histologic examination of the entire specimen for an invasive cancer (Fig. 33-82).

Survival of patients with IPMN, even when malignant and invasive, can be quite good. As with MCN, patients with borderline tumors or carcinoma in situ are usually cured. For this reason, if recurrence occurs in the remaining pancreas, further resection is warranted because several series have shown that some of these cases are salvageable. Patients with IPMN are also at risk for other malignancies and should undergo colonoscopy and close surveillance.

Branch-duct type IPMNs (BD-IPMN) are often found in the uncinate process, are sometimes asymptomatic, and are less frequently associated with malignant transformation (6–46%). Asymptomatic, small suspected BD-IPMNs are frequently
Figure 33-81. Intraductal papillary mucinous neoplasm (IPMN). A. Examples of “fish-eye deformity” of IPMN. Mucin is seen extruding from the ampulla. B. Views of pancreatic duct during ductoscopy; normal (left) and IPMN (right).
observed with serial imaging. High-risk features such as mural nodules, a dilated main duct, positive cytology or cyst fluid CEA >200 need to be ruled out. In the absence of these features, continued observation with serial imaging is appropriate, especially in patients who are not ideal operative candidates. The mean frequency of invasive cancer in resected BD-IPMN is 18%. BD-IPMN mostly occurs in elderly patients, and the annual malignancy rate is only 2% to 3%. These factors support conservative management with follow-up in patients who do not have any symptoms or risk factors predicting malignancy such as mural nodule, rapidly increasing cyst size, and high-grade atypia in cytology. There is insufficient data to support immediate resection for all BD-IPMNs <3 cm without “high-risk stigmata” and “worrisome features.” Branch-duct IPMNs ≥3 cm should be resected.372

Four histologic subtypes of IPMNs have been characterized: gastric, intestinal, pancreaticobiliary, and oncocytic. Most of BD-IPMNs are composed of gastric-type epithelium. However, intestinal type is more common in MD-IPMN. In a recent report, the four subtypes of IPMNs were associated with significant differences in survival.376 Patients with gastric-type IPMN had the best prognosis, whereas those with intestinal and pancreaticobiliary type had a bad prognosis.

Workup of Asymptomatic Pancreatic Cystic Neoplasms

Incidentally discovered asymptomatic pancreatic cystic neoplasms are evaluated by MRI with MRCP to check for “high-risk stigmata or worrisome features.” An enhancing solid component or main pancreatic duct (MPD) dilation ≥10 mm are considered “high-risk stigmata.” Cysts ≥3 cm, thickened enhancing cyst walls, nonenhancing mural nodules, MPD size of 5 to 9 mm, abrupt change in the MPD caliber with distal pancreatic atrophy, and lymphadenopathy are considered “worrisome features.” All cysts with high risk stigmata are resected. All cysts with worrisome features and cysts >3 cm without worrisome features are further evaluated with EUS. If EUS shows a definite mural nodule, main duct features suspicious for involvement or the cytology is positive or suspicious for malignancy, then resection is recommended. In the absence of worrisome features, no further initial work-up is recommended, but surveillance is still required.

The interval between surveillance imaging is based on the size of the cyst with a lengthening of the interval once stability is established. Patients with noninvasive MCNs require no surveillance after resection, but patients with IPMNs need surveillance after resection. In the absence of residual lesions, repeat MRI at 2 and 5 years may be reasonable. If there is low or moderate-grade dysplasia at the margin, MRI every 6 months is recommended.

Resection is indicated in all surgically fit patients with MD-IPMN, and additional resection is indicated if there is high-grade dysplasia at the margin. Resection is also indicated in all surgically fit patients with MCN. BD-IPMN <3 cm without worrisome features or high-risk stigmata can undergo surveillance.

When patients are deemed unacceptable for resection due to comorbidities, ablation of the cyst can be considered. However, at this time, cyst ablation is considered experimental and should be done as part of a clinical trial. Gastroenterologists have limited experience with injection of a cytotoxic agent into the cyst in an attempt to ablate the cyst epithelium. Ethanol has been used and more recently this has been combined with paclitaxel. The combination of ethanol and paclitaxel injection resulted in elimination of the cysts, as determined by CT scanning, in 29 out of 47 (62%) of patients in a median follow-up period of 21.7 months.377

Recently, the American Gastroenterological Association (AGA) published guidelines for asymptomatic mucinous cysts (http://www.gastro.org/guidelines/pancreatic-cysts) that are different from all previously published guidelines in the following areas: 2-year interval for cyst of any size undergoing surveillance, stopping surveillance after 5 years if no change, surgery only if more than one concerning feature on MRI confirmed on EUS and only in centers with high volumes of pancreatic surgery, and no surveillance after surgery if no invasive cancer or dysplasia. Although based on extensive literature review and synthesis, these recommendations have resulted in significant controversy because, in an effort to reduce the costs of health care delivery and perhaps decrease inadvertent harm to patients, they advocate less frequent follow-up and a higher threshold before offering EUS and/or surgery.

**Solid-Pseudopapillary Tumor.** Solid-pseudopapillary tumors are rare and typically occur in young women. Previous names for this entity include, solid and cystic, solid and papillary, cystic and papillary, and papillary-cystic tumor. They are typically well circumscribed on CT (Fig. 33-83). The cysts are not true epithelial-lined cysts but rather represent a necrotic/degenerative process. Histology may be similar to neuroendocrine tumors, but they do not stain positive for neuroendocrine markers such as chromogranin. Most are cured by resection, but liver and peritoneal metastases have been reported.

**Other Cystic Neoplasms.** Rarely, typical ductal adenocarcinoma of the pancreas may undergo cystic degeneration due to central necrosis. Occasionally, this will create difficulty in the proper preoperative diagnosis and should be kept in mind when deciding to conservatively follow a cystic pancreatic neoplasm. It is more common, 5% to 10%, for neuroendocrine tumors of the pancreas to contain cysts. These cysts are filled with serosanguineous fluid rather than necrotic debris. Lymphoepithelial
cysts of the pancreas usually occur in men in their fifth to sixth decade. These benign lesions may be unilocular or multilocular and vary widely in size. The contents of the cyst are also variable and may be thin serous fluid or cheesy/caseous material if there is increased keratin formation. A substantial number of patients with von Hippel-Lindau syndrome develop pancreatic cysts that resemble serous cystadenomas. There may be multiple lesions scattered throughout the pancreas. Patients with polycystic kidney and hepatic disease may also develop benign pancreatic cysts (cystadenomas). With all of these rare cystic neoplasms, careful clinical history, high-quality pancreatic imaging, and sampling of the cyst fluid for analysis will guide proper treatment.

Pancreatic Lymphoma. Lymphoma can affect the pancreas. Primary involvement of the pancreas with no disease outside the pancreas also occurs. The clinical presentation often is similar to pancreatic adenocarcinoma, with vague abdominal pain and weight loss. Identification of a large mass often involving the head and body of the pancreas should raise suspicion. Percutaneous or EUS-guided biopsy will confirm the diagnosis in most cases. If the diagnosis cannot be confirmed preoperatively, laparoscopic exploration and biopsy are indicated. There is no role for resection in the management of pancreatic lymphoma. Endoscopic stenting to relieve jaundice followed by chemotherapy is the standard treatment, and long-term remission is often achieved.

HISTORICAL BACKGROUND

The spleen has been the subject of man’s musings since almost the establishment of the written word. It has been largely misunderstood, often maligned, and certainly underappreciated as a major organ for more than two millennia. The ancients, presumably through patient observation and occasional anatomic exploration, often consigned the spleen to a vestigial role.

Our current understanding of the central role played by the spleen in regulating the immune system and influencing metabolic and endocrine functions has been built upon knowledge gleaned only over the past few decades. Our early notions of the spleen as a dispensable filter of blood or seat of emotion have been dispelled as our understanding of its structure and function has evolved, informing our surgical approach to this hallowed measure of influence of surgical publication, the impact factor, which is most commonly calculated using a 2-year frame of reference.5,6

In the early 17th century, several physician scientists, Malpighi being the most prominent, began testing hypotheses on splenic function by splenectomizing dogs. He reportedly followed several dogs 5 years postoperatively, noting their healthy survival though apparent ravenous hunger and enhanced sexual appetites. The spleen, still in the era of “balanced humors,” was thus felt to play a role in balancing various appetites as well. In addition to melancholy, the spleen became associated with anger and, paradoxically, was also seen as the “seat of laughter.”2

The claim for the first human splenectomy may have predated that of canine splenectomy. Andriano Zaccavello was credited in 1549 with having performed a splenectomy on a middle-aged woman. This claim remains shrouded in controversy, and the indication for the surgery and whether in fact splenectomy was performed have been called into question. The patient apparently survived, but may in fact have undergone resection of an ovarian cyst rather than her spleen.4 Most patients who underwent splenectomy in the three centuries that followed fared badly. The vast majority of splenectomies performed were partial. Most of these patients required surgery for

Galen, in the second century AD, engaged in more serious anatomic investigation espousing the early belief that function followed structure. His investigations, though pioneering, lacked sufficient rigor, evidenced by his contention that black bile or melancholia flowed from the liver to the spleen and then through the short gastric vessels into the stomach to be excreted. The influence of Galen’s teaching endured for more than 1200 years. All the more remarkable considering the current hallowed measure of influence of surgical publication, the impact factor, which is most commonly calculated using a 2-year frame of reference.5,6

In the early 17th century, several physician scientists, Malpighi being the most prominent, began testing hypotheses on splenic function by splenectomizing dogs. He reportedly followed several dogs 5 years postoperatively, noting their healthy survival though apparent ravenous hunger and enhanced sexual appetites. The spleen, still in the era of “balanced humors,” was thus felt to play a role in balancing various appetites as well. In addition to melancholy, the spleen became associated with anger and, paradoxically, was also seen as the “seat of laughter.”2

The claim for the first human splenectomy may have predated that of canine splenectomy. Andriano Zaccavello was credited in 1549 with having performed a splenectomy on a middle-aged woman. This claim remains shrouded in controversy, and the indication for the surgery and whether in fact splenectomy was performed have been called into question. The patient apparently survived, but may in fact have undergone resection of an ovarian cyst rather than her spleen.4 Most patients who underwent splenectomy in the three centuries that followed fared badly. The vast majority of splenectomies performed were partial. Most of these patients required surgery for
left upper quadrant stab wounds sustained in battles or duels resulting in partial or complete splenic prolapse.8

It was in the early 18th century that the growing body of anatomic microstructural knowledge began to turn the tide on the long-held theory of health and disease deriving from a balance of the four humors. William Henson believed the spleen to be a ductless vascular gland similar to the thyroid and adrenals. In 1777, he wrote of the lymphatic nature of the spleen and its filtering function and even suggested its role in hematopoiesis.10

Rudolf Virchow, one of the first to discover leukemia, implicated the spleen as figuring prominently in all leukemia patients. He suspected that the spleen was responsible for generating the leukocytes in large quantities in these patients. There soon followed an enthusiastic effort by surgeons to cure leukemia by splenectomy. Dr. Thomas Bryant performed the first splenectomy in 1866 in a patient with leukemia. The patient died, as did all 14 patients who underwent splenectomy for leukemia over the next 15 years. After his second consecutive mortality in this setting, Bryant declared that “the operation is physiologically unsound & surgically unsafe for leukemia and should not be performed.”11 In 1908, Johnson reported a series of 99 splenectomies for leukemia with an 85% mortality rate. Unfortunately, it took several decades for his words to be heeded.

In 1916, a medical student from Prague named Paul Kaznelson wrote on the key role played by the spleen in the destruction of platelets leading to the first reported (and successful) splenectomy for a patient with idiopathic thrombocytopenia purpura.2

As surgeons’ experience with the procedure grew, the associated morbidity and mortality decreased. By 1920, the Mayo Clinic reported that splenectomy had a reduced mortality rate of 11%.1

O’Donnell in 1929 was the first to describe fatal post-splenectomy sepsis in a child who had undergone the surgery for hemolytic anemia.3 It took Springer’s 1973 review of almost 2800 postsplenectomy patients and the 2.5% incidence of sepsis-induced mortality (vs. 0.01% in the general population) to reorient surgeons to more conservative splenic procedures.2,3

The advent of minimally invasive surgery and laparoscopic splenectomy in the early 1990s represented a clear advance, benefitting the patient through this evolution of surgical technique. Most large series of laparoscopic splenectomy for benign and malignant indication now report a mortality rate of <1%.12,13 As even more contemporary research reveals the spleen to play a central role in immune, metabolic, and endocrine function, it follows that the surgeon’s role going forward will be to preserve this organ and its functions whenever possible.

EMBRYOLOGY AND ANATOMY

Consisting of an encapsulated mass of vascular and lymphoid tissue, the spleen is the largest reticuloendothelial organ in the body. Arising from the primitive mesoderm as an outgrowth of the left side of the dorsal mesogastrium, by the fifth week of gestation, the spleen is evident in an embryo 8 mm long.

Development begins through the formation of the splanchnic mesodermal plate, derived from the mesoderm, at embryonic day 12. The embryonic spleen is first colonized by erythroid and myeloid progenitor cells at 2 weeks of gestation. Following soon thereafter, the hematopoietic stem cells take up residence in the forming spleen.14 The spleen assumes an important hematopoietic role until the fifth month of gestation. After birth, splenic erythropoietic function may persist in some hematologic disorders.15
The organ continues its differentiation and migration to the left upper quadrant, where it comes to rest with its smooth, diaphragmatic surface facing posteroinferiorly.\textsuperscript{16}

The most common anomaly of splenic embryology is the accessory spleen. Present in up to 20\% of the population, one or more accessory spleens may also occur in up to 30\% of patients with hematologic disease. Over 80\% of accessory spleens are found in the region of the splenic hilum and vascular pedicle. Other locations for accessory spleens in descending order of frequency are the gastrocolic ligament, the pancreas tail, the greater omentum, the stomach’s greater curve, the splenocolic ligament, the small and large bowel mesentery, the left broad ligament in women, and the left spermatic cord in men (Fig. 34-1).\textsuperscript{10,16}

The abdominal surface of the diaphragm separates the spleen from the lower left lung and pleura and the ninth to eleventh ribs. The visceral surface faces the abdominal cavity and contains gastric, colic, renal, and pancreatic impressions. Spleen size and weight vary with age, with both diminishing in the elderly and in those with underlying pathologic conditions. The average adult spleen is 7 to 11 cm in length and weighs 150 g (range, 70–250 g).

The spleen’s superior border separates the diaphragmatic surface from the gastric impression of the visceral surface and often contains one or two notches, which are particularly pronounced when the spleen is greatly enlarged.

Of particular clinical relevance, the spleen is suspended in position by several ligaments and peritoneal folds to the colon (splenocolic ligament), the stomach (gastrosplenic ligament), the diaphragm (phrenosplenic ligament), and the kidney, adrenal gland, and tail of the pancreas (splenorenal ligament) (Fig. 34-2). In a related historical footnote it was widely held less than 200 years ago that a “wandering spleen” led women to experience hypochondria. Dietl in 1863 finally clarified that “it was not a patient’s temperament but rather relaxation, extension or the hypoplasia of splenic ligaments that made a spleen wander.”\textsuperscript{17} The gastrosplenic ligament contains the short gastric vessels; the remaining ligaments are avascular, with rare exceptions, such as in patients with portal hypertension. The relationship of the pancreas to the spleen also has important clinical implications. In cadaveric anatomic series, the tail of the pancreas has been demonstrated to lie within 1 cm of the splenic hilum 75\% of the time and to actually abut the spleen in 30\% of patients.\textsuperscript{2}

The spleen derives most of its blood from the splenic artery, the longest and most tortuous of the three main branches of the celiac artery. The splenic artery can be characterized by the pattern of its terminal branches. The distributed type of splenic artery is the most common (70\%) and is distinguished by a short trunk with many long branches entering over three-fourths of the spleen’s medial surface. The less common magistral type of splenic artery (30\%) has a long main trunk dividing near the hilum into short terminal branches, and these enter over 25\% to 30\% of the spleen’s medial surface. The spleen also receives some of its blood supply from the short gastric vessels that branch from the left gastroepiploic artery running within the gastrosplenic ligament. The splenic vein joins the superior mesenteric vein to form the portal vein and accommodates the major venous drainage of the spleen.

When a normal, freshly excised spleen is sectioned, the cut surface is finely granular and predominantly dark red with whitish nodules distributed liberally across its expanse. This gross observation reflects the spleen’s microstructure. The splenic parenchyma is composed of two main elements: the red pulp, constituting approximately 75\% of total splenic volume, and the white pulp (Fig. 34-3). At the interface between the red and white pulp is the narrow marginal zone.
Blood enters the red pulp through cords comprised of fibroblasts and reticular fibers, which contain many macrophages and lack an endothelial lining. The blood then passes from these “open” cords to venous sinuses, which are surrounded and separated by the same reticulum, and ultimately drains into tributaries of the splenic vein. An understanding of the microanatomy of these sinuses has elucidated the mechanical filtration function of the spleen. Unlike the cords of the red pulp, the sinuses of the red pulp are lined by endothelial cells. These cells contain unique stress fibers that connect the endothelial cells and that contain actin and myosin-like filaments capable of producing a sliding action. When activated, these filaments can create slits or gaps between the endothelial cells through which blood can then pass from the cords. Aging erythrocytes with stiffer membranes get stuck trying to pass into the sinus and are phagocytized by macrophages within the red pulp.

The red pulp thus serves as a dynamic filtration system, enabling macrophages to remove microorganisms, cellular debris, antigen-antibody complexes, and senescent erythrocytes from the circulation.

Around the terminal millimeters of splenic arterioles, a periaortic lymphatic sheath replaces the native adventitia of the vessel. The sheath is comprised of T lymphocytes and intermittent aggregations of B lymphocytes or lymphoid follicles. When antigenically stimulated, the follicles, serving as centers of lymphocyte proliferation, develop germinal centers, which regress as the stimulus or infection subsides. This white pulp consists of nodules that normally are ≤1 mm in size but can increase to several centimeters when nodules coalesce, as occurs in certain lymphoproliferative disorders. At the junction between the white and red pulp is the marginal zone, where lymphocytes are more loosely aggregated.

As well as serving as a transit area, the marginal zone is home to its own unique population of cells. Notably two specific types of macrophages reside there, marginal zone macrophages and marginal zone metallophilic macrophages. The former play an important role in the targeting and clearance of certain bacterial pathogens. The latter have been shown to be the main producers of interferons A and B in response to a viral challenge.

**PHYSIOLOGY AND PATHOPHYSIOLOGY**

The spleen is contained by a 1- to 2-mm thick capsule. In humans, the capsule is rich in collagen and contains some elastin fibers. Many mammals have splenic capsules and trabeculae with abundant smooth muscle cells, which upon autonomic stimulation contract to expel large volumes of stored blood into the general circulation. The human splenic capsule and trabeculae, by contrast, contain few or no smooth muscle cells.

Total splenic inflow of blood is approximately 250 to 300 mL/min. Blood flows through successively tapering arteries to arterioles, traverses the white pulp, crosses the marginal zone, and enters the red pulp. From that entry, the flow rate through the spleen may vary greatly. Animal studies measuring the transit times of isotopically labeled blood through the spleen have revealed three distinct velocities of flow. Humans have long been recognized to have both a fast or closed circulation—with blood passing directly from arterioles into venous sinuses—and a slower or open circulation. Most of the spleen’s filtration function occurs via the slower circulation. During open circulation, blood percolates through the reticular space and splenic cords, thus gaining access through gaps or slits in the endothelial cell lining to the sinuses as previously described. Flowing into and out of the venous sinuses through these gaps, the blood is exposed to extensive contact with splenic macrophages. These are responsible for the innate immune response of the spleen, which occurs largely within the marginal zone. The white pulp, by contrast, is involved only in adaptive immunity. In addition, because the passage of plasma through these spaces does not slow in a similar manner, a temporary and unique adhesive contact between blood cells and components of the splenic cord may occur. That there is a selective slowing of blood cell flow versus plasma flow is further evidenced by the fact that within the spleen, the erythrocyte concentration (hematocrit) is twice that of the general circulation. During this contact with splenic macrophages, it is likely that the removal of both cellular debris and senescent blood cells occurs.

The process by which the spleen removes erythrocyte inclusions, such as Heinz bodies (intracellular altered hemoglobin), without cell lysis while red blood cells travel through the spleen is not well understood. The spleen acts as the major site for clearance from the blood of damaged or aged red blood cells and, in addition, has a part in the removal of abnormal white blood cells and platelets. A minimum of 2 days of the erythrocyte’s 120-day life cycle is spent sequestered in the spleen. Daily, approximately 20 mL of aged red blood cells are removed. Evidence suggests that, as erythrocytes age, previously undetected antigens on their surfaces may attach to autoantibodies in the circulation; then macrophages may bind to the antibodies and initiate phagocytosis. It is probable that the erythrocyte is damaged over time by multiple passages through the spleen as well as delayed transit through the congested and relatively hypoxic and acidic environment of the splenic cords.

The spleen can also serve as an extra medullary site for hematopoiesis, if required. Another role played by the spleen is in recycling iron. Erythrocytes in large numbers are destroyed intravascularly throughout the body. The released hemoglobin is then bound to haptoglobin, which is ultimately scavenged from the circulation in the spleen.
The spleen plays a vital, although not indispensable, role in host defense evidenced by the healthy survival of splenectomized patients. Both innate and adaptive immune responses (historically categorized as cell-mediated and humoral immunity) occur within the spleen.

In addition to the previously noted activities of the marginal zone macrophages, marginal zone B cells serve to detect circulating pathogens and respond quickly to either differentiate into immunoglobulin M (IgM)–producing plasma cells or to function as antigen-presenting cells (APCs), which facilitate pathogen removal and destruction.

It is APC entry in the white pulp in particular that is key to the initiation of the adaptive immune response. Antigens are thus presented to immunocompetent centers within the lymphoid follicles. This gives rise to the elaboration of immunoglobulins (predominantly IgM). After an antigen challenge, such an acute IgM response results in the release of opsonic antibodies from the white pulp of the spleen. Antigen clearance is then facilitated by the splenic and hepatic reticuloendothelial systems.

The structure and immunophysiology of the white pulp is very similar to that of lymph nodes, with the notable difference being that material enters the lymph node in the lymph whereas it is delivered to the white pulp in the blood.20

The spleen also produces opsonins, tuftsin, and properdin. Circulating monocytes are converted within the red pulp into fixed macrophages that account for the spleen’s remarkable phagocytic activity.

The spleen also appears to be a major source of the protein properdin, important in the initiation of the alternate pathway of complement activation. The splenic reticuloendothelial system is better able to clear bacteria that are poorly or inadequately opsonized from the circulation than is the hepatic reticuloendothelial system. Encapsulated bacteria generally fit such a profile, hence the risk posed by pneumococcus and Haemophilus influenzae to an asplenic patient. There appears to be sufficient physiologic capacity within the complement cascade to withstand the loss of tuftsin and properdin production without an increase in patient vulnerability after splenectomy.21-23

In patients with chronic hemolytic disorders, splenic tissue may become permanently hypertrophied. The reticular spaces of the red pulp become distended with macrophages engorged with the products of erythrocyte breakdown, and splenomegaly can result. It is important to distinguish between splenomegaly and hypersplenism, two similar but distinct terms that are critical to understand when discussing splenic pathology. Splenomegaly refers simply to abnormal enlargement of the spleen. Splenomegaly is described variably within the surgical literature as moderate, massive, and hyper, which reflects a lack of consensus. Most would agree, however, that splenomegaly applies to organs weighing ≥500 g and/or averaging ≥15 cm in length.

Massive splenomegaly similarly lacks a consensus definition but has been described variably as spleens >1 kg in mass or >22 cm in length (Fig. 34-4).3 Spleens palpable below the left costal margin are thought to be at least double normal size, with an estimated weight of ≥750 g.24

There is not a single, universally accepted standard, but most would agree that an ex vivo mass of >1 kg or a pole-to-pole length of >15 cm generally qualifies as splenomegaly. Hypersplenism often is found in association with splenomegaly but is not synonymous with it. Hypersplenism is defined as the presence of one or more cytopenias in the context of a normally functioning bone marrow.

Figure 34-4. Splenomegaly. A. Computed tomography (CT) scan. B. Three-dimensional reconstruction of CT scan. C. Postoperative specimen.
Disorders causing hypersplenism can be categorized as either (a) those in which increased destruction of abnormal blood cells occurs in an intrinsically normal spleen (e.g., hemolytic anemias) or (b) primary disorders of the spleen resulting in increased sequestration and destruction of normal blood cells (e.g., infiltrative disorders).

The life cycles of cellular elements vary widely in human blood. A neutrophil in circulation has a normal half-life of approximately 6 hours. The spleen’s role in the normal clearance of neutrophils is not well established. It is clear that hypersplenism may result in neutropenia through sequestration of normal white blood cells or the removal of abnormal ones. Platelets, on the other hand, generally survive in the circulation for 10 days. Under normal circumstances, a third of the total platelet pool is sequestered in the spleen. Thrombocytopenia may result from excessive sequestration of platelets as well as accelerated platelet destruction in the spleen. Splenomegaly may result in sequestration of up to 80% of the platelet pool. The spleen may also contribute to the immunologic alteration of platelets, which leads to thrombocytopenia in the absence of splenomegaly (e.g., idiopathic thrombocytopenic purpura [ITP]).

The immunologic functions of the spleen are consistent with those of other lymphoid organs. It is a site of bloodborne antigen presentation and the initiation of T- and B-lymphocyte activities involved in humoral and cellular immune responses. Alteration of splenic immune function often gives rise to antibody production, which results in blood cell destruction.

Although the spleen contributes to the process of erythrocyte maturation, in adult humans there is little evidence of normal hematopoietic function. The spleen does have a minor role in hematopoiesis in the fourth month in the human fetus, and reactivation can occur in childhood if the bone marrow fails to meet the hematologic needs. Splenic hematopoiesis giving rise to abnormal red blood cells is seen in adults with myeloproliferative disorders. In addition, in response to some anemias, elements of the red pulp may revert to hematopoiesis.

### INDICATIONS FOR SPLENECTOMY

Generally speaking, splenectomy is performed for the purposes of cure or palliation of hematological disease including conditions of hypersplenism, to relieve the mass effect and symptoms associated with splenomegaly, to control infection or hemorrhage and finally to diagnose splenic pathology. For the purposes of this chapter, we will divide these indications into the following categories: (a) benign conditions, including red blood cell disorders, hemoglobinopathies, and platelet disorders (Table 34-1a); (b) malignant conditions, including white blood cell disorders, bone marrow disorders (myeloproliferative disorders) and tumors of the spleen (Table 34-1b); and (c) miscellaneous conditions and lesions of the spleen including infections and abscesses, cysts, vascular anomalies, and more (Table 34-1c). We will conclude this chapter with a brief discussion on splenic salvage.

Overall, the most common indication for splenectomy is trauma to the spleen, whether external trauma (blunt or penetrating) or iatrogenic injury (e.g., at the time of other operations). Inadvertent intraoperative injury to the spleen, necessitating removal, also called “incidental splenectomy” is discussed in a

later section. Management of splenic injury in the trauma patient is also beyond the scope of this chapter and discussed elsewhere. The most common indications for elective splenectomy are malignancy and hematologic autoimmune disorders, principally, idiopathic thrombocytopenic purpura (ITP) and autoimmune hemolytic anemia (AIHA).

Benign Disorders

Red Blood Cell Disorders

Congenital

Hereditary Spherocytosis. Hereditary spherocytosis (HS) is the most common type of hemolytic anemia for which splenectomy is indicated and the third most common type of congenital hemolytic anemia overall. HS results from an inherited dysfunction or deficiency in one of the erythrocyte membrane proteins (alpha or beta spectrin, ankyrin, band 3 protein, or protein 4.2). The resulting destabilization of the membrane lipid bilayer allows a pathologic release of membrane lipids. The red blood cell assumes a more spherical, less deformable shape, and the spherocytic erythrocytes are sequestered and destroyed in the spleen and hemolytic anemia ensues. HS is inherited primarily (70–80% of the time) in an autosomal dominant fashion; the estimated prevalence in Western populations is roughly 1 in 2000.

Patients with typical HS forms may have mild jaundice. Splenomegaly usually is palpable on physical examination. Laboratory examination reveals varying degrees of anemia: patients with mild forms of the disease may not have anemia; patients with moderate to severe forms may have hemoglobin levels as low as 4 to 6 g/dL. The mean corpuscular volume is typically low to normal or slightly decreased. For screening, a combined elevated mean corpuscular hemoglobin concentration and an elevated erythrocyte distribution width are an excellent predictor. Other laboratory indicators of HS include those providing evidence of rapid red blood cell destruction, including elevated reticulocyte count, elevated lactate dehydrogenase level, and increased level of unconjugated bilirubin. Spherocytes are readily apparent on peripheral blood film.

Risks and benefits should be assessed carefully before splenectomy and cholecystectomy are performed for HS. The main indications are moderate to severe symptomatic hemolytic anemia, growth retardation, skeletal changes, leg ulcers, and extramedullary hemopoietic tumors in young patients.

If gallstones coexist with spherocytosis, the gallbladder should be removed, but prophylactic cholecystectomy without gallstones is controversial. Near total splenectomy is advocated in children. Dramatic clinical improvement—despite persistent hemolysis—usually occurs after splenectomy in patients with moderate to severe disease. Because children can be affected with HS, the timing of splenectomy is important and is aimed at reducing the diminutive possibility of overwhelming postsplenectomy sepsis. Delaying such an operation until the patient is between the ages of 4 and 6—unless the anemia and hemolysis accelerate—is recommended by most experts.

Red Blood Cell Enzyme Deficiencies. Red blood cell enzyme deficiencies associated with hemolytic anemia may be classified into two groups: deficiencies of enzymes involved in glycolytic pathways, such as pyruvate kinase deficiency, and deficiencies of enzymes needed to maintain a high ratio of reduced to oxidized glutathione in the red blood cell, protecting it from oxidative damage, such as glucose-6-phosphate dehydrogenase (G6PD) deficiency.

Pyruvate Kinase Deficiency. Pyruvate kinase (PK) deficiency is the most common glycolytic defect causing congenital non-spherocytic hemolytic anemia. Since its first description in the early 1960s, vast amounts of information have been elucidated about the genetic diversity of the disease, red blood cell clearance, long-term complications and treatment options including transfusion and splenectomy. PK deficiency affects people worldwide, with a slight preponderance among those of Northern European or Chinese descent. Its estimated prevalence in the Caucasian population is 51 per million. Clinical manifestations of the disease vary widely, from transfusion-dependent severe anemia in early childhood to well-compensated mild anemia in adolescents or adults. Prenatal hydrops fetalis has also been reported. Pyruvate kinase enzyme activity is the gold standard for initial diagnostic testing or by detection of specific mutations at the complementary DNA or genomic level. Splenomegaly is common, and in severe cases, splenectomy can alleviate transfusion requirements. As with other disorders that cause hemolytic anemia in children, splenectomy should be delayed if possible to at least 4 years of age to reduce the risk of postsplenectomy infection.

Glucose-6-Phosphate Dehydrogenase Deficiency. The most common red blood cell enzyme deficiency overall is G6PD deficiency. It is far more prevalent than PK deficiency with more than 400 million people affected worldwide, although most experience only moderate health risks and no longevity reduction. Clinical manifestations—chronic hemolytic anemia, acute intermittent hemolytic episodes, or no hemolysis—depend on the variant of G6PD deficiency. The mainstay of therapy is avoidance of drugs known to precipitate hemolysis in patients with G6PD deficiency. Transfusions are given in cases of symptomatic anemia. Conventional wisdom is that splenectomy is not indicated in this disease, and certainly the overwhelming majority of patients with G6PD deficiency will neither require nor benefit from splenectomy. However, one report described a small case series of six symptomatic G6PD deficiency patients who had severe hemolytic anemia and required transfusion, all of whom were identified to share a common mutation at exon 10. All underwent splenectomy. A complete response occurred in four patients (transfusion requirement eliminated), and a partial response occurred in one patient (transfusion requirement reduced); no follow-up data were provided for the remaining patient. This study indicates that for a carefully select group of patients with severe hemolytic anemia attributable to G6PD deficiency, splenectomy may be of benefit, although more data is needed before strong recommendation can be made.

Acquired

Warm-Antibody Autoimmune Hemolytic Anemia. Autoimmune hemolytic anemias (AIHAs) are characterized by the destruction of red blood cells, whose erythrocyte life span is diminished by autoantibodies leveled against antigens. AIHA is classified as either primary or secondary, depending on whether an underlying cause, such as a disease or toxin, is identified. AIHA is also divided into “warm” and “cold” categories, based on the temperature at which the autoantibodies exert their effect. In cold-agglutinin disease, severe symptoms are uncommon and splenectomy is almost never indicated; therefore, this entity is not discussed further in this section. However, warm-antibody AIHA has clinical consequences with which the surgeon should be familiar.
Warm-antibody AIHA, although occurring primarily in midlife, can affect individuals at all ages. The disorder is more common among women, and fully half of warm-antibody AIHA cases are idiopathic. Clinical presentation may be acute or gradual. Findings include mild jaundice and symptoms and signs of anemia. One-third to one-half of patients present with splenomegaly. Sometimes in such cases the spleen is palpable on physical examination. The diagnosis relies on demonstrating hemolysis as indicated by anemia, reticulocytosis, and/or products of red blood cell destruction, including bilirubin, in the blood, urine, and stool. A positive result on direct Coombs’ test confirms the AIHA diagnosis by distinguishing autoimmune from other forms of hemolytic anemia.

Treatment of AIHA depends on the severity of the disease and whether it is primary or secondary. Severe symptomatic anemia demands prompt attention, often requiring red blood cell transfusion. The mainstay treatment for both primary and secondary forms of symptomatic, unstable AIHA remains long-term corticosteroid administration. Therapy should continue until a response is noted by a rise in hematocrit and fall in reticulocyte count, which generally occurs within 3 weeks.

Clinical response to splenectomy for AIHA varies, and the evidence from a number of small case series is conflicting. For example, one 2004 series reported a favorable response to splenectomy in patients with AIHA secondary to chronic lymphocytic leukemia, whereas more recent series found no benefit from splenectomy in patients with AIHA secondary to systemic lupus erythematosus or inflammatory bowel disease.

Favorable responses to splenectomy have been reported in patients with warm-antibody AIHA, with a recent series showing complete remission of refractory AIHA following laparoscopic splenectomy at 35-month follow-up in patients over 60 years old. Transient responses are more common, however, and many patients eventually experience hemolysis again despite splenectomy. The decision regarding splenectomy in the case of AIHA should be individualized based on careful consideration of the clinical history and frank discussion with the patient. It is considered as a third-line therapy after failure of steroids or anti-CD20 antibody administration.

**Hemoglobinopathies.** Sickle cell disease is an inherited chronic hemolytic anemia that results from the mutant sickle cell hemoglobin (HbS) within the red blood cell and is inherited in an autosomal dominant fashion. Persons who inherit an \( HbS \) gene from one parent (heterozygous) are carriers; those who inherit an \( HbS \) gene from both parents (homozygous) have sickle cell anemia.

In sickle cell disease, the underlying abnormality is the mutation of adenine to thymine in the sixth codon of the \( \beta \)-globin gene, which results in the substitution of valine for glutamic acid as the sixth amino acid of the \( \beta \)-globin chain. Mutant \( \beta \) chains included in the hemoglobin tetramer create HbS. Deoxygenated HbS is insoluble and becomes polymerized and sickled. The subsequent lack of deformability of the red blood cell, in addition to other processes, results in microvascular congestion, which may lead to thrombosis, ischemia, and tissue necrosis. The disorder is characterized by painful intermittent episodes.

Sequestration occurs in the spleen, with splenomegaly resulting early in the disease course. In most patients, subsequent infarction of the spleen and autosplenectomy occur at some later time. The most frequent indications for splenectomy in sickle cell disease are recurrent acute sequestration crises, hypersplenism, and splenic abscess. The occurrence of one major acute sequestration crisis, characterized by rapid painful enlargement of the spleen and circulatory collapse, generally is considered sufficient grounds for splenectomy. Both partial and total splenectomy have been shown to control clinical symptoms in children but may not change hematologic parameters. Preoperative preparation should include special attention to adequate hydration and avoidance of hypothermia.

Transfusions are often indicated for anemia, for moderately severe episodes of acute chest syndrome (i.e., a new infiltrate on chest radiograph associated with new symptoms, such as fever, cough, sputum production, or hypoxia), and preoperatively before splenectomy. Patients experiencing stroke or a severe crisis may require hydration and an exchange transfusion, which may be performed manually or with automated apheresis equipment. Hydroxyurea is an oral chemotherapeutic agent that upregulates fetal hemoglobin, which interferes with polymerization of HbS and thus reduces the sickling process.

**Thalassemia.** Thalassemia is the term for a group of inherited disorders of hemoglobin synthesis prevalent among people of Mediterranean extraction and classified according to the globin chain (\( \alpha \), \( \beta \), or \( \gamma \)) affected. As a group, the thalassemias are the most common genetic diseases known to arise from a single gene defect. Most forms of this disorder are inherited in Mendelian recessive fashion from asymptomatic carrier parents. In the so-called thalassemia belt that extends throughout the shores of the Mediterranean as well as through the Arabian Peninsula, Turkey, Iran, India, and southeastern Asia, the incidence of thalassemia is between 2.5% and 15%. However, thalassemias have been found in people of all ethnic origins.

In all forms of thalassemia, the primary defect is absent or reduced production of hemoglobin chains. From this abnormality, two significant consequences arise: (a) reduced functioning of hemoglobin tetramers, yielding hypochromia and microcytosis; and (b) unbalanced biosynthesis of individual \( \alpha \) and \( \beta \) subunits, which results in insoluble red blood cells that cannot release oxygen normally and may precipitate with cell aging. Both underproduction of hemoglobin and excess production of unpaired hemoglobin subunits contribute to thalassemia-associated morbidity and mortality.

A diagnosis of thalassemia major (homozygous form) is made by demonstrating hypochromic microcytic anemia associated with randomly distorted red blood cells and nucleated erythrocytes (target cells) on peripheral blood smear. Elevated reticulocyte count and white blood cell count are among the associated findings. Because \( \alpha \) chains are needed to form both fetal hemoglobin and adult hemoglobin, \( \alpha \)-thalassemia becomes symptomatic in utero or at birth. By contrast, \( \beta \)-thalassemia becomes symptomatic at 4 to 6 months because \( \beta \) chains are involved only in adult hemoglobin synthesis.

The clinical spectrum of the thalassemias is wide. Heterozygous carriers of the disease are usually asymptomatic. Homozygous individuals, on the other hand, typically present before 2 years of age with pallor, growth retardation, jaundice, and abdominal swelling due to liver and spleen enlargement. Among other characteristics of thalassemia major are intractable leg ulcers, head enlargement, frequent infections, and the need for periodic blood transfusions. Untreated individuals usually die in late infancy or early childhood from severe anemia.

Treatment for thalassemia involves red blood cell transfusions to maintain a hemoglobin level of >9 mg/dL, along with...
intensive parenteral chelation therapy with deferoxamine. Splenectomy is indicated for patients with excessive transfusion requirements (>200 mL/kg per year), discomfort due to splenomegaly, or painful splenic infarction. Careful assessment of the risk-benefit ratio is essential. Thalassemia patients are at high risk for pulmonary hypertension after splenectomy; however, the precise pathophysiology of this sequela remains unclear.\textsuperscript{45,46} The increase in infectious complications is likely to be due to a coexisting immune deficiency, in large part brought about by iron overload, which may be associated both with the thalassemia itself and with transfusions. The disproportionately high rate of overwhelming postsplenectomy infection in thalassemia patients has led some investigators to consider partial splenectomy in children; some success in reducing mortality has been reported.\textsuperscript{47} However, splenectomy should be delayed until after the age of 4 years unless it is absolutely necessary.

**Platelet Disorders**

**Idiopathic Thrombocytopenic Purpura**  Idiopathic thrombocytopenic purpura (ITP), also called immune thrombocytopenic purpura, is an autoimmune disorder characterized by a low platelet count and mucocutaneous and petechial bleeding. The low platelet count stems from premature removal of platelets opsonized by antiplatelet immunoglobulin G autoantibodies produced in the spleen. This clearance occurs through the interaction of platelet autoantibodies with Fc receptors expressed on tissue macrophages, predominantly in the spleen and liver. The estimated incidence of ITP is 100 persons per million annually, about one-half of whom are children.\textsuperscript{48} Adult-onset and childhood-onset ITP are strikingly different in their clinical course and management.

Patients with ITP typically present with petechiae or ecchymoses, although some experience major bleeding from the outset. Bleeding may occur from mucosal surfaces in the form of gingival bleeding, epistaxis, menorrhagia, hematuria, or even melena. The severity of bleeding frequently corresponds to the deficiency in platelets: Patients with counts greater than 50,000/mm\(^3\) usually present with incidental findings; those with counts between 30,000 and 50,000/mm\(^3\) often have easy bruising; those with platelet counts between 10,000 and 30,000/mm\(^3\) may develop spontaneous petechiae or ecchymoses; and those with counts less than 10,000/mm\(^3\) are at risk for internal bleeding.\textsuperscript{49} The incidence of major intracranial hemorrhage is approximately 1%, and it usually occurs early in the disease course. The duration of the bleeding helps to distinguish acute from chronic forms of ITP. Children often present at a young age (peak age of approximately 5 years) with sudden onset of petechiae or purpura several days to weeks after an infectious illness. In contrast, adults experience a more chronic form of disease with an insidious onset. Splenomegaly is uncommon with ITP in both adults and children, and its occurrence should prompt a search for a separate cause of thrombocytopenia. Up to 10% of children, however, have a palpable spleen tip.

Diagnosis of ITP is based on exclusion of other possibilities in the presence of a low platelet count and mucocutaneous bleeding. Other diseases resulting in secondary forms of ITP, such as systemic lupus erythematosus, antiphospholipid syndrome, lymphoproliferative disorders, human immunodeficiency virus (HIV) infection, and hepatitis C, should be identified and treated when present. In addition, any history of use of a drug known to cause thrombocytopenia, such as certain antimicrobials, anti-inflammatories, antihypertensives, and antidepressants, should be sought. In addition to low platelet count, another laboratory finding characteristic of ITP is the presence of large, immature platelets (megakaryocytes) on peripheral blood smear.

The usual first line of therapy is oral prednisone at a dose of 1.0 to 1.5 mg/kg per day.\textsuperscript{49,50} No consensus exists as to the optimal duration of steroid therapy, but most responses occur within the first 3 weeks. Response rates range from 50% to 75%, but relapses are common. IV immunoglobulin, given at 1.0 g/kg per day for 2 to 3 days, is indicated for internal bleeding when platelet counts remain less than 5000/mm\(^3\), when extensive purpura exists, or to preoperatively boost platelets. IV immunoglobulin is thought to impair clearance of immunoglobulin G–coated platelets by competing for binding to tissue macrophage receptors. An immediate response is common, but a sustained remission is not. The medical approach to ITP has been modified with the advent of rituximab and thrombopoietin receptor agonists.\textsuperscript{51} Therapeutic recommendations are summarized in Table 34-2. Splenectomy is selectively indicated for failure of medical therapy, for prolonged use of steroids with undesirable effects, and in selected cases after first relapse.\textsuperscript{1} Prolonged use of steroids can be defined in various ways, but a persistent need for more than 10 to 20 mg/d for 3 to 6 months to maintain a platelet count of greater than 30,000/mm\(^3\) generally prompts referral for splenectomy. Splenectomy is an effective option for refractory ITP and provides a permanent response without subsequent need for steroids in 75% to 85% of patients. Two recent reviews and meta-analyses have assessed the global results of splenectomy for ITP, specifically after the use of laparoscopic techniques.

</table>
In 2004, Kojouri and colleagues reviewed 135 case series from 1966 to 2004, pooling 4955 patients.\textsuperscript{51} The long-term platelet count response was assessed, as was the ability to predict response and the incidence of complications. Complete response was achieved in 66\% of cases with a follow-up ranging from 1 to 153 months, and complete and partial responses occurred in as many as 88\% of patients, regardless of the duration of follow-up. They also analyzed 12 preoperative demographic, clinical, and laboratory parameters and found no predictive capability of platelet response in any of them. Mortality was very low (1\%), and morbidity was 10\%. Limitations of this review included old case series and a low percentage of laparoscopic splenectomies. In a 2009 systemic review involving 1223 patients, Mikael and colleagues evaluated the short- and long-term outcomes after laparoscopic splenectomy.\textsuperscript{52} The conversion rate to open surgery was 5.6\%, and the immediate nonresponder rate was 8.2\%; however, eventually a clinical response was achieved in 72\% of the patients on long-term follow-up (5 years). The initial concerns regarding the potential for missing accessory spleens, longer operative times, and increased cost related to laparoscopic versus open splenectomy have been resolved. Laparoscopy is now the approach of choice for elective splenectomy for ITP, with recent studies showing improved short-term results and comparable long-term results to conventional open splenectomy in this condition.\textsuperscript{53-56}

In children with ITP, the course is typically self-limited, with durable and complete remission in greater than 70\% of patients regardless of therapy. Because of the good prognosis without treatment, the decision to intervene surgically is controversial and is largely to obviate intracranial hemorrhage as discussed earlier. Thus, children with typical ITP—and certainly those without hemorrhage—are managed principally by observation, with short-term therapy in select cases.\textsuperscript{57} Urgent splenectomy, in conjunction with aggressive medical therapy, may play a role in the rare circumstance of severe, life-threatening bleeding in both children and adults.

**Thrombotic Thrombocytopenic Purpura** Thrombotic thrombocytopenic purpura (TTP) is a serious disorder characterized by thrombocytopenia, microangiopathic hemolytic anemia, and neurologic complications. Abnormal platelet clumping occurs in arterioles and capillaries, reducing the lumen of these vessels and predisposing the patient to microvascular thrombotic episodes. The reduced lumen size also causes shearing stresses on erythrocytes, which leads to deformed red blood cells subject to hemolysis. Hemolysis may also be due in part to sequestration and destruction of erythrocytes in the spleen. Research has demonstrated that the underlying abnormality is likely related to the persistence of unusually large multimers of von Willebrand factor associated with platelet clumping in the patient’s blood.\textsuperscript{58,59}

TTP occurs in approximately 3.7 individuals per million, but this rare disorder’s dramatic clinical sequelae and favorable response to early therapy demand an understanding of its clinical presentation to ensure an early diagnosis. Clinical features of the disorder include petechiae, fever, neurologic symptoms, renal failure, and, infrequently, cardiac symptoms such as heart failure or arrhythmias. Petechial hemorrhages in the lower extremities are the most common presenting sign. Along with fever, patients may experience flu-like symptoms, malaise, or fatigue. Neurologic changes range from generalized headaches to altered mental status, seizures, and even coma. Generally, however, the mere presence of petechiae and thrombocytopenia is sufficient to lead to the diagnosis of TTP and consideration of treatment.

The diagnosis is confirmed by the peripheral blood smear, which shows schistocytes, nucleated red blood cells, and basophilic stippling. Although other conditions such as tight aortic stenosis or prosthetic valves may lead to the presence of schistocytes, these conditions generally are not accompanied by thrombocytopenia. TTP may be distinguished from autoimmune causes of thrombocytopenia, such as Evans’ syndrome (ITP and autoimmune hemolytic anemia) or systemic lupus erythematosus, by a negative result on Coombs’ test.

Plasma exchange is the first-line therapy for TTP. This treatment consists of the daily removal of a single volume of the patient’s plasma and its replacement with fresh-frozen plasma until the thrombocytopenia, anemia, and associated symptoms are corrected. Therapy is then tapered over 1 to 2 weeks.\textsuperscript{40} Splenectomy should be considered in patients who experience relapse or who require multiple plasma exchanges to control severe symptoms, and generally is well tolerated without significant morbidity.\textsuperscript{59,60}

**Malignant Conditions**

**White Blood Cell Disorders.** The role of splenectomy in patients with white blood cell disorders varies. As for the myelogenous diseases mentioned previously, splenectomy for white blood cell disorders can be effective therapy for symptomatic splenomegaly and hypersplenism, improving some clinical parameters but generally not altering the course of the underlying disease or long-term prognosis. Historically, splenectomy has played a role during surgical staging for Hodgkin’s disease, although this practice has become largely obsolete with the advent of imaging technologies (Computed tomography [CT] scan and 18F-fluorodeoxyglucose positron emission tomography [18F-FDG PET]).\textsuperscript{61-63} Careful consideration of the intended benefits of splenectomy must be weighed against the significant perioperative and postsplenectomy risks in this often complex patient population.\textsuperscript{64}

**Hairy Cell Leukemia** Hairy cell leukemia (HCL) is an uncommon blood disorder, representing only 2\% of all adult leukemias. HCL is characterized by splenomegaly, pancytopenia, and large numbers of abnormal lymphocytes in the bone marrow. These lymphocytes contain irregular hair-like cytoplasmic projections identifiable on the peripheral smear. Many HCL patients have few symptoms and require no specific therapy. Splenectomy for HCL was historically performed as a palliative procedure, alleviating the symptoms associated with splenomegaly and normalizing peripheral blood counts in the majority of patients, but not leading to morphological bone marrow remissions. However, with the advent of diverse new drugs (e.g., rituximab, pentostatin, cladribine), splenectomy has become rarely performed.\textsuperscript{65} Splenectomy should be considered after exhaustive systemic therapy or for those with nontraumatic rupture, and it has also been used to treat pregnant women with HCL to delay onset of chemotherapy.\textsuperscript{66}

**Hodgkin’s Lymphoma** Hodgkin’s Lymphoma (HL) is a disorder of the lymphoid system characterized by the presence of Reed-Sternberg cells (which actually form the minority of the Hodgkin’s tumor). More than 90\% of patients with HL present with lymphadenopathy above the diaphragm. Lymph nodes can become particularly bulky in the mediastinum, which may result in shortness of breath, cough, or obstructive pneumonia.
Lymphadenopathy below the diaphragm is rare on presentation but can arise with disease progression. The spleen is often an occult site of spread, but massive splenomegaly is not common. In addition, large spleens do not necessarily signify involvement.62

Four major histologic types exist: lymphocyte predominance type, nodular scleros type, mixed cellularity type, and lymphocyte depletion type. The histologic type, along with location of disease and symptomatology, influence survival for patients with HD. Stage I disease is limited to one anatomic region; stage II disease is defined by the presence of two or more contiguous or noncontiguous regions on the same side of the diaphragm; stage III disease involves disease on both sides of the diaphragm, but limited to lymph nodes, spleen, and Waldeyer’s ring (the ring of lymphoid tissue formed by the lingual, palatine, and nasopharyngeal tonsils); and stage IV disease includes involvement of the bone marrow, lung, liver, skin, gastrointestinal tract, or any organ or tissue other than the lymph nodes or Waldeyer’s ring.62

Staging laparotomy for HL is less commonly performed in the current era of minimally invasive surgery and advanced imaging techniques. More liberal use of diagnostic tools (CT scan and 18F-FDG PET) and chemotherapy for patients with HL has drastically reduced the indications for surgical staging. Current indications for surgical staging include clinical suspicion of lymphoma without evidence of peripheral disease or patients requiring restaging for suspicion of failure after chemotherapy.62,67

**Non-Hodgkin’s Lymphoma** Non-Hodgkin’s lymphoma (NHL) encompasses all malignancies derived from the lymphoid system except classic HL.63 A proliferation of any one of the three predominant lymph cell types—natural killer cells, T cells, or B cells—may be included in the category of NHL. Because of the wide net cast by NHL, the clinical presentations of the disorders under its umbrella vary. The subentities of NHL may be clinically classified into nodal or extranodal, as well as indolent, aggressive, and very aggressive groups. Patients with indolent lymphomas may present with mild or no symptoms and seek medical attention for a swollen lymph node, whereas the aggressive and very aggressive lymphomas create easily noticeable symptoms, such as pain, swelling due to obstruction of vessels, fever, and night sweats. Surgical staging is no longer indicated for NHL because the combination of history and physical examination, chest radiograph and abdominal/pelvic CT scan, biopsy of involved lymph nodes (including laparoscopically directed nodal and liver biopsies), and bone marrow biopsy is sufficient.63 Splenomegaly exists in some, but not all, forms of NHL. Splenectomy does not alter the natural history of the disease, but it is indicated in cases where a diagnosis cannot be established by obtaining peripheral tissue and clinical suspicion remains or for management of symptoms related to an enlarged spleen as well as for improvement of cytopenias.68-72

**Chronic Lymphocytic Leukemia** Chronic lymphocytic leukemia (CLL) is currently considered a subtype of NHL. The main characteristic of CLL is a progressive accumulation of old and nonfunctional lymphocytes.63,73 Symptoms of CLL are nonspecific and include weakness, fatigue, fever without illness, night sweats, and frequent bacterial and viral infections. The most frequent finding is lymphadenopathy. When the spleen is enlarged, it may be massive or barely palpable below the costal margin. Splenectomy is indicated to improve cytopenias and was shown to be 75% effective in a combined group of patients who had either CLL or nonmalignant HD.29 Splenectomy may facilitate chemotherapy in patients whose cell counts were prohibitively low before spleen removal. Palliative splenectomy also is indicated for symptomatic splenomegaly.

**Bone Marrow Disorders (Myeloproliferative Disorders).** The myeloproliferative disorders are characterized by an abnormal growth of cell lines in the bone marrow. They include chronic myeloid leukemia, acute myeloid leukemia, chronic myelomonocytic leukemia, essential thrombocytopenia, polycythemia vera, and myelofibrosis, also known as agnogenic myeloid metaplasia (see “Myelofibrosis [Agnogenic Myeloid Metaplasia]” later in this chapter). The common underlying problem leading to splenectomy in these disorders is symptomatic splenomegaly. Symptoms due to splenomegaly are due to mass effect and consist of early satiety, poor gastric emptying, heaviness or pain in the left upper quadrant, and even diarrhea. Hypersplenism, when it occurs in these conditions, usually is associated with splenomegaly. Splenectomy performed in the setting of the myeloproliferative disorders is generally for treatment of the pain, early satiety, and other symptoms of splenomegaly. Radiation has been used since 1903 to treat symptomatic splenomegaly in myeloproliferative disorders, but today it is principally used in situations in which splenectomy is not an option.

**Chronic Myelogenous Leukemia** Chronic myelogenous leukemia (CML) is a disorder of the primitive pluripotent stem cells in the bone marrow that results in a significant increase in erythroid, megakaryotic, and pluripotent progenitors in the peripheral blood smear. The genetic hallmark is a transposition between the bcr gene on chromosome 9 and the abl gene on chromosome 22. CML accounts for 7% to 15% of all leukemias, with an incidence of 1.5 in 100,000 in the United States.44 It is often asymptomatic, but CML can cause fatigue, anorexia, sweating, and left upper quadrant pain and early satiety secondary to splenomegaly. Enlargement of the spleen is found in roughly one-half of patients with CML. Current therapy includes imatinib or allogeneic stem cell transplantation. Splenectomy is indicated to relieve symptoms of massive splenomegaly, but it does not prevent blast crisis or alter the disease process.45,70

**Acute Myeloid Leukemia** Like CML, acute myeloid leukemia (AML) involves the abnormal growth of stem cells in the bone marrow. Unlike CML, AML has a presentation that is more rapid and dramatic. The proliferation and accumulation of hematopoietic stem cells in the bone marrow and blood inhibit the growth and maturation of normal red blood cells, white blood cells, and platelets. Death usually results within weeks to months if AML goes untreated. The incidence of AML is approximately 9200 new cases each year in the United States, and it accounts for 1.2% of all cancer deaths.74 Patients with other myeloproliferative disorders, such as polycythemia vera, primary thrombocytosis, or myeloid metaplasia, are at increased risk for leukemic transformation to AML. Presenting signs and symptoms of AML include a viral-like illness with fever, malaise, and frequently bone pain due to the expansion of the medullary space. Standard treatment is combined induction therapy with daunorubicin, cytarabine, and stem cell transplantation. Splenectomy is indicated in AML only in the uncommon circumstance that left upper quadrant pain and early satiety become unbearable. The benefit must be weighed against the heightened risk of postsplenectomy infection in AML patients immunocompromised due to neutropenia and chemotherapy.74
**Chronic Myelomonocytic Leukemia** Like CML and AML, chronic myelomonocytic leukemia (CMML) is characterized by a proliferation of hematopoietic elements in the bone marrow and blood. CMML differs from CML in that it is associated with monocytosis in the peripheral smear (>1 × 10^3 monocytes/mm^3) and in the bone marrow. Splenomegaly occurs in one-half of these patients, and splenectomy can result in symptomatic relief.75

**Essential Thrombocytopenia** Essential thrombocytopenia (ET) represents abnormal growth of the megakaryocyte cell line, resulting in increased levels of platelets in the bloodstream. The diagnosis is made after the exclusion of other chronic myeloid disorders such as CML, polycythemia vera, and myelofibrosis that may also present with thrombocytosis.76 Clinical manifestations of ET include vasomotor symptoms, thrombohemorrhagic events, recurrent fetal loss, and the transformation to myelofibrosis with myeloid metaplasia or AML. Hydroxyurea is used to reduce thrombotic events in ET but does not alter transformation to myelofibrosis or leukemia. Splenomegaly occurs in one-third to one-half of patients with ET. Splenectomy is not felt to be helpful in the early stages of ET and is best reserved for the later stages of disease, when myeloid metaplasia has developed.69 Even in these circumstances, candidates should be chosen selectively because significant bleeding has been reported to complicate splenectomy in these patients.

**Polycythemia Vera** Polycythemia vera (PV) is a clonal, chronic, progressive myeloproliferative disorder characterized by an increase in red blood cell mass, frequently accompanied by leukocytosis, thrombocytosis, and splenomegaly. Patients with PV typically enjoy longer survival than those affected by hematologic malignancies but remain at risk for transformation to myelofibrosis or AML. The disease is rare, with an annual incidence of 5 to 17 cases per million population.76,77 Physical findings include ruddy cyanosis, conjunctival plethora, hepatomegaly, splenomegaly, and hypertension. Treatment should be tailored to the risk status of the patient and ranges from phlebotomy and aspirin administration to the use of chemotherapeutic agents. As in ET, splenectomy is not helpful in the early stages of disease and is best reserved for patients with late-stage disease in whom myeloid metaplasia has developed and splenomegaly-related symptoms are severe.76,77

**Myelofibrosis (Agnogenic Myeloid Metaplasia)** The term myelofibrosis may be used to describe either the generic condition of fibrosis of the bone marrow (which may be associated with a number of benign and malignant disorders) or a specific, chronic, malignant hematologic disease associated with splenomegaly, the presence of red blood cell and white blood cell progenitors in the bloodstream, marrow fibrosis, and extramedullary hematopoiesis, otherwise known as agnogenic myeloid metaplasia (AMM). AMM also can be referred to as myelosclerosis, idiopathic myeloid metaplasia, and osteosclerosis. In this chapter, the term myelofibrosis is synonymous with AMM.

In AMM, fibrosis of the bone marrow is believed to be a response to a clonal proliferation of hematopoietic stem cells. Marrow failure is common. The true incidence of AMM is unknown due to the scarcity of epidemiologic data, but one study estimated its U.S. incidence at 1.46 per 100,000 population.78-80 The diagnosis is made by a careful examination of the peripheral blood smear and bone marrow. Nucleated red blood cells and immature myeloid elements in the blood are present in 96% of cases and strongly suggest the diagnosis. Teardrop poikilocytosis is another frequent finding. Care must be taken, however, to exclude a history of a primary neoplasm (such as lymphoma or adenocarcinoma of the stomach, lung, prostate, or breast) or tuberculosis because patients with these conditions may develop secondary myelofibrosis.

Treatment depends on symptoms: Asymptomatic patients are closely followed, whereas symptomatic patients undergo therapeutic intervention targeted to their symptoms. The only curative therapy is allogeneic bone marrow transplantation in younger, high-risk patients. Supportive therapy for clinically symptomatic anemia includes steroids, danazol, erythropoietin, or blood transfusion.78,80 Splenomegaly-related symptoms are best treated with splenectomy. Although some chemotherapeutic agents (busulfan, hydroxyurea, interferon-α) and low-dose radiation can reduce splenic size, their discontinuation usually results in rapid splenic regrowth.

A thorough preoperative workup must precede splenectomy in patients with AMM. The candidate must possess acceptable cardiac, pulmonary, hepatic, and renal reserve for the operation. The coagulation system should be examined; testing should include measurement of coagulation factors V and VIII and fibrin split products, platelet count, and bleeding time. Low platelet counts may require administration of steroids and/or platelet transfusion at the time of surgery. Splenectomy provides durable, effective palliation for nearly all patients with AMM, although postoperative complications are more common in patients with AMM than in those with other hematologic indications. The Mayo Clinic recently published its 30-year experience with 314 myelofibrosis patients who underwent splenectomy. Nearly half of the operations (49%) were performed to alleviate the mechanical symptoms of splenomegaly; the remainder were undertaken to manage anemia, thrombocytopenia, or portal hypertension. Response to splenectomy was 76% overall at 1 year; overall complication rate was 28%, including 21 perioperative deaths.80 Thrombosis, hemorrhage, and infection complications were common, with perioperative thrombocytopenia an independent predictor of mortality risk. These data underscore the severity of this malignancy and emphasize the need for careful patient selection when considering splenectomy in AMM.70

**Tumors and Metastasis.** Primary tumors of the spleen are typically benign or malignant variants of vascular neoplasms. The most common primary tumors of the spleen are sarcomas, many of which have been linked to various environmental and occupational exposures such as vinyl chloride or thorium dioxide. Isolated splenic metastases are extremely unusual but may occur in the setting of a concomitant carcinoma.81 Lung carcinoma is the tumor that most commonly spreads to the spleen, although, colorectal, ovarian, and melanoma may also metastasize to the spleen.82,83 If after a thorough examination, an isolated splenic metastasis is confirmed, a laparoscopic splenectomy with intact spleen retrieval may be considered.81-83

**Miscellaneous Disorders and Lesions**

**Infections and Abscesses.** Primary infections of the spleen although uncommon in immunocompetent adults, are particularly reported in the immunocompromised population or those with a history of intravenous recreational drug abuse.84,85 The potential effects of certain systemic infections on the spleen merit close attention, mostly because of the dreaded risk of spontaneous splenic rupture. Infectious mononucleosis due to
either Epstein-Barr virus or cytomegalovirus infection imparts a small but often-discussed risk of spontaneous splenic rupture in both adults and children. The true incidence may be underreported, however. Recent case reports abound in the literature regarding spontaneous splenic rupture due to a variety of infectious causes (malaria, *Listeria* infection, fungal infections, dengue, and Q fever, to name a few) as well as a variety of neoplastic and other noninfectious causes (lymphoma, angiosarcoma, amyloidosis, pregnancy). The presumed pathophysiologic mechanism is inhibition of the splenic parenchyma with inflammatory cells, which distorts the architecture and fibrous support system of the spleen and thins the splenic capsule. In this setting, splenic rupture can occur spontaneously or after a seemingly minor external trauma or even a Valsalva maneuver.

Abscesses of the spleen are uncommon, with an incidence reported to be 0.14% to 0.7%. They occur more frequently in tropical locations, where they are associated with thrombosed splenic vessels and infarction in patients with sickle cell anemia. Five distinct mechanisms of splenic abscess formation have been described: (a) hematogenous infection; (b) contiguous infection; (c) hemoglobinopathy; (d) immunosuppression, including HIV infection and chemotherapy; and (e) trauma. The presentation of splenic abscess frequently is delayed, with most patients enduring symptoms for 16 to 22 days before diagnosis. Clinical manifestations include fever, left upper quadrant pain, leukocytosis, and splenomegaly in about one-third of patients. The diagnosis is confirmed by ultrasound or CT scan, which has a 95% sensitivity and specificity. Common organisms are aerobic microbes (streptococci and *Escherichia coli*), but other microorganisms have also been isolated (*Mycobacterium tuberculosis* and *Salmonella typhi*). Upon discovery of a splenic abscess, broad-spectrum antibiotics should be initiated, with adjustment to more specific therapy based on culture results and continuation of treatment for a minimum of 14 days. Splenectomy is the operation of choice, but percutaneous and open drainage are options for patients who either cannot tolerate splenectomy or where the clinical scenario warrants splenic preservation, particularly in children. Percutaneous drainage is often successful for patients with unilocular disease and may result in avoidance of splenectomy. Patients with multilocular disease will often require multiple drains and therefore often benefit from total splenectomy.

**Cysts.** Splenic cysts (Fig. 34-5) can be categorized according to a number of criteria; one clinically relevant scheme is to characterize true splenic cysts as either parasitic or nonparasitic. Parasitic Infections. Parasitic infection is the most common cause of splenic cysts worldwide, and the majority are due to *Echinococcus* species. These cysts are more commonly found in areas where the pathogen is endemic. Symptoms, when present, generally are related to the presence of a mass lesion in the left upper quadrant or a lesion that impinges on the stomach. Ultrasound can establish the presence of a cystic lesion and occasionally incidentally detect asymptomatic lesions as well. Serologic testing for echinococcal antibodies can confirm or exclude the cystic lesion as parasitic, an important piece of information when planning operative therapy. Symptomatic parasitic cysts are best treated with splenectomy. Avoidance of spillage of parasitic cyst contents into the peritoneal cavity to avoid the possibility of anaphylactic shock is an important principle in surgical management despite its rare occurrence.

Cysts resulting from trauma are termed *pseudo* cysts due to their lack of an epithelial cell lining. Less common examples of nonparasitic cysts are dermoid, epidermoid, and epithelial cysts. The treatment of nonparasitic cysts depends on whether or not they produce symptoms. Asymptomatic nonparasitic cysts may be observed with close follow-up by ultrasound to exclude significant growth or expansion. Patients should be advised of the risk of cyst rupture with even minor abdominal trauma if they elect nonoperative management for large cysts. Small symptomatic nonparasitic cysts may be excised with splenic preservation, and large symptomatic nonparasitic cysts may be unroofed. Both of these operations may be performed laparoscopically.

**Storage Diseases and Infiltrative Disorders**

**Gaucher’s Disease** Gaucher’s disease is an inherited lipid storage disorder characterized by the deposition of glucocerebrosides in cells of the macrophage-monocyte system. The underlying abnormality is a deficiency in the activity of a lysosomal hydrolase. Abnormal glycolipid storage results in organomegaly, particularly hepatomegaly and splenomegaly. Patients with Gaucher’s disease frequently experience symptoms related to splenomegaly, including early satiety and abdominal discomfort, and to hypersplenism, including thrombocytopenia, normocytic anemia, and mild leukopenia. These latter findings occur as a result of excessive sequestration of formed blood elements in the spleen. Other symptoms in patients with Gaucher’s disease include bone pain, pathologic fractures, and jaundice. Splenectomy may alleviate hematologic abnormalities in these patients with hypersplenism, but it does not correct the underlying disease process.

**Niemann-Pick Disease** Niemann-Pick disease is an inherited disorder of abnormal lysosomal storage of sphingomyelin and cholesterol in cells of the macrophage-monocyte system. Four types of the disease (A, B, C, and D) exist, with unique clinical presentations. Types B and D result from a deficiency in lysosomal hydrolase and are the forms most likely to demonstrate splenomegaly with its concomitant symptoms. Symptoms of splenomegaly are relieved by splenectomy.

**Amyloidosis** Amyloidosis is a disorder of abnormal extracellular protein deposition and protein conformation disorder associated with a clonal plasma cell dyscrasia. There are multiple forms of amyloidosis, each with its own individual clinical presentation, and the severity of disease may range from asymptomatic to multiorgan failure. Patients with primary amyloidosis, associated with plasma cell dyscrasia, have splenic involvement in approximately 5% of cases. Secondary amyloidosis, associated with chronic inflammatory conditions, also may present with an enlarged spleen and even spontaneous rupture. Symptoms of splenomegaly are relieved by splenectomy.

**Sarcoidosis** Sarcoidosis is an inflammatory disease of young adults characterized by noncaseating granulomas in affected tissues. Signs and symptoms of the disease range in severity and typically are nonspecific, such as fatigue and malaise. Any organ system may be involved. The most commonly involved organ is the lung, followed by the spleen. Splenomegaly occurs in approximately 25% of patients. Massive splenomegaly (>1 kg) is rare with a reported incidence of 3% to 6%. Other affected tissues include the lymph nodes, eyes, joints, liver, spleen, and heart. When splenomegaly occurs and causes symptoms related to size or hypersplenism, splenectomy effectively relieves symptoms and corrects hematologic abnormalities such as anemia.
as anemia and thrombocytopenia. Spontaneous splenic rupture has been reported in sarcoidosis.94

**Splenic Artery Aneurysm** Although splenic artery aneurysm is rare, it is the most common visceral artery aneurysm. Women are four times more likely to be affected than men. The aneurysm usually arises in the middle to distal portion of the splenic artery.99,100 Indications for treatment include presence of symptoms, pregnancy, intention to become pregnant, and presence of pseudoaneurysms associated with inflammatory processes. Aneurysm resection or ligation alone is acceptable for amenable lesions in the mid-splenic artery, but distal lesions in close proximity to the splenic hilum should be treated with concomitant splenectomy. An excellent prognosis follows elective treatment.

Splenic artery embolization has been used to treat splenic artery aneurysm; however, this may result in painful splenic infarction or abscess.

**Portal Hypertension** Portal hypertension can result from numerous causes but is usually due to liver cirrhosis. Splenomegaly and splenic congestion often accompany portal hypertension, which leads to sequestration and destruction of circulating cells in the spleen. Splenectomy is not indicated for hypersplenism per se in patients with portal hypertension as there is no correlation between the degree of pancytopenia and long-term survival in these patients.7 In rare circumstances in which splenectomy is required to reduce bleeding from esophageal varices exacerbated by thrombocytopenia, a concomitant splenorenal shunt procedure may be performed to decompress the portal system.

Sinistral hypertension secondary to splenic vein thrombosis, on the other hand, is potentially curable with splenectomy. Patients that are bleeding from isolated gastric varices who have normal liver function test results, especially those with a previous history of pancreatitis, should be examined for splenic vein thrombosis and treated with splenectomy if findings are positive.

Idiopathic portal hypertension (IPH) is extremely rare, and it is characterized by the absence of cirrhosis or other clear etiologies such as hepatic or portal vein thrombosis, cardiac failure, or hematologic disorders.101-104 Hypersplenism often develops in these patients due to hyperactivity of the spleen; defined as a triad of splenomegaly, pancytopenia,
and normocellularity of bone marrow warranting intervention by way of splenic artery embolization or splenectomy. Partial splenic embolization (PSE) has recently been utilized with good success in prohibitively high operative risk patients with severe hypersplenism. 105

**Felty’s Syndrome** The triad of rheumatoid arthritis, splenomegaly, and neutropenia is called *Felty’s syndrome*. It exists in approximately 3% of all patients with rheumatoid arthritis, two-thirds of whom are women. Immune complexes coat the surface of white blood cells, which leads to their sequestration and clearance in the spleen with subsequent neutropenia. This neutropenia (<2000 neutrophils/mm³) increases the risk for recurrent infections and often drives the decision for splenectomy. The size of the spleen is variable, from nonpalpable in 5% to 10% of patients to massively enlarged upwards of 4 times heavier than normal in others. Corticosteroids, hematopoietic growth factors, methotrexate, and splenectomy have all been used to treat the neutropenia of Felty’s syndrome. More recently, rituximab has been tried as a second line agent in refractory Felty’s syndrome. 106,107

Overall response to splenectomy is excellent, with >80% of patients showing a durable increase in white blood cell count. More than one-half of patients who had infections before surgery may clear their infections after surgery. 108 Besides symptomatic neutropenia, other indications for splenectomy include transfusion-dependent anemia and profound thrombocytopenia.

**Wandering Spleen** A very uncommon anatomic abnormality is the “wandering spleen.” In this condition, the spleen “floats” inside the abdominal cavity due to an anomaly during embryogenesis and may present itself in a variety of ways including acute abdomen. 109 The wandering spleen is not normally attached to adjacent viscera in the splenic fossa. This may lead to splenic torsion and infarction. Splenectomy or splenectomy may be required. 110

**Partial Splenectomy and Splenic Salvage.** The increased awareness of asplenia-related life-threatening complications such as overwhelming postsplenectomy infection (OPSI) has led to the development of parenchyma sparing splenic resections for select patients and disorders. The first successful partial splenectomy was reported in 1979 by Shapiro and was followed by Uranus who would perform the first laparoscopic partial splenectomy in 1995. 111,112 Previously, many surgeons had been reluctant to perform partial splenectomy because of the technical difficulties and bleeding risk. However, with a better understanding of the segmental vascular anatomy of the spleen and the development of improved laparoscopic skills and technologies, laparoscopic partial splenectomy has been used successfully in patients with hematologic diseases such as hereditary spherocytosis in children, who may benefit the most from splenic preservation, as well as for benign splenic cysts. 113-119 The technique of partial splenectomy will be discussed later in this chapter.

**IMAGING FOR EVALUATION OF SIZE AND PATHOLOGY**

Thorough assessment of anatomic detail and functional status of the spleen are essential for proper surgical planning. Special preoperative consideration needs to be given to patients with splenomegaly because minimally invasive methods of resection may be fraught with additional difficulty in patients with very large spleens, even in skilled hands. Other indications for splenic imaging include trauma, investigations of left upper quadrant pain, characterization of splenic lesions such as tumors, cysts, and abscesses, and guidance for percutaneous procedures. 140,146

Preoperative imaging of the spleen is primarily performed to obtain an accurate assessment of the splenic volume in order to confirm and document splenomegaly as well as to exclude any large splenic lesion that could affect the surgical resection plane. Identification of the presence of accessory spleens in the preoperative setting is also important, although lack of accessory tissue on the imaging should not preclude a thorough intraoperative search.

The guidelines of the European Association for Endoscopic Surgery suggest that for all patients in whom splenectomy is indicated, preoperative imaging should be obtained. 24 Two of the most commonly used imaging modalities include ultrasound and CT, both enabling measurement of splenic size and volume. When desired, the splenic volume may be calculated using a formula for the volume of a prolate ellipsoid:

\[
\text{Volume (cc)} = \text{length (cm) \times width (cm) \times height (cm) \times 0.5264}.
\]

Other imaging modalities, although not as commonly used, include nuclear medicine studies and magnetic resonance imaging (MRI).

**PREOPERATIVE CONSIDERATIONS**

As part of preoperative discussion prior to splenectomy, patients should be consulted on potential complications associated with this procedure, including overwhelming postsplenectomy sepsis, splenic vein thrombosis, bleeding, arterial thrombosis (myocardial infarction, stroke), deep vein thrombosis, and pulmonary hypertension.

**Vaccination and Patient Education**

Considering that infection is the most common complication, patient education and vaccinations against encapsulated pathogens are the mainstay of preventive therapy. 52,120 Although rare, the most feared and extreme infectious complication is overwhelming postsplenectomy sepsis (OPSI). (See later section, “Overwhelming Postsplenectomy Infection,” for detailed discussion.) Patients undergoing splenectomy for hematologic or malignant indications have the greatest risk, whereas patients who undergo splenectomy for trauma or iatrogenic injury have the lowest risk. OPSI is more common in the pediatric population, with 4.4% of children less than 16 years of age versus 0.9% of adults developing this life-threatening condition. The risk has been observed to be the greatest in the first 2 years after splenectomy; however, asplenic patients remain at lifelong risk. 121-123 Considering that the spleen is the site for special adaptation of macrophages that target encapsulated organisms, asplenic patients are at higher risk of infection caused by *Streptococcus pneumoniae* (responsible for >50% of OPSI), *H influenzae* type b, *Neisseria meningitidis*, and *Capnocytophaga canimorsus* (transmitted by dog bites). 124

In the setting of elective splenectomy, patients should be vaccinated two weeks prior to surgery to optimize antigen recognition and processing. If splenectomy is performed emergently, vaccinations can be administered postoperatively and consideration should be given to delaying administration...
for 2 weeks to avoid the transient immunosuppression associated with surgery. International guidelines also recommend annual influenza vaccine for asplenic patients. The influenza vaccination provides protection from influenza syndrome and secondary bacterial infection. This immunization is associated with a 54% reduced risk of death compared with unimmunized asplenic persons.125

Preoperative and postoperative patient education regarding OPSI is paramount because patients with OPSI may rapidly progress from a febrile illness to circulatory collapse and death within a matter of hours. In one study, 28% of asplenic patients were unaware of the potential infection risks, and the main reasons for this lack of awareness were that correct advice was not given or that that advice was forgotten.121,126 The use of currently available vaccines against pneumococcus and other encapsulated organisms has led to a drop in the overall incidence of OPSI to <1%. The mechanism by which vaccination protects asplenic patients is not entirely understood. Serum antibody titers do not necessarily correspond to clinical immunity. Moreover, antibody levels after pneumococcus vaccination decline steadily within 5 to 10 years. Revaccination is reasonably recommended for these patients, although the efficacy of this measure is not proven.121-124,126

**Deep vein Thrombosis Prophylaxis**

Deep vein thrombosis (DVT) after splenectomy is not infrequent, especially in cases involving splenomegaly and myeloproliferative disorders.76 Risk of portal vein thrombosis (PVT) may reach 50% for patients presenting with both splenomegaly and myeloproliferative disorders.127,128

Postsplenectomy PVT typically presents with anorexia, abdominal pain, leukocytosis, and thrombocytosis. Effective PVT treatment is possible by maintaining a high index of suspicion, achieving early diagnosis with contrast enhanced CT, and starting anticoagulation immediately. DVT prophylaxis, including use of sequential compression devices and subcutaneous administration of heparin (5000 U), should be initiated for patients undergoing splenectomy.16,77 Each patient’s risk factors for DVT should be evaluated, and when elevated risk exists (obesity, history of prior venous thromboembolism, known hypercoagulable state, older age), a postoperative antithrombotic regimen of up to two weeks of low molecular weight heparin should be maintained.

**Splenectomy Techniques**

**Patient Preparation**

Assessment of the potential need for transfusion of blood products and optimization of preoperative coagulation status are necessary. It is the authors’ practice to order blood typing and antibody screening tests for normosplenic patients undergoing elective splenectomy. Anemic patients should be transfused before surgery to a hemoglobin level of 10 g/dL. In more complex cases, including patients with splenomegaly, at least 2 to 4 units of cross-matched blood should be available at the time of surgery. Thrombocytopenia may be transiently corrected with platelet transfusions. Thrombocytopenic patients preferably should not undergo transfusion before the day of surgery and ideally not before the intraoperative ligation of the splenic artery. Several authors recommended a platelet count of $30 \times 10^9$ /L before the surgery; this may require treatment with IV immunoglobulin or oral corticosteroids if the platelets are below this number. Pooled normal human immunoglobulin is effective in elevating the platelet count in approximately 75% of patients.129-131

Patients who have been maintained on corticosteroid therapy preoperatively should receive parenteral corticosteroid therapy perioperatively. Bowel preparation is not routinely performed for patients undergoing elective splenectomy. All splenectomy patients do receive DVT prophylaxis, as discussed previously. After endotracheal intubation, a nasogastric (NG) tube is inserted for stomach decompression.

**Open Splenectomy**

Although laparoscopic surgery increasingly has achieved acceptance as the standard approach for normosplenic patients requiring splenectomy, open splenectomy (OS) is still widely practiced. The largest published series is a report of the Nationwide Inpatient Sample (NIS), where of 37,006 nontraumatic splenectomies identified during a 6-year study period (2005–2010), 81.4% of those cases were approached by open surgery.132

Traumatic rupture of the spleen continues as the most common indication for OS. Several other clinical scenarios favor an OS approach, including massive splenomegaly, ascites, portal hypertension, multiple prior operations, extensive splenic irradiation, and possible splenic abscess.

During OS, the patient is placed in the supine position with the surgeon situated at the patient’s right. A left subcostal incision paralleling the left costal margin and lying two finger-breadths below it is preferred for most elective splenectomies. A midline incision is optimal for exposure when the spleen is ruptured or massively enlarged. The spleen is mobilized by dividing ligamentous attachments, usually beginning with the splenocolic ligament (Fig. 34-6). In patients with significant splenomegaly, once lesser sac access has been achieved through either the gastrosplenic or gastrohepatic attachments, ligating the splenic artery in continuity along the superior border of the pancreas may be preferable. This maneuver may serve several purposes: allowing safer manipulation of the...
spleen and dissection of the splenic hilum, facilitating some shrinkage of the spleen, and providing an autotransfusion of erythrocytes and platelets. Further medial mobilization of the spleen is achieved by incising its lateral peritoneal attachments, most notably the splenophrenic ligament. Then follows individual ligation and sequential division of the short gastric vessels, steps that if carefully executed reduce the risk of these vessels’ retracting and bleeding. Splenic hilar dissection then takes place. Whenever possible, care should be taken to dissect and individually ligate the splenic artery and vein (in that order) before dividing them. As noted in the discussion of splenic anatomy, the tail of the pancreas lies within 1 cm of the splenic hilum in 75% of patients; therefore, during hilar dissection, great care must be taken to avoid injuring the pancreas. Once the spleen is excised, hemostasis is secured by irrigating, suctioning, and scrupulously inspecting the bed of dissection. The splenic bed is not routinely drained. A thorough search for accessory spleens must be undertaken when a hematologic disorder has occasioned splenectomy. At the completion of surgery, the nasogastric tube is removed.

**Laparoscopic Splenectomy**

Laparoscopic splenectomy (LS) has become the procedure of choice over the last two decades, since it has been first described Delaitre and Maignien in 1991. In fact, LS is now the gold standard for elective splenectomy in patients with normal-sized spleens. In experienced hands, LS is associated with decreased intraoperative blood loss, shorter hospital length of stay, and lower morbidity rates when compared to OS. Since the introduction of the lateral approach, most LS procedures are now performed with the patient in the right lateral decubitus position (Fig. 34-7). A midway “double-access” technique in which the patient is in a 45° right lateral decubitus position has also been advocated. This positioning permits concomitant surgery, such as laparoscopic cholecystectomy, more easily than does the lateral approach. The double-access technique requires the placement of five or six trocars. The lateral approach routinely involves the use of three or four trocars positioned as shown in Fig. 34-7. Use of an angled (30° or 45°) laparoscope (2, 5, or 10 mm) greatly facilitates the procedure. Exposure of the vital anatomy in a manner that allows for a more intuitive sequence of dissection, paralleling that of OS, may be considered an additional advantage of the lateral approach.

Placement of trocars in the left upper quadrant should be performed under laparoscopic visualization, particularly if any degree of splenomegaly exists, because the latter can significantly reduce the available operating space. As with OS, the splenocolic ligament and the lateral peritoneal attachments are divided with resultant medial mobilization of the spleen. The short gastric vessels may be divided usually with hemostatic energy sources such as ultrasonic dissection, diathermy, or radiofrequency ablation. With the lower pole of the spleen gently retracted, the splenic hilum is accessible to further applications of clips or an endovascular stapling device. The splenic artery and vein are divided separately when possible. Good long-term outcomes, however, are increasingly being achieved with mass hilar stapling (Fig. 34-8). Using the lateral approach with the spleen thus elevated, the surgeon can easily visualize the tail of the pancreas and avoid injury when placing the endovascular stapler within the sack and allows piecemeal extraction; a blunt instrument should be used to disrupt and remove the spleen to avoid the risk of sack rupture, spillage of contents, and subsequent splenosis (Fig. 34-9 and Fig. 34-10).

**Hand-Assisted Splenectomy**

When LS is performed in patients with splenomegaly, there have been reports of high rates of both complications and conversion to open splenectomy. Hand-assisted laparoscopic surgery (HALS) has been described as an alternative to the LS approach. Spleens greater than 22 cm in craniocaudal length or 19 cm in width may benefit from HALS over a purely laparoscopic approach. It has been reported that the

---

**Figure 34-7.** Patient positioning and trocar placement for laparoscopic splenectomy.
use of this technique has resulted in a marked reduction in average operative time for patients with massive splenomegaly (146 vs. 295 minutes). Although HALS does require a small incision (7–8 cm) for hand insertion and specimen extraction, no differences in length of stay were observed when comparing these patients to those managed purely laparoscopically.

When performing HALS splenectomy, patient positioning is similar to that of LS (Fig. 34-11). For patients with massive spleens, lateral positioning is altered slightly, such that the patient is placed supine with the left side elevated at 45°. Depending on the hand dominance of the surgeon, the hand-assist device can be placed in either a midline position for right-handed dominant or a subcostal position for left-hand dominant surgeons. A 7- to 8-cm incision should be made 2 to 4 cm caudal to the inferior pole of the enlarged spleen. The hand-assisted technique allows for a tactile feedback and atraumatic manipulation of the enlarged spleen.

The nondominant hand provides medial retraction and rotation of the spleen through a hand-assist port, while the dominant hand carries out the dissection using laparoscopic instruments. The anterior and posterior attachments of the spleen are taken down as in the laparoscopic approach, and the hilar pedicle is ligated using an endoscopic vascular stapler.

**Single-Incision Laparoscopic Surgery Splenectomy**

Single-incision laparoscopic surgery (SILS) splenectomy emphasizes the concept of surgery through one small transabdominal incision rather than the standard multiple trocar sites, with theoretical benefits of less pain and better cosmetics. The incision can be hidden periumbilically and is used as the specimen extraction site at the end of the case. This approach for solid organs poses several technical challenges. Since all instruments are closely aligned together, “fencing” of instruments and the laparoscope and limited degrees of movement are commonly encountered. The spleen, being a solid organ, cannot be grasped, and thus retraction may be more challenging in these cases. Furthermore, it has been reported that periumbilical port position may result in technical challenges when dealing with high body mass index or tall patients, precluding

**Figure 34-8.** Splenic hilum can be divided laparoscopically en masse once the spleen has been rotated medially having been mobilized from its lateral attachments.

**Figure 34-9.** Spleen extraction. A. Spleen is placed into a ripstop nylon bag before morcellation. B. Splenic morcellation.
the surgeon from adequately reaching the spleen. Other alternatives to single port placements have been reported, although to date, no proven benefits of SILS splenectomy have been demonstrated.\textsuperscript{140-142}

**Robotic Splenectomy**

The da Vinci surgical robot (Intuitive Surgical, Sunnyvale, CA) was cleared by the U.S. Food and Drug Administration (FDA) for use in humans in the year 2000 and has been applied to clinical practice in a variety of abdominal procedures including splenectomy since 2002.\textsuperscript{143,144} The term robotic surgery, referencing the da Vinci device should more accurately be described as computer assisted surgery (CAS), as it requires a surgeon sitting at a console controlling distant end effectors. A truly robotic, automated system has not yet been devised nor deployed to perform splenectomy. The reported advantages of CAS have inspired many surgeons to investigate its potential and to broaden its application in the minimally invasive surgery armamentarium. Some of these advantages include increased degrees of freedom as compared to standard “straight-stick” laparoscopy, improved optics including three-dimensional imaging of the operative field, improved instrument stabilization and reduction in hand tremor, and finally purported enhanced ergonomic and comfort factors for the operating surgeon.\textsuperscript{145-147}

However, detractors of this emerging technology cite high capital expenses as well as on-going disposable costs and the loss of haptic feedback as major downsides of CAS such that the benefits of the robotic platform are still not fully clear in the extant literature. Recent studies suggest that ergonomic benefits of robotic surgery may not be as pronounced as previously thought, as “robotic surgeons” still manifested chronic pain related to poor ergonomics.\textsuperscript{148}

There have been few published works comparing conventional laparoscopic splenectomy to CAS splenectomy. In one recent retrospective case-matched analysis, the authors compared hospital length of stay, operating room times and cost between these two groups. Although they were able to conclude that the application of CAS was feasible and safe for splenectomy, they cited a nearly 30-minute increase in operative time and over $4000 increase in cost of the procedures.\textsuperscript{149} This is consistent with a prior study supporting the notion that robotic-assisted splenectomy takes longer and is more costly than conventional laparoscopic surgery.\textsuperscript{150}

Splenectomy has also been reported using a single-incision CAS approach.\textsuperscript{151} However, this procedure is likely associated with an even steeper learning curve than traditional multiport robotic-assisted splenectomy, which calls into question the utility of this technique.

Robotic splenectomy has been performed in the pediatric population, also proving feasibility and safety, but much like the adult population, larger series are needed to determine the true benefits of this procedure as compared to conventional laparoscopic splenectomy in children.\textsuperscript{152}

The role of CAS in the patient requiring more complex surgery, for example, partial splenectomy or resection of a massive spleen, is yet to be determined. At present there appears to be no argument supporting the application of CAS over standard laparoscopy for routine splenectomy in terms of clinical or cost advantage. The entry into the market of competing devices is likely to favorably alter these considerations.

**Partial Splenectomy**

The past few decades have witnessed ever-widening endorsement for and practice of partial splenectomy. This technique, initially reported in the early 18th century, is particularly indicated to minimize the risk of postsplenectomy sepsis in children. Certain lipid storage disorders leading to splenomegaly (e.g., Gaucher’s disease), some forms of traumatic splenic injury (blunt and penetrating), spherocytosis in children, and focal benign splenic lesions are amenable to treatment with partial splenectomy.\textsuperscript{153} Both the laparoscopic and open approaches for partial splenectomy have been well described.\textsuperscript{153} The spleen must be adequately mobilized, and the splenic hilar vessels attached to the targeted segment, ligated, and divided. The devascularized segment of spleen is transected along an obvious line of demarcation.

A useful technical tip is to transect the parenchyma 1 cm inside the ischemic demarcation line to minimize blood loss.\textsuperscript{154} Bleeding from the cut surface of the spleen usually is limited and can be controlled by various methods, including cautery, argon coagulation, or application of direct hemostatic agents such as cellulose gauze and fibrin glue.

**Inadvertent Intraoperative Splenic Injury**

Inadvertent intraoperative injury to the spleen is a noted occurrence in the surgical literature, familiar to and dreaded by the abdominal surgeon. The true incidence is unknown. The gravity of such injury is not to be underestimated. Significant short-term morbidity is associated with injury to the spleen, including increased blood loss, need for transfusion, and prolonged hospital stay.\textsuperscript{155}

Intraoperative injury to the spleen has been linked with numerous operations, such as gastric fundoplication, colectomy,
Figure 34-11. A. Patient table placement for hand-assisted laparoscopic splenectomy (HALS) in case of splenomegaly. B and C. Intraoperative images of HALS.
paraesophageal hernia repair, nephrectomy, and abdominal and pelvic vascular surgery. There are also reports of splenic injuries after endoscopic procedures, such as colonoscopy.

Improper traction on the spleen against its peritoneal attachments is the most common mechanism of intraoperative injury. Capsular tears are the most common type of injury, but parenchymal lacerations and subcapsular hematomas also occur. The lower pole is more commonly injured, owing to its orientation and the greater concentration of peritoneal attachments found here.

As with all hemorrhage, prompt temporary control of bleeding should be obtained by direct compression of the spleen itself, packing of the left upper quadrant, compression of the vessels at the splenic hilum, or pressure on the splenic artery at the superior pancreatic margin. The spleen should then be mobilized from its peritoneal attachments and the nature of the injury assessed. Overall, the patient’s condition is the primary determinant of whether splenic salvage can be attempted, although hilar injury is best managed by splenectomy. When dealing with capsular tears (most common injury), strong consideration should be given to splenorrhaphy techniques: application of topical hemostatics, suture plication of disrupted parenchyma with or without omental buttress, and the use of bioabsorbable mesh sheets.

The time-honored surgical tenets of liberal exposure and visualization are particularly germane to the avoidance of splenic injury. Incisions and approaches must be tailored to both patient circumstances and surgeon experience. There is some evidence to support the assertion that use of the laparoscopic approach may reduce the incidence of splenic injury for certain operations. As with all hemorrhage, prompt temporary control of bleeding is required. Direct compression of the spleen itself, packing of the left upper quadrant, compression of the vessels at the splenic hilum, or pressure on the splenic artery at the superior pancreatic margin can slow or stop hemorrhage and allow more deliberate consideration of management options.

The type of injury plays a role as well; it has been suggested that hilar injury is best managed by splenectomy.84 Barring these unfavorable circumstances, however, and recalling that the majority of intraoperative splenic injuries are capsular tears, it is reasonable to expect that splenic preservation can be achieved in many appropriately selected situations. Presented with one of these situations, the surgeon has at his or her disposal a number of useful and well-described splenorrhaphy techniques: application of topical hemostatics, suture plication of disrupted parenchyma with or without omental buttress, and the use of bioabsorbable mesh sheets.

Currently, incidental splenectomies during laparoscopic procedures such as colorectal resections are rare events, but they are associated with worse short-term outcomes.156

Preoperative Grading Score to Predict Technical Difficulty in Laparoscopic Splenectomy

A splenectomy grading system based on preoperative parameters was developed to predict the surgical difficulty and morbidity for elective laparoscopic splenectomies.157,158 Preoperative data concerning demographic, clinical, pathological, anatomical, laboratory and radiological factors were compared with three surgical outcomes: operative time, intraoperative bleeding, and surgical conversion. Four preoperative parameters (male gender, age, type of pathology, and spleen weight) were found to be associated with a difficult splenectomy (Table 34-3). This grading score is simple to calculate from the physical examination, laboratory tests, and US or CT images and could be highly practical in a daily clinical setting. It could facilitate training and development of skills while simultaneously fostering dissemination of laparoscopic procedures.

*Spleen weight formula: width (cm) × length (cm) × height (cm) × 0.6 = splenic weight in grams.

Splenectomy Outcomes

Changes in blood composition resulting from splenectomy include the appearance of Howell-Jolly bodies and siderocytes. After splenectomy, leukocytosis and increased platelet counts are common as well. Although platelet counts most often rise within 2 days, they may not peak for several weeks in patients with preoperative thrombocytopenia (see “Hematologic Outcomes” later). Similarly, within 1 day after splenectomy, the white blood cell count typically rises, and such elevation may continue for several months.

Overwhelming Postsplenectomy Infection

The prevalence of asplenia in the United States is estimated to be 1 million; which is comparable to the number of patients carrying the human immunodeficiency virus (HIV).185,186 As with other forms of immunodeficiency, asplenic patients bear an increased susceptibility to specific types of infections for the remainder of their lives. Asplenic patients are at highest risk for infection with encapsulated organisms, most commonly *Streptococcus pneumoniae*, but also *Haemophilus influenzae*.
Complications
Complications of splenectomy may be classified as pulmonary, hemorrhagic, infectious, pancreatic, and thromboembolic. Left lower lobe atelectasis is the most common complication after OS; pleural effusion and pneumonia also can occur. Hemorrhage can occur intraoperatively or postoperatively, presenting as subphrenic hematoma. Transfusions have become less common since the advent of LS, although the indication for operation influences the likelihood of transfusion as well. Subphrenic abscess and wound infection are among the perioperative infectious complications. The placement of a drain in the left upper quadrant may be associated with postoperative subphrenic abscess and is not routinely recommended. Pancreatitis, pseudocyst, and pancreatic fistula are among the pancreatic complications that may result from intraoperative trauma to the pancreas during dissection of the splenic hilum.

Hematologic Outcomes
The results of splenectomy may be appraised according to the level of hematologic response (e.g., rise in platelet and hemoglobin levels) in those disorders in which the spleen contributes to the hematologic problem. Hematologic responses may be divided into initial and long-term responses. For thrombocytopenia, an initial response typically is defined as a rise in platelet count within several days of splenectomy. Reported series demonstrate the effectiveness of LS in providing a long-term platelet response in approximately 80% of individuals with ITP (Table 34-4). These results are consistent with the long-term success rate associated with OS.

For chronic hemolytic anemias, a rise in hemoglobin levels to >10 g/dL without the need for transfusion signifies a successful response to splenectomy. By this criterion, splenectomy has been reported to be successful for the vast majority of patients with chronic hemolytic anemia. For hemolytic anemia due to spherocytosis, the success rate is usually higher, ranging from 90% to 100%.

Splenectomy results also may be examined in terms of surgical and postsurgical characteristics, including operative time, recovery time, and morbidity and mortality rates, all of which tend to vary according to hematologic indication (see Tables 34-4 and 34-5).

Results of few prospective, randomized trials comparing LS and OS have been published. However, several recent meta-analyses of published comparative series including 38 papers with more than 2914 patients indicate that the laparoscopic approach typically results in longer operative times, shorter hospital stays, lower morbidity rates, similar blood loss, and similar mortality rates compared with OS. Questions of the cost effectiveness of LS persist, although analysis of this issue is hindered by a lack of universally accepted metrics as well as a paucity of recent objective data. Proponents of LS argue that the generally higher operating room charges are offset by the reduced hospital stay and presumably shorter time of lost productivity. For those institutions with experienced personnel and technical capability, the laparoscopic approach has emerged as the standard for elective, nontraumatic splenectomy.

Cancer
A Taiwanese population-based study found that individuals who had splenectomy have higher risks of developing certain types of cancer (adjusted hazard ratios were 2.64 and 1.29 for nontraumatic and traumatic reasons, respectively). Splenectomy patients were found to have significantly higher risks in esophagus, stomach, liver, other head and neck, non-Hodgkin’s lymphoma, and leukemia cancers. Although the exact mechanism for the possible association between splenectomy and cancer remains unclear, a plausible explanation is that the spleen is thought to be involved in immunological defenses and provides active response through humoral and cell-mediated pathways and that splenectomy may impair immune surveillance in the host.

Ultrasound

Ultrasound is the least invasive mode of splenic imaging. It is rapid, relatively easy to perform, and does not expose the patient to ionizing radiation. It is often the first imaging modality used to evaluate the spleen in a trauma patient, although questions of sensitivity and specificity remain. In the elective setting, such as for routine diagnostic purposes or for preoperative planning, it is the least costly modality available, and the sensitivity of ultrasound for detecting textural lesions of the spleen can be quite good in experienced hands. When examining a normal spleen, differentiation between red and white pulp, the spleen appears heterogeneously enhancing due to the possibility of segmental blood flow and its effect on area of resection.

Percutaneous ultrasound-guided procedures for splenic disease (e.g., cyst aspiration, biopsy), historically avoided due to the risk of hemorrhage and other complications, are becoming more common as the safety of these procedures has become increasingly demonstrated. Computed Tomography

CT affords a high degree of resolution and detail of the splenic parenchyma, vasculature, and its relationship to neighboring structures, making it the preferred imaging modality for many surgeons. CT has become an invaluable tool in the evaluation and management of the blunt trauma patient, and standardized scoring systems for splenic trauma based on CT images now aid in management decisions. In the nontrauma setting, CT is extremely useful for assessment of splenomegaly, identification of solid and cystic lesions, and guidance of percutaneous procedures. The use of iodinated contrast material adds diagnostic clarity to CT imaging of the spleen, although at the cost of, the small but real risks, possible renal impairment or allergic reactions. Three-dimensional reconstruction after CT scan may help to predict the difficulty of the procedure and to choose the best surgical approach.

The appearance of normal splenic tissue on a noncontrast CT is uniform parenchymal attenuation with values ranging between 40 and 60 Hounsfield units (HU). On a contrast-enhanced CT, the appearance of the spleen depends largely on the timing of the intravenous bolus administration of contrast material. Due to the different rates of flow through the red and white pulp, the spleen appears heterogeneously enhancing during the first minute after initiation of intravenous administration of contrast material during the arterial and early portal venous phases. The frequency of these artifacts increases with advancing patient age. When evaluating for splenic abscess, a contrast-enhanced CT should be utilized.

EBL = estimated blood loss; ITP = idiopathic thrombocytopenic purpura; LOS = length of hospital stay; LS = laparoscopic splenectomy; OR = operating room; OS = open splenectomy; TTP = thrombotic thrombocytopenic purpura.

Plain Radiography

Rarely is plain radiography used for primary splenic imaging. Plain films can indirectly provide an outline of the spleen in the left upper quadrant or suggest splenomegaly by revealing displacement of adjacent air-filled structures (e.g., the stomach or splenic flexure of the colon). Plain films may also demonstrate splenic calcifications. Splenic calcifications are often found in association with splenomegaly but are otherwise a nonspecific finding. Splenic calcifications can indicate a number of benign, neoplastic, or infectious processes, including phlebolith, splenic artery aneurysm, sickle cell changes, tumors (e.g., hemangioma, hemangiosarcoma, lymphoma), echinococcosis, or tuberculosis.

Magnetic Resonance Imaging

Although MRI offers excellent detail and versatility in abdominal imaging, it is more expensive than CT scan or ultrasound and offers no obvious advantage for primary imaging of the spleen. MRI can be a valuable adjunct to the more commonly used imaging techniques when splenic disease is suspected but not definitively diagnosed.

Magnetic resonance (MR) signal characteristics of the spleen are related to the relative ratio of red and white pulp and the relationship of the timing of the intravenous (IV) contrast bolus and the time of image acquisition. The spleen will generally have a homogeneous MR signal on noncontrast images.
On contrast MRI, the spleen appears to have heterogeneous enhancement during the arterial phase of contrast enhancement.

**Angiography**

Angiography of the spleen most commonly refers to invasive arterial imaging, and when it is combined with therapeutic splenic arterial embolization (SAE), there are multiple applications for this procedure: localization and treatment of hemorrhage in select trauma patients; delivery of a variety of therapies in patients with cirrhosis or portal and sinistral hypertension and in transplant patients; and adjunct (or, more controversially, as an alternative) to splenectomy for treatment of hematologic disorders such as ITP or hypersplenism. Preoperative or intraoperative SAE for elective splenectomy is also a common, although not universal, practice. Few prospective data have been published in the last 5 years on preoperative SAE. Preoperative SAE is purported not only to facilitate less intraoperative blood loss but also possibly to allow a laparoscopic approach in patients whose spleens had previously been considered too large for, or otherwise not amenable to, safe laparoscopic resection. Limited success in using partial SAE as an alternative to therapeutic splenectomy in chronic ITP has been previously reported. Its detractors argue that the need for increased analgesics and occasional extended hospital stay preoperatively, the possibility of pancreatitis, and the well-described risks of invasive arteriography associated with the passage of wires and catheters through the vasculature, may negate any presumed benefits of preoperative SAE.

**Nuclear Imaging**

Radioscintigraphy with technetium-99m sulfur colloid demonstrates splenic location and size. It may be especially helpful in locating accessory spleens after unsuccessful splenectomy for ITP and has recently proven useful in diagnosing splenosis. Unfortunately, no conclusive outcome benefit has been shown for preoperative technetium scanning before splenectomy. When dealing with diseases of platelet sequestration, indium-labeled autologous platelet scanning (ILAPS) demonstrates whether platelet sequestration is predominantly in the spleen, liver, or both. This becomes important in deciding whether or not a patient will benefit from a splenectomy. ILAPS is a nuclear imaging modality in which autologous platelets are infused into the patient after ex vivo labeling. Subsequent scintigraphy demonstrates the site(s) of platelet sequestration and clearance. It has been proposed that patients with purely or predominantly splenic sequestration determined by ILAPS may be more likely to respond to splenectomy than those exhibiting hepatic, mixed, or diffuse patterns.

An emerging and novel application for spleen scintigraphy may be as a noninvasive method to diagnose nonalcoholic steatohepatitis (NASH). Conventional imaging methods are reliable for the detection of moderate to severe fatty changes in the liver, though they are not reliable for detecting NASH or hepatic fibrosis. NASH, which may lead to cirrhosis, can result from nonalcoholic fatty liver disease (NAFLD), the most common cause of steatosis. With the alarming rise of obesity worldwide, NAFLD is also increasingly common with prevalence ranging from 6.3% to 33%. The diagnosis of progression from NAFLD to NASH has been dependent on histologic assessment of tissue obtained from liver biopsy. Characteristics unique to NASH have been reported, among them the association of splenic enlargement, not seen to a similar degree in NAFLD.

In addition, the ratio of liver-to-spleen uptake determined by scintigraphy has been found to be predictably altered in NASH patients. The liver-to-spleen uptake ratio is significantly decreased in NASH patients, but not NAFLD patients, leading some to conclude that technetium-99m-phytate scintigraphy is a reliable tool to differentiate NASH from NAFLD. Although additional studies are needed to identify the role of these nuclear medicine studies in prognostication and monitoring of those patients at high risk for the development of NASH, recent studies show promise in this regard.

**Microbiology and Pathogenesis.** Life-threatening infection in the asplenic patient is attributable to four main factors: loss of splenic macrophages, diminished tuftsin production, loss of the spleen’s reticuloendothelial screening function, and dysregulated coagulation. In the normal host, these factors work in concert to eliminate opsonized bacteria from the bloodstream. This system is particularly suited for the removal of encapsulated bacteria, whose polysaccharide coating is a natural defense against opsonization (such as S. pneumoniae, H influenzae, and N meningitidis are the classic examples). Infections with protozoa that invade the red blood cell, such as Babesia microti (transmitted by tick bites), Ehrlichia, and Plasmodium, occur more frequently in splenectomized individuals than in normal hosts. Other potential infectious bacterial sources include group A streptococci, C canimorsus (transmitted by dog bites), group B streptococci, Enterococcus species, Bacteroides species, Salmonella species, and Bartonella species. In the absence of the spleen, elimination of these pathogens from the bloodstream falls solely to the liver, a process that has been demonstrated to be less effective. Further, the pathophysiology of infection in asplenic patients has also been implicated in their increased risk of thrombosis and pulmonary hypertension.

More recently, the bacterial patterns of splenectomy sepsis have been changing. After the introduction of vaccinations and new oral antibiotics, postsplenectomy patients can suffer from diverse strains of bacterial infection, which are not strictly correlated with the splenic function. In recent cohort series, gram negative bacteria are prevalent, representing 45% to 50% of infections in asplenic patients. In vaccinated patients, the rate of sepsis by pneumococcus is very low. In fact, encapsulated bacteria, such as S. pneumoniae, N meningitidis, and H influenzae, were rarely encountered in those series in whom vaccination was routinely adopted.

Sepsis by uncommon bacteria as well by protozoa infections such as malaria and babesiosis are also known to affect asplenic patients.

**Clinical Features.** OPSI is uniformly fatal without treatment, and thus sepsis in a splenectomized patient is a medical emergency. Therefore, any clinical suggestion of infection, including seemingly isolated fevers, must be viewed with a high index of suspicion and treated empirically as thorough investigation proceeds. OPSI may begin with a relatively mild-appearing prodrome of symptoms. In addition to fever, nonspecific symptoms such as malaise, myalgias, headache, vomiting, diarrhea, abdominal pain, and others should be viewed with alarm in the asplenic patient. This process can progress rapidly to fulminant bacteremic septic shock, with hypotension, anuria, and disseminated intravascular coagulation.

The true incidence of OPSI is not precisely known because defining criteria vary among published series. Overall lifetime risk remains low, ranging from <1% to 5%. Among
those who develop OPSI, some characteristics can be identified that impart greater risk. Reason for splenectomy is the single most influential determinant of OPSI risk. Case series demonstrate that those who undergo splenectomy for hematologic disease (malignancy, myelodysplasia, or hemoglobinopathy) are far more susceptible to OPSI than patients who undergo splenectomy for trauma or iatrogenic reasons. Age is also an important consideration, with children 5 years of age or less and adults 50 years or older being at elevated risk. Finally, time interval from spleen removal must be considered. A large number of OPSI cases occur many years to decades after splenectomy.\textsuperscript{186,189} This observation underscores both the threat of this lethal disease and the need for lifelong vigilance.

**Antibiotics and the Asplenic Patient.** Antibiotic therapy for the asplenic patient can be considered in three contexts: therapy for established or presumed infections, prophylaxis in anticipation of invasive procedures (e.g., dental procedures), and general prophylaxis. The most critical action in the treatment of established or presumed OPSI is the immediate use of broad-spectrum intravenous antibiotics, ideally after the collection of blood cultures. Vancomycin provides broad-spectrum Gram-positive coverage, including coverage against penicillin-resistant *S pneumoniae*.\textsuperscript{190} Ceftriaxone should be added to include Gram-negative coverage for *N meningitidis* and *H influenzae*.\textsuperscript{190} Early implementation of antibiotics and goal-directed therapy for sepsis can significantly reduce mortality rates.\textsuperscript{21,191} For the latter two indications, unfortunately, evidence supporting efficacy is scant, and guidelines for antibiotic prophylaxis are not uniform. Optimal duration of chemoprophylaxis in children also remains unclear; however, a daily dose of antibiotics until 5 years of age or at least 5 years after splenectomy are commonly recommended, although some advocate continuation into at least early adulthood.\textsuperscript{121,122,192} Concerns regarding compliance and bacterial resistance have been raised, which have led some authors to suggest that lifelong daily antibiotic prophylaxis be recommended only for those patients whose antibody titers fail to respond appropriately to vaccination or, alternately, that asplenic patients be advised to carry at all times a reserve supply of antibiotic to be self-administered at the earliest sign of infection.\textsuperscript{122} Considering the grave consequences of OPSI and its relatively low incidence, controlled trials resulting in meaningful data on this issue seem unlikely to be performed.

**Education.** Several risk management strategies are commonly recommended to patients following splenectomy, including wearing a medical bracelet, carrying a laminated medical alert card, possessing a medical letter with specific empiric therapy instructions (including drug names and dosages), and keeping a 5-day supply of standby antibiotics, particularly when travel is anticipated.\textsuperscript{187,189} The need for a high index of suspicion, prompt action, and aggressive education of the patient, family, and medical providers cannot be overstated in asplenic patients.

ABDOMINAL WALL

General Considerations

Incision and closure of the abdominal wall is among the most common surgical procedures performed. Knowledge of its layered anatomy is critical in the management of surgical patients. Cranially defined by the costal margin and xiphoid process and caudally ending over the pubic bones of the pelvis, the abdominal wall provides support and protection to the peritoneal and retroperitoneal organs.

Surgical Anatomy

Embryologically, the abdominal wall is derived from the mesoderm and envelops the future abdominal contents as bilateral migrating layers originating from the paravertebral area. The leading bars of these sheets fuse in the midline as the linea alba at 7 weeks after gestation and reach the umbilicus at 8 weeks.

The abdominal wall consists of nine distinct layers: skin, subcutaneous tissue, superficial fascia, external oblique muscle, internal oblique muscles, transversus abdominis muscle, transversalis fascia, preperitoneal adipose tissue, and peritoneum. The subcutaneous tissue is composed of superficial adipose tissue that is contiguous with Camper’s fascia anteriorly. Deep to this, Scarpa’s fascia consists of a fibrous matrix of tissue that fuses with the anterior layer of fascia of the flank and back.

The muscles of the abdominal wall consist of the rectus abdominis medially and the external oblique, internal oblique, and transversus abdominis laterally. The rectus abdominis is a paired longitudinal muscle spanning the length of the abdomen. Divided by the linea alba, both rectus muscles originate at the pubic symphysis and crest and insert on the xiphoid process, the fifth and sixth ribs, and the seventh costal cartilage. Three tendinous insertions cross the rectus muscle along its length. The muscle is contained within an aponeurotic sheath formed from the fusion of differing components of the lateral fascial layers.

Laterally, the three muscular layers (external oblique, internal oblique, and transversus abdominis) have obliquely oriented fibers relative to one another. The external oblique arises from the eighth rib and inserts medially into the linea alba and anterior iliac crests. The fibers of this muscular layer travel medial and caudal from its insertion. The internal oblique originates from the thoracolumbar fascia. Its fibers travels cranially and anteriorly, inserting on the lower costal margin and the xiphoid process. The deep muscular layer, the transversus abdominis muscle, begins at the costal margin and lumbar fascia, runs horizontally and anteriorly, and inserts on the linea alba, xiphoid process, and pubis symphysis.

Altogether, these muscular layers provide fascial aponeurotic sheaths anteriorly. These fascial layers provide variable contributions to the separate layers of the rectus sheath and ultimately fuse in the midline as the linea alba. The rectus sheath that encloses the rectus muscles has differing compositions above and below the arcuate line. The anterior rectus sheath is composed of the external oblique aponeurosis throughout its length. The internal oblique aponeurosis is bilaminar and contributes to the anterior and posterior rectus sheaths above the arcuate line. Below this line, the internal aponeurosis contributes only to the anterior rectus sheath. The transversus abdominis aponeurosis contributes the posterior rectus sheath above the arcuate line and the anterior rectus sheath below the arcuate line. Therefore, below the arcuate line, all the aponeurotic layers of the lateral musculature form the anterior sheath, leaving the transversalis fascia as the only posterior fascial covering. This layer is a weak fibrous layer separated from the peritoneum by preperitoneal fat.

Along the posterior abdominal wall are folds corresponding to underlying vasculature and embryologic remnants. The median umbilical fold is formed by the obliterated urachus traveling from the dome of the bladder to the umbilicus in the midline. The bilateral medial folds are formed by remnants of the umbilical arteries. Lastly, the lateral folds are associated with the inferior epigastric vessels.

The deep blood supply of the abdominal wall is supplied mostly from the inferior and superior epigastric arteries. The superior epigastric artery is the final branch of the internal thoracic artery. It enters the rectus sheath below the costal margin.
Key Points

1. There are differences in the anatomic structure in the rectus sheath above and below the arcuate line. Below the arcuate line, all the lateral fascial layers combine and travel anteriorly forming the anterior rectus sheath and leaving the posterior aspect of the lower portion of the rectus muscles without an aponeurotic covering. Above the arcuate line, the posterior rectus sheath is formed by a portion of the internal oblique aponeurosis and the transversus abdomenus sheath, and the anterior rectus sheath is formed by the remaining fibers of the internal oblique and the external oblique aponeuroses.

2. Two randomized trials have found that closure of midline incisions with small fascial stitches of five to eight mm length and five mm width is beneficial in preventing incisional hernias of the abdominal wall.

3. Primary repair of ventral incisional hernias results in high recurrence rates, and repair utilizing other methods, including prosthetic mesh and component separation, are preferred techniques of repair.

4. Laparoscopic incisional hernia repair results in similar recurrence rates and wound infections, compared to open repair. Laparoscopic repair may result in a faster recovery and shorter hospitalization; however, there may be an increase in bowel injury when compared to an open repair.

5. Desmoid tumors should be monitored for asymptomatic patients as there is a possibility of spontaneous regression. For patients with rapidly growing or symptomatic tumors resection is recommended. If complete pathologic resection is not achievable without significant morbidity, more modest resection is recommended along with treatment with adjuvant therapies.

6. The omentum provides an immunogenic and fibrotic response to foreign stimuli, allowing the abdomen to wall off infections preventing diffuse peritonitis.

7. The role of surgery in the treatment of sclerosing mesenteritis is minimal and is most often undertaken to obtain tissue for diagnosis. Most cases should be treated medically with surgical interventions reserved for cases of bowel obstruction and ischemia.

8. Surgical interventions for retroperitoneal fibrosis include obtaining tissue for pathologic diagnosis, relieving ureteral obstructions via ureterolysis or ureteral stenting, and relieving vascular obstructions via endovascular stenting of affected vessels. Most cases are treated successfully with the use of steroids.

and travels along the posterior surface of the anterior sheath and forms an anastomosis with the inferior epigastric artery at the umbilicus. The inferior epigastric artery arises from the external iliac artery. These arteries provide a collateral circulation between the vasculature of the upper and lower extremities (Fig. 35-3). The abdominal wall is also supplied by branches of the subcostal and lumbar arteries. Superficially, the abdominal wall subcutaneous and skin tissue is supplied by branches of the superficial epigastric arteries, femoral arteries, superficial external pudendal, and superficial circumflex arteries. Venous drainage of the abdominal wall is variable but typically follows the aforementioned arteries. Above the umbilicus, the lymphatics of the abdominal wall drain into the superficial axillary nodes. Below the umbilicus, these drain into the inguinal nodes. Lymphatics near the umbilicus can drain along the falciform ligament toward the hepatic nodes.

Innervation of the abdominal wall is segmental, leading to a dermatomal sensory pattern. Afferent branches of the T4 to L1 nerve roots provide sensation of the abdominal wall (see Fig. 35-3). The muscles of the abdominal wall are innervated by the efferent branches of spinal nerves T6 to T12.

Physiology

Aside from providing protection of the intraabdominal and retroperitoneal organs, the abdominal wall muscles assist with flexion, extension, and rotation of the torso along with the muscles of the back and trunk. Working as a unit, the rectus muscles and external/internal obliques activate to flex the trunk anteriorly and laterally. Rotation of the torso is performed by simultaneous stimulation of the contralateral external oblique and ipsilateral internal oblique. To rotate the torso to the right requires simultaneous contraction of the right internal oblique muscle and left external oblique muscle, and vice versa for leftward rotation. Altogether, the muscles of the abdominal wall can act to raise intraabdominal pressure providing assistance with respiration, coughs, defecation, urination, and parturition.

Abdominal Surgical Incisions and Closure

Knowledge of the abdominal wall anatomy is an important aspect of safe entry into the abdomen. The goal of an efficacious incision is to provide adequate exposure to perform the procedure with minimal perturbation of the abdominal wall function.

Incisions for open abdominal surgery are generally located in proximity to operative targets. There are two general types of incisions: longitudinal or transverse/oblique (Fig. 35-4). There does not appear to be differences in early or late postoperative complications or recovery time between these two types of incisions. However, transverse incisions may be associated with lower incisional hernia rates but higher rates of wound infection. Overall, without clear evidence of superiority the choice of incision remains a surgeon-dependent decision. Several retractor systems can be used to provide exposure using these open incisions. Examples include the Bookwalter, Omni-Tract, and Thompson retractors (Fig. 35-5).

The most common longitudinal incision is the midline incision. Providing access to most intraabdominal organs and some retroperitoneal structures, the midline incision is carried down to the linea alba to allow access to the abdomen with minimal injury to skeletal muscles, nerves, and vessels. Paramedian longitudinal incisions are made lateral to the midline through the rectus sheath or in the pararectus location. These incisions restrict access to the contralateral abdomen and pelvis and risk damage to the musculature, vessels, and nerves.

Closure of the midline incision requires reapproximation without undue tension or strangulation of the tissue to prevent...
perioperative dehiscence or incisional hernia formation. Classically, the midline fascia of the incision is closed using sutures placed 1 cm from the edge and a width of 1 cm apart. Two European randomized controlled trials demonstrated reduced rates of incisional hernia with shorter stitch width (5–8 mm) compared to the standard 1 cm stitches. Studies are ongoing in the United States at this time. Several studies have evaluated the use of prophylactic mesh implantation in the closure of the midline incision. While these studies demonstrate reduced incisional hernia formation in the short-term, more long-term data is needed to determine the incidence of mesh-related complications. Furthermore, the optimal location of mesh implantation and type of mesh used are still being evaluated.

When performing a transverse or oblique incision, a surgeon can either divide or separate the muscle fibers of the abdominal wall. The classic McBurney’s incision for appendectomy, an oblique incision performed one-third of the way from the iliac spine to the umbilicus, is an example of a muscle-splitting approach. A subcostal incision can be used to access the upper abdomen, liver, gallbladder, spleen, pancreas, or adrenals. On closure of these incisions, two layers must be approximated. The deep layer includes the internal oblique, transversus abdominus muscle, and the transversalis fascia. The superficial layer includes the anterior aponeurotic tissue of the rectus sheath medially and the external muscle/aponeurosis laterally. A bilateral subcostal incision, or a chevron incision, can be used to access organs of the upper abdomen and diaphragm. A Mercedes-Benz modification includes a midline incision superiorly, providing further access to the upper abdomen or the lower mediastinum.

Pelvic procedures are commonly performed through a Pfannenstiel incision. This incision is performed via a transverse skin incision carried down to the anterior rectus sheath. The sheath is also transversely incised and dissected off the underlying rectus muscle. The rectus muscles are separated, and access through the transversalis fascia is performed longitudinally. Closure of this incision requires approximation of the peritoneum and rectus muscles and closure of the anterior rectus sheath.

Laparoscopic port site incision placement must be carefully planned based on approach angles and working distances both to the operative site and between ports. Placement of a...
nasogastric tube and Foley catheter may help to decompress the stomach and bladder reducing injury to these structures on entry. Initial entry into the abdomen may be completed using the open Hasson or closed Veress needle techniques. The Hasson technique involves direct visualization and systematic opening of each fascial layer encountered on entry. The closed technique utilizes the Veress needle to access the abdomen in a controlled fashion. Access to the peritoneum is confirmed using one or a combination of several techniques (saline drop method or measurement of intraabdominal pressure), and gas insufflation is begun. The abdomen can then be accessed using either a visual entry port or a nonvisualized entry port at the site of the needle track or an alternative site. Choice of entry method is still controversial and based on surgeon preference. Retrospective reviews suggest that complications may be lower using the Hasson technique, but randomized trials (although small) have not found significant differences in techniques.

Abdominal incisions can lead to significant patient morbidity. Complications include hematomas/seromas, surgical site infections, fascial dehiscence, incisional hernias, and nerve injuries among others. In general, minimizing operative incision lengths to only that which is necessary for a safe operation is prudent to reduce these complications and morbidity.
Congenital Abnormalities

The folds of mesodermal cells that form the abdominal wall layers begin to form in the early weeks after gestation. The folds develop in the cephalic, caudal, and right/left lateral directions and converge at the umbilicus around 8 weeks. At around 6 weeks of development the contents of the abdominal cavity outgrow the space allowed by the surrounding layers of the...
abdominal wall, resulting in temporary herniation of the abdominal contents through a central defect. At this time, the vitelline duct (omphalomesenteric duct) and allantois also pass through the central defect. The vitelline duct serves as a conduit to the embryologic midgut and the yolk sac. As the midgut develops outside of the abdomen, it undergoes a 270° counterclockwise rotation and reenters the abdomen at around 12 weeks. Failure of the midgut to reenter the abdomen leads to the congenital abdominal wall defect known as an omphalocele, in which the contents of the defect protrude through an open umbilicus and are covered by an amniotic/peritoneal membrane. Gastrochisis, on the other hand, results from either malformation or disruption of the abdominal wall, either from genetic defects or vascular compromise. Gastrochisis presents as protruding viscera through a defect lateral to the umbilicus (usually along the right side) without the amniotic sac covering.

The vitelline duct usually involutes at around the eighth to ninth week after gestation. Failure of vitelline duct regression can lead to several abnormalities depending on the spectrum of involution. This spectrum includes total persistence of the vitelline duct leading to omphalomesenteric fistula causing drainage of intestinal contents at the umbilicus, to partial closure leading to omphalomesenteric cyst. If the vitelline remnant persists at the ileal border, a Meckel’s diverticulum forms. The vitelline duct (omphalomesenteric duct) and allantois also pass through the central defect. At this time, the vitelline duct may also persist as a fibrous attachment of the intestine to the abdominal wall predisposing the patient to bowel obstructions. Fistulas, cysts, and fibrous attachments should be resected when diagnosed.

The urachus is the proximal portion of the allantois forming as the bladder descends into its pelvic position. The urachus closes and forms the median umbilical ligament of the abdominal wall as previously described. Failure of the urachus to close results in urinary fistula or cyst. These are treated by urachal excision and closure of the bladder defect.

Acquired Abnormalities

Abdominal Wall Hernias. A protrusion or bulge of abdominal contents through the abdominal wall muscle/fascia represents an abdominal wall hernia. This may be present at birth or acquired from weakening or disruption of the overlying fascia, or from failed healing of a surgical incision. Hernias may present as asymptomatic bulges that increase with Valsalva maneuvers, or with significant discomfort. On physical exam, the patient’s abdominal wall should be evaluated with the patient both standing and in the recumbent position. Hernias may reduce spontaneously or without manual pressure. If a hernia is incarcerated, it cannot be reduced and generally requires surgical correction. If intestine is incarcerated in the hernia defect, bowel obstruction may ensue, which represents a surgical emergency. Incarcerated hernias present with significant pain, nausea, and vomiting. A hernia is considered strangulated if blood supply to its contents is compromised. Localized ischemia may lead to infarction and eventual perforation if left untreated.

Nonincisional hernias are named based on their location on the abdominal wall. Epigastric hernias are defects in the abdominal wall located between the umbilicus and the xiphoid process. These hernias are usually small but may be associated with multiple defects. They result from multiple factors, including muscle weakness, congenitally weakened epigastric fascia, or increases in intra-abdominal pressure. Epigastric hernias rarely contain bowel and usually contain portions of the omentum or falciform ligament. Given the rarity of incarceration, repair of an epigastric hernia is indicated for symptomatic patients only. Laparoscopic repair can be attempted, but this type of hernia usually can be managed with a small incision where the defect is closed with interrupted sutures.

Umbilical hernias may be congenital or acquired. Umbilical hernias are common in newborns, especially in premature infants. Closure of an umbilical defect occurs after birth as the muscles of the rectus abdominis grow toward one another. Most umbilical hernias close spontaneously by 5 years of age and can be monitored as they will spontaneously resolve. Indications for repair include incarceration, symptomatic hernia, failure to decrease in size or if the defect fails to close by the age of 5 years.

In adults, umbilical hernias form because of increased abdominal pressure due to pregnancy, obesity, or ascites. Females are at higher risk for this type of hernia than men. Small, asymptomatic hernias may be followed clinically. However, if an umbilical hernia enlarges in size, causes symptoms, or incarcerates surgical treatment should be offered. Hernias can be repaired laparoscopically or with an open procedure. Mesh should be employed for large defects where the fascial edges cannot be approximated without tension. In this case, mesh should be placed as a sublay technique (below the fascia) and sutured in place to prevent migration.

Patients with cirrhosis and associated ascites with an umbilical hernia pose a significant clinical dilemma. Umbilical defects enlarge in these patients because of high intra-abdominal pressure associated with uncontrolled ascites. With severe liver disease, these patients are at high risk of operative complications. Most hernias contain ascites; however, omentum and bowel may also enter the defect. Given the high pressure, skin breakdown may ensue leading to hernia rupture or weeping as well as risk of spontaneous bacterial peritonitis. All attempts should be made to control the patient’s ascites prior to repair. Therefore, asymptomatic patients should be managed conservatively with aggressive management of ascites. Liver transplant candidates should undergo repair at the time of transplantation as pretransplant repair has high morbidity and mortality. Patients with incarcerated hernias or with thinning or ruptured skin overlying the hernia should be treated emergently.

Hernias that occur along the arcuate line are known as Spigelian hernias. While rare, these hernias form due to the anatomic weakness of lack of a posterior rectus sheath below the arcuate line. As the hernia develops, peritoneum that passes through the arcuate line will pass laterally toward the external oblique muscle given the overlying aponeurosis (Fig. 35-6). Most patients present with pain and swelling in the mid to lower abdomen. Incarceration is common as up to 20% of patients present with a nonreducible hernia. Given the high rate of incarceration, surgical repair is usually recommended. Either open or laparoscopic repair can be performed. The defect is closed by approximating the medial and lateral edges of the transversalis fascia to the rectus sheath.

Incisional Hernias. Hernias that develop at sites of previous abdominal incisions are known as incisional hernias. Hernias can develop at the site of any previous abdominal incision. Up to 20% of midline incisions will develop hernias eventually. Vertical incisions may have a higher risk of hernia formation than transverse or oblique incisions. Upper
abdominal incisions are also at higher risk than lower incisions. Laparoscopic port sites may also develop hernias. The etiology of incisional hernias is complex. Several patient-derived factors increase the risk of hernia, including diabetes, immunosuppressant use, obesity, smoking, malnutrition, and connective tissue disorders. Local operative factors may also be implicated, including technique, wound infection, or high tension at the time of closure. Hernias can develop up to 10 years after surgery but normally occur in the early postoperative period. Incisional hernias can present as asymptomatic bulges or with severe discomfort. Multiple hernias can be present along the length of the incision. Elective surgery should be recommended in patients who are symptomatic. Small defects pose a higher risk of incarceration and should be repaired. To improve operative outcome, patient associated factors, including smoking and obesity, should be remedied prior to surgical repair.

Surgical management of incisional hernias include either primary tissue or mesh repairs. Hernias can also be repaired via a laparoscopic or open approach. Simple suture repair is associated with recurrence rates as high as 54%. A Cochrane review of several randomized controlled trials found that open mesh repair improved hernia recurrence rates when compared to simple closure (33% with simple repair vs. 16% with mesh repair). Mesh repairs are, however, associated with a higher rate of infections.

To reduce tension at the suture line associated with primary suture repair Ramirez described the components separation technique in 1990. This procedure entails dividing portions of the bilateral external oblique aponeuroses forming musculo-fascial advancement flaps. The posterior rectus sheath can also be incised, allowing up to 10 cm of medial mobilization and tensionless approximation of the midline fascia. This technique can cause large skin flaps and initially had high rates of infection. Overtime, techniques have been developed to decrease flap formation and decreased rates of surgical site infection. Endoscopic component separation can also be used to mobilize flaps with minimal ischemia to overlying subcutaneous and skin tissue, theoretically decreasing infection rates. Mobilization of midline fascia is reduced with endoscopic methods. Mesh can also be utilized to reinforce the repair. Overall, component separation without mesh compares to standard mesh repair with respect to hernia recurrence, but precludes the risk of mesh implantation. When mesh is added to component separation, recurrence rates may be as low as 4% to 10% depending on follow up period.

Mesh repair has become the standard for elective management of most incisional hernias. Position of mesh placement is controversial. Mesh can be placed above the midline fascia (overlay), bridged across fascial defects (interlay), underneath fascia (sublay), or within the abdominal cavity (underlay). A systematic review found that sublay placement of mesh may reduce hernia recurrence and prevent wound related complications. The sublay technique is performed by developing the plane between the rectus muscle and the posterior sheath, and affixing mesh in this space. The anterior sheath can be approximated if there is no tension.

Material used for mesh manufacturing can be classified into two classes: synthetic and biologic. Synthetic meshes can be either permanent or degradable, while all biologic meshes are degradable. Permanent mesh is currently made of either polypropylene, polyethylene terephthalate polyester, or expanded polytetrafluoroethylene. Permanent mesh is durable and of relatively low cost. Degradeable synthetic mesh, including Vicryl mesh, is eventually eliminated and loses structural support, but it does offer the advantage of lower mesh infection rates. Degradeble mesh is associated with high recurrence rates, but it can be used for temporary abdominal wall closure in contaminated or infected fields. Newer synthetic biomaterial meshes, including Gore BioA or Phasix, degrade over a longer period of time and may reduce recurrence rates, but long-term effectiveness is unknown. Biologic meshes are decellularized, collagen-rich porcine, bovine, or human tissue. These meshes are designed to allow host cellular ingrowth, promoting incorporation and eventual replacement of the mesh with host tissue. Biologic meshes are a high cost alternative to synthetic degradable mesh and can be used in infected fields. However, their efficacy in preventing recurrence is unclear. Composite products contain two components and are used during intraperitoneal repair. One side of composite mesh, which is placed on the abdominal wall side of implantation, is made of typical nondegradable synthetic material and promotes integration of host tissue. The other side is covered in a synthetic or biologic material, allowing contact with viscera and preventing adhesion formation. These materials include polyglactin, collagen, cellulose, titanium, omega-3, and hyaluronate. This allays concerns of direct mesh contact
with viscosa that may cause adhesions, erosion, and eventual fistula formation. Pore size and mesh weight are also important aspects of mesh design. Recently, large-pore, lightweight mesh has been developed. This was initially thought to delay incorporation, but that has not been seen in practice. They do allow the theoretical advantage of increased incorporation of host tissue and potentially better elasticity and improved postoperative pain when compared to microporous heavier meshes. There is also initial data which suggests lower rates of mesh infection with the use of large pore mesh.

Initially described by LeBlanc and Booth in 1993, laparoscopic repair is now an accepted modality for treatment of incisional hernias. Several studies have found that laparoscopic repair has a lower incidence of surgical site and mesh infections compared to open repair. It also seems that laparoscopic repair allows faster recovery with less postoperative pain. A meta-analysis of 11 studies comparing laparoscopic and open ventral hernia repair found no difference in hernia recurrence and lower rates of wound infection and wound drainage. There was however, a higher risk of bowel injury in the laparoscopic group. Another meta-analysis of six randomized controlled trials had similar findings. Follow-up in these studies is relatively short, and more long-term data is needed at this time to compare these two modalities of repair.

Laparoscopic hernia repair is performed by initially placing lateral ports for midline defects and contralaterally placed ports for lateral defects. Adhesions between the abdominal wall and intestine are carefully taken down, and the hernia contents are completely reduced. The sac is normally left in situ. Once the fascial defect is defined, a mesh is properly shaped and fashioned over the hernia. Transfascial sutures are placed circumferentially to position the mesh with sufficient overlap (4–5 cm) with healthy abdominal wall. Spiral tacks may be placed according to surgeon preference. Even more recently, robotic surgery has been established as another surgical modality in the treatment of ventral hernias. The theoretical advantage of improved visualization and articulating instruments may improve outcomes, but the cost-effectiveness of robotic repair is unclear. Overall, more studies are needed to evaluate the role of robotics in ventral hernia surgery.

Although still rare, given the increase in laparoscopic procedures, the incidence of laparoscopic port site hernias is becoming more common. Given the size of the hernias, there is a substantial risk of bowel strangulation and ischemia. These hernias commonly present as Richter’s hernia, or a hernia containing only a portion of bowel wall. A recent meta-analysis found that the incidence of port site hernia after laparoscopic procedure was less than 1%. Patients can present either early or several years after surgery. Risk factors are similar to other incisional hernias. The most common site of herniation is at an umbilical incision, but it may be found elsewhere. In adults, hernias usually occur in ports that are greater than 5 mm in size, but they can occur in any size ports in children. Depending on the timing of presentation, these are usually repaired via an open approach by increasing the size of the skin incision, reducing the hernia, and approximating all layers of fascia.

Rectus Abdominis Diastasis. Rectus abdominis diastasis (diastasis recti) is an anatomic term referring to an abnormal separation of rectus muscles and a laxity at the linea alba. Although there is controversy regarding normal separation distances between rectus muscles, a distance of two centimeters is usually considered abnormal in the midline abdomen above the umbilicus. This can either be a congenital or acquired abnormality. This is not a true hernia as the midline fascia is intact, and as such incarceration and strangulation do not occur. Risk factors for acquired rectus abdominis diastasis include conditions that elevate intraabdominal pressure, including obesity and pregnancy, as well as conditions which weaken the abdominal wall, including connective tissue disorders or prior abdominal surgery. Risk factors of developing a diastasis recti after pregnancy include older age at the time of pregnancy, multiple pregnancies, and recurrent cesarean sections. Postpartum exercise reduces the risk of developing diaasthesis recti. Most patients with diastasis recti can be diagnosed based on physical exam where a fusiform bulge is usually apparent. This bulge worsens with contraction of the rectus muscles or Valsalva maneuver. If imaging is needed, ultrasonography can be used to confirm diagnosis and rule out hernia. CT scan can also be used to confirm diagnosis and measure distance between muscle pillars. Rectus diastasis does not require surgical repair and may be improved via weight loss and exercise. Indications for repair include disability of abdominal wall muscular function or cosmesis. Surgical repair includes both open and laparoscopic plication of the rectus sheath. Mesh can also be used to bridge the muscle; however, complication rates increase with mesh usage. These procedures do, unfortunately, have a high risk of recurrence long term and introduce a new risk of incisional hernia.

Rectus Sheath Hematoma. Disruption of one of the branches of the inferior epigastric artery as well as an inability to tamponade the hemorrhage results in a rectus sheath hematoma. This occurs commonly around the arcuate line where the artery and its branches are relatively fixed causing vulnerability to shearing forces. Several risk factors are associated with rectus hematoma formation via either proclivity to disruption of blood vessels or by inability to cease bleeding. Trauma to the abdominal wall, including iatrogenic trauma with laparoscopic trocar placement, can lead to disruption of blood vessels. Vigorous contraction of the rectus muscle, either with coughing, sneezing, or exercise, can also induce hemorrhage formation. Chronic pulmonary disease can lead to hemorrhage because of coughing fits. Patients on anticoagulation also present with higher risk of hematoma formation. This condition presents with acute abdominal pain and a palpable abdominal wall mass. Rectus sheath hematoma may be mistaken with intraperitoneal pathology, including appendicitis if on the right side. However, in patients with rectus sheath hematomas, pain usually increases with contraction of the rectus muscles as opposed to intraperitoneal conditions. In addition, palpation of a mass that does not change during contraction of the rectus muscle, known as Fothergill’s sign, is also associated with rectus sheath pathology. The diagnosis should be confirmed via ultrasound or CT scan with intravenous contrast. Obtaining a type and screen, hemoglobin/hematocrit, and coagulation factors are critical in the management of these patients.

Treatment of patients with rectus sheath hematoma depends on the hemodynamic stability of the patient as well as the size of the hematoma. Hemodynamically stable patients with small hematomas, stable serial hemoglobin/hematocrits, and normal coagulation factors may be observed without hospitalization. Hemodynamically stable patients with larger or bilateral hematomas and decreases in hemoglobin should be monitored in the hospital setting, with serial hemoglobin levels, compression of the hematoma, and bedrest. If anticoagulated, reversal is necessary and transfusions of packed red blood cells may
be required in some situations. Patients in hypovolemic shock should be aggressively resuscitated with the use of blood products and treated via angiographic embolization. Angiographic intervention may also be required if the hematoma increases in size or if clinical deterioration occurs. Surgical therapy can be performed if angiographic intervention has failed. Surgical treatment includes operative evacuation of hematoma and ligation of bleeding vessels.

**Desmoid Tumors.** Also known as aggressive fibromatosis, desmoid tumors are fibroblastic neoplasms with aggressive infiltrative behavior but no metastatic potential. These tumors can occur anywhere in the body but commonly occur in the abdomen or abdominal wall. Desmoid tumors are rare and usually occur sporadically. They are, however, also associated with familial adenomatous polyposis (FAP), with an even greater risk in patients with Gardner’s syndrome. Of patients with FAP, 10% to 15% develop desmoid tumors. After prophylactic colectomy, desmoid tumors becomes the primary cause of death in patients with FAP. Risk factors for sporadic development of desmoid tumors include previous surgical incision, pregnancy, hormonal exposure, and trauma. Females have a higher predilection for formation of desmoid tumors. Diagnosis can be performed via core-needle or incisional biopsy. Larger tumor size, young patient age, and extra-abdominal tumor location all predict poor recurrence free survival.

The gold standard of treatment of abdominal wall desmoid tumors, historically, is margin-negative resection with immediate mesh reconstruction. However, more recently there has been controversy as to whether complete microscopic resection is necessary. It is now commonly agreed that while complete microscopic resection is ideal, with the emergence of adjuvant therapy a positive margin may not require additional surgery, especially if re-resection would cause high morbidity. There is also some evidence to suggest a period of close watchful waiting, as some tumors appear to remain stable or even regress over time. In one cohort of 106 abdominal wall desmoids managed initially without surgery, 16% of patients went on to require surgery in a follow-up period of three years. Interestingly, 29 patients had spontaneous regression of their tumors over that time. The National Comprehensive Cancer Network (NCCN) now suggests initial close observation for patients with asymptomatic, non–life-threatening tumors. Surgery is indicated in patients with symptomatic disease, risk of invasion of surrounding structures, or enlarging tumors. There may be a role for adjuvant or neoadjuvant radiation therapy, although the data are unclear at this time. Primary radiation therapy may be an option for patients who are not surgical candidates. There may also be a role for systemic therapy, especially if tumors are unresectable. Options include hormonal therapy, nonsteroidal anti-inflammatory agents, cytotoxic chemotherapies (doxorubicin or carboplatin), or imatinib.

**Other Abdominal Wall Tumors.** Various tumors may also be found within the abdominal wall including lipomas and neurofibromas (Fig. 35-7). Surgical resection is recommended for symptomatic or enlarging lesions. Abdominal wall malignancies are exceedingly rare and include several histologic subtypes of sarcomas, dermatofibrosarcoma protuberans, schwannomas, and melanomas. Workup of abdominal wall tumors should include core needle biopsy or excisional biopsy if the tumor is small enough. Magnetic resonance imaging (MRI) or CT scan with IV contrast should be utilized to define local extent of disease.

MRI is preferred as this modality provides more detail on extent of disease. Chest CT should also be obtained to rule out pulmonary metastasis in high-grade tumors. Chest X-ray may be sufficient to stage tumors that are low grade, given the lower risk of distant disease. Surgical resection is the mainstay of treatment for nonmetastatic disease. For most soft tissue sarcomas, 1 cm margins are usually sufficient, but 2 cm margins may be needed for dermatofibrosarcoma protuberans. Tumors of the superficial abdominal wall should be resected with the underlying fascia, which may require use of mesh to prevent abdominal wall laxity or hernia.

Given the rarity of these tumors, the efficacy of adjuvant or neoadjuvant chemoradiation is unclear. Adjuvant or neoadjuvant therapy may be recommended in patients with large (>5 cm) or high-grade tumors. Some centers administer neoadjuvant radiation therapy to patients with high-risk tumors to monitor response. Chemotherapy may also be used in certain situations. If tumors involve underlying viscera, en bloc resection may be required. Primary closure may be feasible, but prosthetic mesh use (even in the setting of bowel resection) may be required. Options for abdominal wall closure after resection include absorbable or biologic mesh reinforcement, and myocutaneous flap reconstruction.

**OMENTUM**

**Surgical Anatomy**

The omentum is a fibrous adipose apron providing support and protection of the intraabdominal viscera. Embryologically, the omentum originated from the dorsal mesogastrium. Anatomically, the omentum is divided into the greater and lesser omentums. The greater omentum begins to form during the fourth week of gestation. Initially, the omentum forms as a double-layered structure, with the spleen developing between the two layers. As development proceeds, the layers of mesentery fuse, the spleen assumes its position in the peritoneum, and the gastroplenic ligament forms. The greater omentum, therefore, is a double-layered sheet of visceral fibroadipose tissue descending from the greater curvature of the stomach, covering the small intestines. The omentum folds back on itself and attaches onto the anterior peritoneum of the transverse colon (Fig. 35-8).
In an adult, the greater omentum lies between the abdominal wall and the hollow viscera, usually extending into the pelvis. The greater omental tissue connecting the stomach to transverse colon, as well as the stomach to the spleen, are known as the gastrocolic and gastrosplenic ligaments, respectively. The blood supply to the greater omentum is derived from the right and left gastroepiploic arteries. The venous system parallels the arterial supply and ultimately drains into the portal system. Lymphatic drainage of the greater omentum occurs via the subpyloric or splenic nodes depending on laterality ultimately culminating in the celiac nodes and subsequently the thoracic duct.

Forming the anterior boundary of the lesser sac, the lesser omentum extends between the liver and lesser curvature of the stomach. Also known as the hepatoduodenal and hepato gastric ligaments, the portal triad (including the common bile duct, portal vein, and hepatic artery) is located within the inferolateral margin of the lesser omentum. This free edge of lesser omentum forms the foramen of Winslow, which is used to encircle the portal triad during a pringle maneuver (see Fig. 35-8).

**Figure 35-8.** Greater and lesser omentum. The greater omentum begins along the greater curvature of the stomach, drapes over the transverse colon into the pelvis, and folds back on itself inserting along the posterior wall of the transverse colon. The greater omentum includes the gastrophrenic and gastro splenic ligament. The lesser omentum includes the gastrohepatic and hepatoduodenal ligaments, covering the lesser sac of the abdomen. The free lateral edge of the lesser omentum includes the portal triad, forming the foramen of Winslow below. (Reproduced with permission from Moore KL, Agur AM: Essential Clinical Anatomy, 5th edition. Philadelphia, PA: Lippincott Williams & Wilkins; 2014.)

**Physiology**

Initially described by the British surgeon Rutherford Morison as the “policeman of the abdomen,” the greater omentum is understood as a peritoneal defense organ. The omentum forms fibrin adhesions at sites of inflammation, effectively attempting to wall off peritoneal infections. The greater omentum is known to respond to a foreign stimulus by expanding stromal tissue that expresses chemotactic, inflammatory, and hemostatic factors, which promote tissue inflammation and subsequent repair. Forming a fibrin bridge between omental tissue and the injured site allows passage of inflammatory factors and immune cells. The Graham Patch repair of a perforated ulcer utilizes the complex inflammatory interactions of the omentum to improve leak rates after repair.

The visceral fat of the greater omentum is also involved in metabolic functions of the body. Increased visceral fat, including the greater omentum, is an independent risk factor for insulin resistance and high triglyceride levels. This may be, in part, mediated by the increase in visceral inflammation seen in intra-abdominal obesity. Several adipokines, or cell-signaling molecules secreted by adipose tissue, are secreted by the greater omentum and act on peripheral tissues, affecting metabolic health throughout the body.

**Acquired Disorders**

**Omental Infarction.** Omental infarction is a rare cause of acute abdominal pain. Omental infarction may be primary or
secondary depending on the etiology. Primary infarction may be caused by torsion of the omentum from sudden or forceful movements, thrombosis or vasculitis of omental vessels, or omental venous outflow obstruction. Secondary causes of torsion are most often due to hernias, tumors, or adhesions. Only about 250 cases of primary omental infarction have been reported in the literature. This occurs most often in male and obese patients. Omental infarction may mimic other intra-abdominal pathologies such as appendicitis, cholecystitis, or diverticulitis. Abdominal exam usually demonstrates peritoneal tenderness, with a possible palpable mass. Ultrasonography (US) and abdominal CT scan are used to assist diagnosis. US may demonstrate a hyperechoic, noncompressible intra-abdominal mass attached to the abdominal wall. CT scan demonstrates a streaking whirling pattern of fatty tissue in the anterior abdomen (Fig. 35-9). Regardless, only a small percentage of patients are preoperatively diagnosed. Omental infarction can be treated conservatively, but this leads to several possible complications, including abscess or adhesion formation. Laparoscopic exploration and resection of infarcted tissue is the usual treatment of choice and leads to rapid resolution of symptoms.

Omental Cysts. Cystic lesions of the omentum are rare disorders, related in pathogenesis to mesenteric cysts. Most are thought to form through degeneration or inclusion of lymphatic structures. Case reports described these lesions presenting as vague abdominal pain or nausea or vomiting. Cysts may also present as a lead point for omental torsion and infarction. Physical exam may or may not reveal evidence of an intra-abdominal mass. Cysts may also be diagnosed incidentally on imaging exams performed for other reasons. CT scan and US are largely diagnostic and reveal a well-circumscribed cystic appearing lesion arising from the greater omentum. A very small percentage may transform to malignancy. Most are resected, especially if symptomatic, via open or laparoscopic approaches. Cysts may relapse if treated conservatively via laparoscopic unroofing or percutaneous drainage.

Omental Neoplasms. Most omental neoplasms are metastatic disease. Ovarian cancer is the most common cancer to have omental involvement. Other metastatic cancers include gastrointestinal tract tumors, melanoma, endometrial cancer, and kidney cancer.

Primary tumors of the omentum are exceedingly rare. Benign masses may include lipomas, myxomas, and desmoid tumors. Extra gastrointestinal stromal tumors are a rare malignant tumor of the omentum that have been described in several case series. These tumors share many genetic and immunophenotypic similarities to classical GISTs, including c-kit and PDGFRA mutations. In one review of case reports, the median age of diagnosis was noted to be 65 years and had equal predilection for male and female patients.

**MESENTERY**

**Surgical Anatomy**

The mesentery is a contiguous structure suspending and fixing bowel to the abdominal wall providing housing for arterial, venous, nervous, and lymphatic structures connecting hollow viscera with the body. The mesentery is derived from the mesodermal germ layer becoming the dorsal mesentery. Previous theories of development included sliding and regression models of mesenteric development. However, with a new contiguous model of development of the mesentery, several key simple steps are proposed to take place. Initially, the mesentery provides a point of suspension from vascular connections. As the intestine and mesentery elongate, they undergo a 270° counterclockwise rotation leaving the primordial abdominal cavity. Eventually, the duodenum and ascending/descending colon flatten against the posterior abdominal wall returning the bowel back into the abdomen and taking its normal shape. The resultant development of the white line of Toldt along the lateral border of the ascending and descending large bowel provides an avascular fascial plan between the colon, its mesentery, and the underlying retroperitoneal space. The small intestine mesentery, transverse colon mesentery, and sigmoid colon mesentery remain mobile.

Defects in the proper rotation and fixation of the bowel results in the spectrum of congenital disorders known as intestinal malrotation. In this scenario, the intestine and mesentery are simply suspended from vascular connection, making intestinal volvulus common. Defects that form in anatomical positions may act as routes for intestinal herniation. Common sites of herniation include the paraduodenal or mesocolic areas, leading to either acute or chronic intestinal obstruction in pediatric or adult populations. Areas where mesenteric attachment is incomplete may predispose patients to volvulus. Attachments of the cecum may degrade overtime leading to an area of laxity and possible twisting. The sigmoid mesentery can also increase in size over time also leading to possible sigmoid volvulus. Rarely, other areas of the colon can develop volvulus if differential mesenteric lengths form.

**Sclerosing Mesenteritis**

Sclerosing mesenteritis is a rare disorder characterized by idiopathic fibrosis of the mesentery, affecting hollow viscera as well as mesenteric vessels. The disease is part of a spectrum of inflammation and fibrosis, which when localized is known as mesenteric lipodystrophy and when diffuse is known as mesenteric panniculitis. The cause of this disease is unknown, but it may be instigated by antecedent abdominal surgery, an autoimmune disease, a paraneoplastic syndrome, a previous infection (including typhoid, tuberculosis, influenza, and rheumatic fever), or vascular insult. This disease most commonly effects
white patients between 50 and 70 years of age, although it has been rarely described in children. Most studies report a predilection for male patients. Most patients with this disease present with abdominal pain. Other symptoms include nausea and vomiting, weight loss, anorexia, and altered bowel habits. This may appear as a chronic or acute disorder. On physical exam, patients may be found to have tenderness and distension. Up to 50% of patients are found to have an abdominal mass that often transmits aortic pulsations.

Abdominal CT with IV contrast is used to assist in diagnosis (Fig. 35-10). The most common finding is that of a soft tissue mass with a higher density than normal mesenteric tissue. Although it is sometimes difficult to distinguish mesenteric fibrosis from a mesenteric tumor, two CT findings may add specificity. The “tumor pseudocapsule” refers to a hypodense zone around the associated fibrotic mass, and the “fat ring sign” refers to an area of preserved fat near mesenteric vessels coursing through areas of fibrosis. These lesions may also be calcified on CT scan.

Pathologic confirmation is required to confirm the diagnosis. This usually requires laparoscopic or open biopsy to provide adequate tissue for confirmation. Treatment of sclerosing mesenteritis is complex, with surgery having a minimal role. Patients who present with bowel ischemia may require bowel and mesenteric resection; however, the extent and location of mesenteric involvement may preclude complete resection. If obstructive symptoms are dominant, intestinal bypass may be indicated. Aggressive surgical treatment is not indicated because in many cases symptoms may improve with medical treatment or even without intervention. Steroids, hormonal therapy, colchicine, thalidomide, and cyclophosphamide have all been reported to be beneficial.

Mesenteric Cysts
Mesenteric cysts are a rare benign disorder with an incidence ranging from 1 in 27,000 to 1 in 250,000 admissions. Cysts are thought to be caused by disruption of the lymphatics in the mesentery either by traumatic disruption, mechanical obstruction, or congenital lymphatic malformations. Most cysts are unilocular, but they also may have multiple loculations. They are usually lined with a single layer of columnar epithelial cells. Presentation of mesenteric cyst is varied, with some being found incidentally on imaging exams and others causing acute abdominal pain because of cyst rupture or bowel torsion. Chronic symptoms are usually nonspecific, including abdominal pain or discomfort, anorexia, distension, nausea, vomiting, or changes in bowel habits. Symptoms are due to local compression of abdominal structures. Up to 45% of cysts are found incidentally.

Physical exam reveals an abdominal mass in up to 60% of patients. The classic Tillaux’s sign is an abdominal mass lesion that is only mobile laterally, contrasting omental cysts which are usually freely mobile in all directions. CT scan and ultrasound can be used to make an accurate diagnosis. Cystic lesions usually appear as a fluid filled mass without solid components (Fig. 35-11). It can sometimes be difficult to differentiate cystic masses from solid tumors based on imaging. Mesenteric cystic lymphangioma may present as numerous cysts on imaging. Up to 3% of mesenteric cysts contain malignancy, mostly as a sarcomatous lesion. In one recently published series, 19% of patients harbored malignancy. Solid components within the cystic structure are associated with higher rates of malignancy.

Most mesenteric cysts are treated surgically. Marsupialization and simple aspiration have high rates of recurrence and...
are generally discouraged. Benign lesions should be enucleated, and malignant cysts should be resected with clear margins. Intestines or surrounding viscera may require resection if the associated vasculature is excised. Resection can be performed either via a laparoscopic or open procedure.

**Mesenteric Tumors**

Primary mesenteric tumors are rare but represent several histologic patterns. Benign tumors include desmoid tumors, lipomas, and cystic lymphangiomas. The most common malignant neoplasm of the mesentery is lymphoma. On imaging, lymphoma may appear as bulky adenopathy, usually surrounding and not obstructing nearby structures. Lymphomas should not be resected, but they may require operative biopsy for diagnosis. Other malignant tumors of the mesentery include gastrointestinal stromal tumors, carcinoids, liposarcoma, leiomyosarcoma, malignant fibrous histiocytomas, lipoblastomas, or lymphangiosarcoma. Treatment of malignant mesenteric masses usually involves wide resection; however, given the proximity to mesenteric vessels, resection may not be feasible or require removal of large portions of bowel.

**RETROPERITONEUM**

**Surgical Anatomy**

The retroperitoneum is bound by the peritoneum anteriorly, the iliopsoas and lumbar muscles posteriorly, the diaphragm superiorly, and the levator ani muscles inferiorly. It is divided into the three spaces: the anterior pararenal space, the perirenal space, and the posterior pararenal space (Fig. 35-12). The anterior pararenal space refers to the area anterior to the renal fascia but posterior to the peritoneum. This area contains the ascending and descending colon, the duodenum, and the pancreas. Posterior to this space is the perirenal space, which houses the inferior vena cava, the aorta, kidneys, and adrenal glands. The posterior pararenal space is in continuity with preperitoneal fat of the anterior abdomen. Given the compliance of the anterior boundary of the retroperitoneum and the rigidity of other margins, tumors, hematomas, and abscesses tend to expand anteriorly toward the peritoneal cavity.

With the expansion of minimally invasive techniques in surgery, the retroperitoneoscopic approach has emerged as a potential modality for access to retroperitoneal organs. Patients are positioned in the prone or lateral decubitus positions. The retroperitoneoscopic approach allows access to the kidneys, adrenal glands, and retroperitoneal lymph nodes. One systematic review found no difference when comparing laparoscopic to retroperitoneoscopic adrenalectomy in terms of operative outcomes, complications, or postoperative recovery. Retroperitoneoscopic approach did, however, lead to shorter hospital stay likely because of reduced postoperative pain. The majority of the studies evaluating the retroperitoneoscopic approach are retrospective, and more randomized trials are needed to provide further guidance.

**Retroperitoneal Infections**

Infections of the retroperitoneum can be due to primary hematogenous spread of microbes or due to secondary infection from retroperitoneal or nearby organs. Examples include abscesses due to a perforated retrocecal appendix, diverticulitis, a contained perforated duodenal ulcer, iatrogenic perforation of the gastrointestinal tract, or pancreatitis. Patients may develop back,
flank, or groin pain and suffer from fevers or chills. Depending on severity, patients may present with fulminant sepsis. Abscesses may become quite large given the substantial retroperitoneal space. On physical exam, patients may present with erythema of the umbilicus or flank. Abscesses are usually found easily on CT scan of the abdomen with IV contrast, which can also show if the collection is loculated. Treatment of retroperitoneal abscesses includes source control via treatment of the underlying condition, drainage of well-defined collections, and IV antibiotics. Image guided drainage is preferred, but it may be unsuccessful if the abscess is multifocal or in an inaccessible area. For these cases, operative drainage may be required. Given the insidious nature of this disease and a lack of abdominal findings on physical exam, recognition of a retroperitoneal abscess may be delayed. Delays in diagnosis and insufficient drainage may lead to high morbidity and mortality. Depending on severity, mortality of retroperitoneal abscess can be as high as 25%. Rarely, patients may develop necrotizing fasciitis of the retroperitoneum, a condition with high mortality.

Retroperitoneal Fibrosis

Retroperitoneal fibrosis is a rare disease characterized by inflammation and fibrosis of the tissue of the retroperitoneum. It exists as a spectrum of disease with chronic periaortitis, which affects the retroperitoneal tissue near large arteries of the retroperitoneum. Fibrosis gradually expands, encasing the ureters, inferior vena cava, aorta, mesenteric vessels, or sympathetic nerves. Bilateral involvement is noted in up to 70% of cases. The condition may either be idiopathic or due to a secondary cause, including aortic aneurysms, pancreatitis, certain drugs (Ergot-derivatives, β-blockers, hydralazine, methyldopa, among others), malignancies (including lymphoma, carcinoids, sarcomas, colorectal, breast, and others), infections such as tuberculosis, radiation, retroperitoneal hematoma, surgery, asbestos, or tobacco use. Retroperitoneal fibrosis has been described in association with several autoimmune disorders including ankylosing spondylitis, systemic lupus erythematosus, Wegener’s granulomatosis, and polyarteritis nodosa.

Idiopathic retroperitoneal fibrosis accounts for 70% of cases and is thought to be an immune-mediated disorder. Theories regarding the pathogenesis of idiopathic fibrosis of the retroperitoneum include exaggerated local reactions to aortic or iliac atherosclerosis or autoimmune deposition of fibroinflammatory cytokines. Retroperitoneal fibrosis is also a manifestation of IgG4-related disease, a multisystem disease characterized by lymphocytic infiltrate and variable degrees of fibrosis of several affected organs. One study has associated retroperitoneal fibrosis with the HLA-DRB1*03 allele, which has been linked to autoimmune diseases such as systemic lupus erythematosus, type 1 diabetes mellitus, and myasthenia gravis.

Idiopathic retroperitoneal fibrosis is rare, with an incidence of 1.3 per 100,000 people per year. It most commonly affects individuals in the fourth to sixth decades of life. Some studies suggest a 2:1 male-to-female predominance, but others have not found a gender predilection. Patients with this condition present with nonspecific findings. Most patients are diagnosed after ureteral obstruction. Patients may complain of dull or acute back or flank pain. Systemic complaints include anorexia, weight loss, nausea, vomiting, fever, and malaise. Decreased urinary output may ensue if the ureters become fibrotic. Because of renal artery impingement, patients are commonly hypertensive on exam. Other physical exam findings include lower extremity edema and diminished lower extremity pulses if the vessels of the lower extremities are compressed. New hydrocele or varicocele can also be associated with fibrosis of the retroperitoneum. Laboratory analysis is also nonspecific. If there is renal obstruction, patients may have elevated serum blood urea nitrogen and creatinine. Erythrocyte sedimentation rate and C-reactive protein is elevated in most patients with retroperitoneal fibrosis. Antinuclear antibodies may also be elevated, highlighting the autoimmune nature of this disease.

Contrast-enhanced CT scan is the modality of choice to visualize the extent of disease. On CT scan, fibrotic retroperitoneum appears to have similar attenuation to muscle tissue (Fig. 35-13). The fibrotic mass can appear to encase the aorta and often compresses the inferior vena cava. If renal insufficiency predominates the use of IV contrast, MRI can be used to clarify the extent of fibrosis. Renal US can also be used to document ureteral compression and hydronephrosis. In some cases, a compressing mass lesion can also be found on abdominal US. Lower-extremity US may show deep venous thrombosis.

Pathologic examination of tissue is necessary to confirm the diagnosis and to rule out malignancy. Differential of retroperitoneal masses include lymphomas or sarcomas, desmoid

Figure 35-13. Computed tomography findings of retroperitoneal fibrosis. Arrows point to a soft tissue mass surrounding the aorta and common iliac arteries. Also present is hydronephrosis of the right kidney because of ureteral compression. (Reproduced with permission from Vaglio A, Salvarani C, Buzio C. Retroperitoneal Fibrosis, Lancet. 2006 Jan 21;367(9506):241-251.)
tumors, and infections such as tuberculosis. Biopsy can be obtained either via image-guided or surgical techniques, which may be performed laparoscopically or during an open procedure.

Once the diagnosis of retroperitoneal fibrosis is established, treatment is initiated. Surgical treatment is aimed at relieving ureteral obstruction either by ureterolysis or stenting. Surgery is reserved for patients who develop renal insufficiency as any surgical intervention in these patients carries several associated risks. In patients with secondary fibrosis, treatment is aimed at the underlying etiology or discontinuation of the causative medication. For patients with idiopathic retroperitoneal fibrosis, corticosteroids are the mainstay of treatment. Patients are usually started on one month of high-dose prednisone, followed by maintenance therapy and subsequent taper. Alternatively, tamoxifen can be used if patients have contraindications to steroids. Within days of instituting therapy, symptoms and inflammatory markers should improve. Over the course of a few weeks, renal function should improve. Interval imaging studies are usually obtained after 1 month to evaluate for efficacy. If steroids fail to cause regression of disease, patients can be started on immunosuppressant medications including methotrexate, azathioprine, cyclophosphamide, or mycophenolate mofetil. Recurrence of retroperitoneal fibrosis varies between studies from 10% to 30%. In patients who respond to steroid therapy, 5-year survival is as high as 90%.

 **Retroperitoneum**

Sarcomas are a heterogeneous group of neoplasms that arise predominantly from cells of the embryonic mesoderm. While the majority of sarcomas are soft tissue sarcomas, other types of sarcoma include bone sarcomas (osteosarcoma, chondrosarcoma, and rare bone tumors like chordoma, angiosarcoma, and leiomyosarcoma of bone) and Ewing’s sarcoma/peripheral primitive neuroectodermal tumor, which can occur either in the bone or in the soft tissues. The primary focus of this chapter is soft tissue sarcomas. Most primary soft tissue sarcomas originate in an extremity (50–60%); the next most common sites are the trunk (19%), retroperitoneum (15%), and head and neck (9%). The anatomic site of a primary sarcoma influences treatment and outcome.\(^1\)

Soft tissue sarcomas include more than 70 histologic subtypes (Table 36-1). Historically, the most common subtypes in adults (excluding Kaposi’s sarcoma) were malignant fibrous histiocytoma (28%), liposarcoma (15%), leiomyosarcoma (12%), synovial sarcoma (10%), and malignant peripheral nerve sheath tumor (6%).\(^2\) Today, malignant fibrous histiocytoma is classified as either leiomyosarcoma, pleomorphic undifferentiated sarcoma, myxofibrosarcoma, or dedifferentiated liposarcoma based on cellular differentiation and genetics. Embryonal/alveolar rhabdomyosarcomas are the most common soft tissue sarcomas of childhood, whereas pleomorphic rhabdomyosarcoma occurs predominantly in adults, and although it shares part of the name, it has a different biology and should not be treated as a pediatric sarcoma.

During the past 25 years, patients with extremity sarcomas have been treated with a multimodality approach, which has led to some improvements in survival, local control, and quality of life.\(^3\) However, patients with abdominal sarcomas continue to have high rates of recurrence and poor overall survival.\(^4\) The overall 5-year survival rate for patients with all stages of soft tissue sarcoma is 50% to 60%. Of the patients who die of sarcoma, most succumb to lung metastasis, which 80% of the time occurs within 2 to 3 years after initial diagnosis.

In the United States in 2012, approximately 11,280 new cases of soft tissue sarcoma were diagnosed, and 3900 deaths were attributable to this disease.\(^5\) The incidence of soft tissue sarcomas increased 1.3% per year from 1995 to 2009, and subsequently leveled off while mortality rates increased slightly (0.5% per year) from 2001 to 2014.\(^6\) The true incidence of sarcoma is thought to be higher than reported, and gastrointestinal stromal tumors (GISTs) likely account for an additional 5000 new sarcoma cases per year.\(^1\) Overall, sarcomas affect 5 to 6 individuals per 100,000 inhabitants per year,\(^5\) accounting for less than 1% of all malignancies in adults and 15% of malignancies in children.\(^7\)
Key Points

1. Sarcomas are a heterogeneous group of tumors that can occur throughout the body and encompass more than 50 subtypes with distinct histologic lines of differentiation.

2. Approximately two-thirds of soft tissue sarcomas arise in the extremities; the remaining one-third is distributed between the retroperitoneum, trunk, abdomen, head, and neck.

3. Multimodality treatment, including surgical resection, radiation therapy, and, in selected cases, systemic chemotherapy, has been applied to patients with locally advanced, high-grade, extremity sarcomas.

4. Overall 5-year survival rate for patients with all stages of soft tissue sarcoma is 50% to 60%.

5. These rare tumors account for less than 1% of cancer in adults (estimated 10,000 cases per year in the United States) and represent 15% of cancers in children.

6. The treatment algorithm for soft tissue sarcomas depends on tumor stage, site, and histology.

7. Of the patients who die of sarcoma, most will succumb to metastatic disease in the lungs, which 80% of the time occurs within 2 to 3 years of the initial diagnosis.

8. Progress in the understanding of soft tissue sarcoma biology is crucial for the development of new treatments.

Epidemiology

Except for malignant peripheral nerve sheath tumors in patients with neurofibromatosis, sarcomas do not seem to result from progression or dedifferentiation of a benign soft tissue tumor. While most sarcomas are of unknown cause, a few sarcoma subtypes have been observed in settings suggesting etiology.

Radiation Exposure

External radiation therapy is a rare but well-established risk factor for soft tissue sarcoma that may be associated with radiation-induced mutations of the p53 gene.8 The incidence of sarcoma among patients who are often treated with radiation for cancer of the breast, cervix, ovary, testes, or lymphatic system is 8 to 50 times the general-population risk.9,10 In a review of 160 patients with postirradiation sarcomas, the most common histologic types were osteogenic sarcoma, pleomorphic undifferentiated sarcoma, angiosarcoma, and lymphangiosarcoma.9 The risk of developing a sarcoma increased with radiation dose, and the median time between radiation therapy and diagnosis of sarcoma was 10 years.9 A review of 44 patients with radiation-associated sarcomas identified between 1989 and 2009 noted that the average period from initial radiation treatment to diagnosis was 16 years and that radiation-associated sarcomas occurred most commonly in patients treated for breast cancer (36% of the patients in the series) and lymphoma (34% of the patients in the series).11 The 5-year overall survival rate for patients presenting without metastasis was 44%. A recent review of undifferentiated pleomorphic sarcoma characterizing outcomes between sporadic and radiation-associated presentation identified a higher incidence of local recurrence and worse overall and disease specific survival among patients who presented with radiation-associated undifferentiated pleomorphic sarcoma.12

Occupational Chemical Exposure

Exposure to herbicides such as phenoxyacetic acids and to wood preservatives containing chlorophenols has been linked to an increased risk of soft tissue sarcoma.13 Several chemical carcinogens, including thorium oxide (Thorotrast), vinyl chloride, and arsenic, have been associated with hepatic angiosarcomas.14

Trauma

Although patients with sarcoma often report a history of trauma, no causal relationship has been established. More often, a minor injury calls attention to a preexisting tumor.

Chronic Lymphedema

In 1948, Stewart and Treves first described the association between chronic lymphedema after axillary dissection and subsequent lymphangiosarcoma (Fig. 36-1).13 Lymphangiosarcoma has been estimated to occur in 0.07% of patients who undergo axillary node dissection.16 It also has been reported to occur after filarial infections and in the lower extremities of patients with congenital lymphedema.17,18 Lymphangiosarcoma is generally an aggressive tumor; average survival of patients with lymphangiosarcoma is 19 months.19
Figure 36-1. A 57-year-old with a chronic, progressive lymphedema of the left upper extremity developed lymphangiosarcoma 10 years after breast cancer treatment.

MOLECULAR PATHOGENESIS

Sarcomas can be broadly classified into three groups according to the genetic events underlying their development: specific translocations or gene amplification, defining oncogenic mutations, and complex genomic rearrangements.20 In general, sarcomas resulting from identifiable molecular events tend to occur in younger patients with histology suggesting a clear line of differentiation. The identifiable molecular events include point mutations, translocations causing overexpression of an autocrine growth factor, and oncogenic fusion transcription factor producing a cellular environment prone to malignant transformation. In contrast, sarcomas without identifiable genetic changes or expression profile signatures tend to occur in older patients and exhibit pleomorphic cytology and p53 dysfunction.21 Improved understanding of the molecular pathogenesis of sarcomas has revealed several potential targets against which investigators are working to develop subtype-specific targeted therapy.

Translocation-Associated Sarcomas

To date, translocations have been identified in 14 subtypes of soft tissue sarcoma, accounting for 20% to 30% of all sarcomas22 (Table 36-2). Translocations result in in-frame gene fusion, which in turn results in fused products encoding oncoproteins that function as transcriptional activators or repressors.23,24 The best characterized gene fusions are in Ewing’s sarcoma (EWS-FLI1), clear cell sarcoma (EWS-ATF1), myxoid/round cell liposarcoma (TLS-CHOP), alveolar rhabdomyosarcoma (PAX3-FKHR), desmoplastic small round cell tumor (EWS-WT1), and synovial sarcoma (SS18-SSX). Fusion gene–related sarcomas have been estimated to account for 30% or more of all sarcomas.25 Direct or indirect interactions between fusion transcripts and cell cycle regulators have been elucidated by several investigators and identify these transcripts as potentially promising molecular therapeutic targets.26 However, fusion genes in sarcoma have been successfully targeted in only a few cases, in which fusion resulted in overexpression of a growth factor or growth factor receptor. Several growth factors and their receptors (e.g., epidermal growth factor receptor) previously reported to play an important role in autocrine or paracrine stimulation of carcinoma growth have been associated with high histologic grade and poor prognosis in soft tissue sarcomas.

Amplification-Associated Sarcomas

Oncogenes are genes that can induce malignant transformation and tend to drive cell proliferation. Several oncogenes have been associated with soft tissue sarcomas, including MDM2, N-myrc, c-erbB2, and members of the ras family. These oncogenes produce specific oncoproteins that either play a role in nuclear function and cellular signal transduction or function as growth factors or growth factor receptors. This typically occurs in dedifferentiated liposarcoma, where the amplification of MDM2 drives the neoplastic process. Amplification of these genes has been shown to correlate with adverse outcome in several types of soft tissue sarcoma.23

Oncogenic Mutations

GISTs are the classic example of sarcomas in which tumorigenesis is primarily driven by a single activating mutation, in the

</table>
gene encoding KIT receptor tyrosine kinase or platelet-derived growth factor receptor-α (PDGFRα). The majority of GISTs have mutations in either exon 11 or exon 9 of KIT and respond dramatically to the tyrosine kinase inhibitor imatinib mesylate, although this treatment rarely produces cure.

**Complex Genomic Rearrangements**

The largest group of sarcomas is the group with complex cytogenetic alterations, which includes high-grade spindle cell sarcomas and pleomorphic sarcomas. Many sarcomas in this group exhibit inactivation of tumor suppressor genes. The two genes most relevant to soft tissue sarcoma are retinoblastoma (Rb) and p53. Mutations or deletions in Rb can lead to retinoblastoma, the most common malignant ocular neoplasm of childhood. Survivors of retinoblastoma are at risk for developing soft tissue and bone sarcomas later in life. Patients with germline mutations in p53 (Li-Fraumeni syndrome) have a high incidence of soft tissue sarcomas. Mutant p53 expression is thought to correlate with poor overall survival.

*Neurofibromatosis type 1 (von Recklinghausen’s disease)* occurs in approximately 1 of every 3000 people and is due to various mutations in the *NF1* tumor suppressor gene, located on chromosome 17. Patients with neurofibromatosis type 1 have an estimated 3% to 15% additional risk of malignant disease compared with the general population lifetime risk, including malignant peripheral nerve sheath tumors (MPNST) and GIST. In turn, 25% to 50% of patients with MPNST have a mutation in *NF1*.

**INITIAL ASSESSMENT**

The clinical behavior of most soft tissue sarcomas is determined by anatomic location (depth in relation to the investing fascia), histologic subtype and grade of aggressiveness, and size. The dominant pattern of metastasis is hematogenous, primarily to the lungs. Lymph node metastasis is rare (affecting <5% of patients) except in a few histologic subtypes, including epithelioid sarcoma, pediatric rhabdomyosarcoma, clear cell sarcoma, angiosarcoma, and, more rarely, synovial sarcoma and myxofibrosarcoma.

**Clinical Presentation**

Soft tissue sarcomas most commonly present as an asymptomatic mass. Extremity sarcomas may present as a deep venous thrombosis, particularly in patients without significant risk factors for thrombosis. Tumors in the distal extremities are generally smaller, whereas tumors in the proximal extremities and retroperitoneum can grow quite large before becoming apparent. Tumors often grow centrifugally and can compress surrounding normal structures. Infrequently, tumor impingement on bone or neurovascular bundles produces pain, edema, and swelling. Less frequently, tumors cause obstructive gastrointestinal symptoms or neurologic symptoms related to compression of lumbar or pelvic nerves. Often an extremity mass is discovered after a traumatic event that draws attention to a preexisting lesion.

The differential diagnosis of a soft tissue mass should include consideration of lipoma (which is 100 times more common than sarcoma), lymphangioma, leiomyoma, neurinoma, primary or metastatic carcinoma, melanoma, and lymphoma. Superficial small lesions (<5 cm) that are new or that are not enlarging as indicated by clinical history can be observed. Enlarging masses and masses larger than 5 cm or deep to the fascia should be evaluated with a history, imaging, and biopsy.

**Diagnostic Imaging**

Diagnostic imaging of the primary should be performed before any invasive procedure to avoid the possibility of soft tissue swelling or hemorrhage complicating the image interpretation. Pretreatment diagnostic imaging is helpful for defining the size and anatomic location of a tumor and its proximity to adjacent structures; staging disease with respect to regional or metastatic spread; guiding percutaneous biopsy; and establishing whether a tumor is benign or malignant and low grade or high grade.

Radiographs are useful in the evaluation of primary bone tumors but not in the evaluation of soft tissue sarcomas of the extremities unless there is underlying bone involvement from an adjacent soft tissue tumor or mineralization patterns suggestive of histologic subtype. Magnetic resonance imaging (MRI) is the preferred imaging technique for soft tissue sarcomas of the extremities, whereas computed tomography (CT) is most useful for evaluating retroperitoneal, intra-abdominal, and truncal sarcomas. CT of the chest should be performed to assess for lung metastases in patients with high-grade tumors larger than 5 cm; while chest X-ray is sufficient for smaller or low-grade lesions. Abdominal/pelvic CT should be performed in patients with myxoid round cell liposarcomas, leiomyosarcomas, epithelioid sarcomas, or angiosarcomas because of their propensity to metastasize to the abdomen and/or pelvis. Total Spine MRI has been advocated for myxoid round cell liposarcoma. MRI of the brain should be considered for patients with alveolar soft part sarcomas and angiosarcomas because of their propensity to metastasize to the brain.

**Ultrasoundography.** Ultrasoundography may have a diagnostic role in patients with soft tissue sarcoma who cannot undergo MRI. Ultrasoundography can also be a useful adjunct to MRI when findings on MRI are indeterminate and for delineating adjacent vascular structures. Finally, ultrasoundography can be used for postoperative surveillance and to guide biopsies.

**Computed Tomography.** Chest CT should be performed to evaluate for lung metastasis at presentation and before any radical treatment. CT is also the preferred imaging technique for evaluating retroperitoneal sarcomas (Fig. 36-2).

![Figure 36-2. A 55-year-old man with a leiomyosarcoma involving the inferior vena cava. Note the displacement of the inferior vena cava to the right hemiabdomen adjacent to the liver (arrow).](image-url)
techniques can provide a detailed image of the abdomen and pelvis and can delineate adjacent organs and vascular structures. For extremity sarcomas, CT may be useful if MRI is not available or cannot be used. When histologic assessment of an extremity sarcoma reveals a myxoid liposarcoma, CT of the abdomen and pelvis should be done because this subtype is known to metastasize to the abdomen.32

**Magnetic Resonance Imaging.** MRI is the most useful imaging modality for extremity sarcomas because of its superior soft tissue contrast resolution and multiplanar capabilities. MRI accurately delineates muscle groups and distinguishes among bone, vascular structures, and tumor. Sagittal and coronal views allow evaluation of anatomic compartments in three dimensions (Fig. 36-3). Soft tissue sarcomas of the extremities usually present on MRI as a heterogeneous mass. Their signal intensity tends to be equal to or slightly higher than that of adjacent skeletal muscle on T1-weighted images and heterogeneous and high on T2-weighted images. Hemorrhagic, cystic, or necrotic changes may also be observed in the tumor. If adjacent vascular structures must be delineated, special MRI techniques may be performed, including magnetic resonance angiography. MRI may also be an important adjunct to cytologic analysis in distinguishing benign lesions such as lipomas, hemangiomas, schwannomas, neurofibromas, and intramuscular myxomas from their malignant counterparts. In patients undergoing preoperative chemotherapy, contrast-enhanced T1-weighted MRI can be useful in evaluating intratumoral necrosis.

MRI is also valuable for assessing tumor recurrence after surgery. A baseline image is usually obtained 3 months after surgery. Some clinicians forego routine postoperative imaging of the primary extremity tumor site in asymptomatic patients, citing the difficulties in detecting early recurrence in scarred, irradiated tissue.31 Others advocate routine imaging every 3 to 4 months for the first 2 years, every 6 months in years 3 through 5, and then annually.

**Positron Emission Tomography.** Positron emission tomography (PET) is a functional imaging modality that measures tumor uptake of the glucose analog [18F] fluorodeoxyglucose (FDG). PET imaging allows evaluation of the entire body. Although PET/CT may be useful in specific circumstances, FDG-PET is not currently recommended for the initial staging of patients with soft tissue sarcoma.

Roberge and colleagues compared FDG-PET/CT versus chest CT alone in the initial staging of 75 patients with soft tissue sarcoma and found that only one patient had disease upstaged as a result of PET, whereas two had false-positive findings and three had indeterminate findings with no subsequent development of metastasis.33 Previous studies that reported a marginal benefit of PET/CT for detecting metastasis at the time of sarcoma staging included patients with more heterogeneous tumors, such as osseous tumors, soft tissue osteosarcomas, Ewing’s sarcoma, and rhabdomyosarcoma.34-36

In patients with sarcoma, PET has primarily been used to assist with tumor grading and to assess response to chemotherapy.37-40 In 50 patients with resectable high-grade soft tissue tumors scheduled for preoperative chemotherapy and tumor resection, a 35% or greater reduction in tumor FDG uptake following an initial cycle of chemotherapy was associated with histopathologic tumor response defined as pathologic necrosis in 95% or more of the resected specimen.41 While this is helpful in determining response controversy exists as to whether this translates into a predictor of overall survival.

**Biopsy Techniques**

**Fine-Needle Aspiration.** At centers where cytopathologists have experience with evaluation of mesenchymal tumors, fine-needle aspiration is an acceptable method of diagnosing most soft tissue sarcomas, particularly when the results correlate closely with clinical and radiologic findings.42 Fine-needle aspiration of primary tumors has a lower diagnostic accuracy rate (60–90%) than core needle biopsy and is often not sufficient for establishing a specific histologic diagnosis and grade.43 However, fine-needle aspiration is the procedure of choice to confirm or rule out the presence of a metastatic focus or local recurrence.44 Although fine-needle aspiration of superficial lesions can often be done in the clinic, fine-needle aspiration of deeper tumors may need to be done by an interventional radiologist.

![Figure 36-3](image_url). A 62-year-old man presented with right thigh mass. Magnetic resonance imaging demonstrated an 18 × 15 cm² dedifferentiated liposarcoma within the posterior compartment. Note the atypical fatty mass (left) with a large necrotic and peripherally enhancing nodule (left).
under sonographic or CT guidance. Generally, a 21- to 23-gauge needle is introduced into the mass after appropriate cleansing of the skin and injection of local anesthetic. Negative pressure is applied, and the needle is moved back and forth several times in various directions. After the negative pressure is released, the needle is withdrawn, and the contents of the needle are used to prepare smears. A cytopathologist then examines the slides to determine whether sufficient diagnostic material is present.

**Core Needle Biopsy.** Core needle biopsy is safe, accurate, and economical, and has become the preferred technique for diagnosing soft tissue lesions. Dupuy and colleagues found that core needle biopsy had an accuracy of 93% in 221 patients with musculoskeletal neoplasms.

Image guidance (ultrasound or CT) can prevent sampling of nondiagnostic necrotic or cystic areas of the tumor and thus increase the positive yield rate. Image guidance also permits biopsy of tumors in otherwise inaccessible locations and tumors located near vital structures with less risk of injury or complication.

The tissue sample obtained from core needle biopsy is usually sufficient for several diagnostic tests, such as electron microscopy, cytogenetic analysis, and flow cytometry. The risk for needle track seeding is negligible, and the reported complication rate for core needle biopsy is less than 1%.

**Incisional Biopsy.** Historically, an open surgical biopsy was the gold standard for achieving adequate tissue for definitive and specific histologic diagnosis of bone or soft tissue sarcomas. Contemporary guidelines recommend incisional biopsy when core needle biopsy cannot produce adequate tissue for diagnosis or when findings on core needle biopsy are nondiagnostic.

The disadvantages of incisional biopsy include the need to schedule the procedure, the need for general anesthesia, and high costs. In addition, an inappropriately placed incision can necessitate more extensive definitive resection to incorporate the biopsy incision. In a series of 107 patients with soft tissue sarcoma, planned surgical treatments had to be changed because of poorly oriented biopsies in 25% of cases. Complication rates up to 17% have been reported after incisional biopsies. Potential complications include hematoma, infection, wound dehiscence, and tumor fungation, any of which can delay definitive treatment.

Incisional biopsies should be performed only by surgeons experienced in the management of soft tissue sarcoma, ideally in a center specializing in the treatment of sarcoma and by the surgeon who will perform the definitive surgery. The biopsy incision should be oriented longitudinally along the extremity to allow a subsequent wide local excision that encompasses the biopsy site, scar, and tumor en bloc minimizing the risk for increasing the complexity of the subsequent curative procedure. A poorly oriented biopsy incision often necessitates an excessively large surgical defect for a wide local excision, which in turn can result in a larger postoperative radiation therapy field to encompass all tissues at risk. Adequate hemostasis must be achieved at the time of biopsy to prevent dissemination of tumor cells into adjacent tissue planes by hematoma.

**Excisional Biopsy.** Excisional biopsy can be performed for easily accessible (superficial) extremity or truncal lesions smaller than 3 cm. However, excisional biopsy rarely provides benefits over other biopsy techniques. Excisional biopsies should not be performed for lesions involving the hands and feet because such biopsies may complicate definitive reexcision.

For sarcomas with initial diagnosis confirmed with excisional biopsy, microscopic residual disease has been reported in up to 69% of reexcision specimens; without reexcision, the reported rate of local recurrence is 30% to 40% when margins are positive or uncertain.

Wide en bloc excision is seldom performed as a diagnostic procedure. When en bloc excision is done for diagnosis, the margin status is often not adequately evaluated during pathologic assessment of the specimen. Unless detailed descriptions of the surgical procedure and the pathology specimen are provided, the margins should be classified as uncertain or unknown, a classification associated with the same prognosis as resection margins that are positive for tumor cells. In patients with uncertain or unknown margins, reexcision should be performed if possible to ensure negative margins. The biopsy site or tract (if applicable) should be included en bloc with the re-resected specimen.

**Pathologic Assessment and Classification**

Sarcoma is generally diagnosed by morphologic assessment based on microscopic examination of histologic sections by an experienced sarcoma pathologist. However, even expert sarcoma pathologists disagree on the specific histologic diagnosis and the tumor grade in 25% to 40% of cases.

Morphologic assessment can be supported by ancillary techniques, including conventional cytogenetics; immunohistochemistry; and molecular genetic testing, which is useful for classifying soft tissue sarcoma subtypes with multiple genetic aberrations. Other molecular diagnostic techniques include cytogenetic analysis, fluorescence in situ hybridization, and polymerase chain reaction–based methods. However, molecular genetic techniques are associated with significant technical limitations and should be interpreted in the context of the sarcoma’s morphologic features.

Some experts have suggested that pathologic classification of soft tissue sarcomas has more prognostic significance than does tumor grade when other pretreatment variables are taken into account. Tumors with limited metastatic potential include desmoid, atypical lipomatous tumor (also called well-differentiated liposarcoma), dermatofibrosarcoma protuberans, and solitary fibrous tumor. Tumors with an intermediate risk of metastatic spread usually have a large myxoid component and include myxoid liposarcoma, myxofibrosarcoma, and extraskelatal myxoid chondrosarcoma. Among the highly aggressive tumors with substantial metastatic potential are angiosarcoma, clear cell sarcoma, pleomorphic and dedifferentiated liposarcoma, leiomyosarcoma, MPNST, rhabdomyosarcoma, and synovial sarcoma.

It has recently been noted that malignant fibrous histiocytoma is not associated with a distinct gene cluster, suggesting that malignant fibrous histiocytoma is not a separate tumor entity but rather a common morphologic appearance of various sarcoma subtypes. For example, most tumors initially diagnosed as malignant fibrous histiocytoma in the retroperitoneum have been reclassified using genomic profiling as dedifferentiated liposarcoma, whereas those in the extremities have been reclassified as leiomyosarcoma, myxofibrosarcoma, or pleomorphic undifferentiated sarcoma.

Guidelines for the pathologic reporting of sarcoma have been established. Included in the report should be the primary diagnosis, anatomic site, depth, size, and histologic grade, presence or absence of necrosis, status of excision margins and lymph nodes, TNM stage, and additional features of the tumor (i.e., mitotic rate and presence or absence of vascular invasion).
Staging and Prognostic Factors

Soft tissue sarcoma is most commonly staged using either the American Joint Committee on Cancer (AJCC) system (generally used in the United States) or the World Health Organization system. A unique aspect of sarcoma staging is the inclusion of tumor grade, which is one of the most important prognostic factors.57

The seventh edition of the AJCC staging system for soft tissue sarcomas is based on histologic grade of aggressiveness, tumor size and depth, and the presence of nodal or distant metastases.58 This system does not apply to GIST, fibromatoses (desmoid tumor), Kaposi’s sarcoma, or infantile fibrosarcoma.

Histologic Grade of Aggressiveness. Histologic grade is the most important prognostic factor for patients with soft tissue sarcoma. For accurate determination of grade, an adequate tissue sample must be appropriately fixed, stained, and reviewed by an experienced sarcoma pathologist. The features that define grade are cellularity, differentiation (good, moderate, or poor/anaplastic), pleomorphism, necrosis (absent, <50%, or ≥50%), and amount of mitoses per high-power field (<10, 10–19, or ≥20). Tumor grade has been shown to predict metastasis and overall survival.59 Metastasis has been estimated to occur in 5% to 10% of low-grade lesions, 25% to 30% of intermediate-grade lesions, and 50% to 60% of high-grade lesions.

The number of grades varies according to the classification system used. The most common classification systems, those of the National Cancer Institute and the French Federation of Cancer Centers, use three-tier tumor grades.60 The National Cancer Institute system is based primarily on histologic subtype, location, and amount of necrosis. The French Federation of Cancer Centers system is based on tumor differentiation (good, moderate, or poor/anaplastic), number of mitoses per high-power field (<10, 10–19, or ≥20), and amount of tumor necrosis (absent, <50%, or ≥50%). A comparative analysis of the two systems suggested that the French Federation of Cancer Centers system has better prognostic capability, predicting 5-year survival rates of 90%, 70%, and 40% for grade 1, 2, and 3 tumors, respectively.60

Following the recommendation of the College of American Pathologists, the committee that developed the 2008 AJCC staging system changed the system from a four-grade to a three-grade system in which the grades are well differentiated (grade 1), moderately differentiated (grade 2), and poorly differentiated (grade 3).61 Grade 1 is considered low grade, and grades 2 and 3 are considered high grade.

Tumor Size and Location. Tumor size is an important prognostic variable in soft tissue sarcomas. Sarcomas have classically been stratified into two size groups; T1 lesions are 5 cm or smaller, and T2 lesions are larger than 5 cm. The staging of soft tissue sarcomas has changed considerably in the eighth edition of the AJCC Cancer Staging Handbook.62 Previously, all soft tissue sarcoma sites were staged as one. In the new edition, subsites have been created, and they include head and neck; extremity and trunk; gastrointestinal tract; genitourinary tract; viscera and peritoneum; gynecological sites; breast lung, pleura and mediastinum; and other histologies. Size criteria for head and neck tumors have been reduced from the classic criteria because of a worse prognosis at smaller sizes. Trunk and extremity sarcoma has been reclassified relative to size criteria for tumor stage, changing the four categories: T1 tumors are smaller than 5 cm; T2 tumors are 5 to 10 cm; T3 tumors are 10 to 15 cm; and T4 tumors are larger than 15 cm.62

Anatomic tumor location was incorporated into the AJCC staging system in 1998. Soft tissue sarcomas above the superficial investing fascia of the extremity or trunk are designated “a” lesions within the T category, whereas tumors invading or deep to the fascia and all retroperitoneal, mediastinal, and visceral tumors are designated “b” lesions. However, in this most recent AJCC staging system, the superficial versus deep distinction is less important and has been eliminated.62

Nodal Metastasis. Overall, lymph node metastases arising from soft tissue sarcomas are rare,29 but the incidence of nodal involvement is higher for epithelioid sarcoma, pediatric rhabdomyosarcoma, clear cell sarcoma, synovial sarcoma, myxofibrosarcoma, and angiosarcoma. In the seventh edition of the AJCC staging system, sarcoma associated with nodal metastases was reclassified as stage III rather than stage IV because several studies reported better survival for patients with isolated regional lymph node metastases treated with radical lymphadenectomy than for patients with distant metastases.28,63-65 However, in the eighth edition of the AJCC, nodal disease has been revisited: N1 disease behaves similarly between stages III and IV and is now captured as stage IV.62 Patients with clinically or radiologically suspicious regional nodes should have metastases confirmed or ruled out by either fine-needle aspiration or core biopsy before radical lymphadenectomy.

Distant Metastasis. Distant metastases occur most often in the lungs (Fig. 36-4). Selected patients with pulmonary metastases may survive for long periods after surgical resection and chemotherapy. Other potential sites of metastasis include bone (Fig. 36-5), brain (Fig. 36-6), and liver (Fig. 36-7). Visceral and retroperitoneal sarcomas have a higher incidence of liver and peritoneal metastases.

Prognostic Factors. Prognostic variables in soft tissue sarcoma include primary tumor size, grade, and depth, all of which are incorporated into the staging system, as well as histology.
tumor site, and presentation (local recurrence or initial diagnosis). Patient factors such as older age and gender have also been associated with recurrence and mortality in several studies. A positive microscopic margin and early recurrence after resection of an extremity sarcoma have been shown to be associated with decreased survival.

Several groups have reported that Ki-67, a proliferation marker, is correlated with a poor clinical outcome in high-grade extremity sarcomas. E-cadherin and catenins, proteins essential for intercellular junctions, have been associated with poor outcome in patients with soft tissue sarcoma. Similarly, higher CD100 expression has been shown to correlate with higher proliferative potential and poorer outcome.

Prognostic Nomograms. Prognostic nomograms for soft tissue sarcoma have been introduced for use in patient counseling, selecting appropriate surveillance strategies, and selecting patients for clinical trials. One such nomogram, developed by Kattan and colleagues at Memorial Sloan-Kettering Cancer Center, considers age, histology, grade, location, depth, and size to determine the likelihood of 12-year sarcoma-specific survival. Two validation studies using the nomogram demonstrated good predictive value. More recently, the same group of investigators developed histology subtype-specific nomograms for patients with liposarcoma, synovial sarcoma, and GIST and demonstrated that they were accurate in predicting disease-specific survival. Other investigators have just developed a site-specific nomogram for patients with retroperitoneal sarcoma, demonstrating an accurate prediction of survival and disease recurrence.

TREATMENT OF EXTREMITY AND TRUNK WALL SARCOMA

The goals of treatment of soft tissue sarcoma are to maximize the likelihood of long-term recurrence-free survival while minimizing morbidity and maximizing function. In the past two decades, a multimodality treatment approach with optimal sequencing of treatments for individual patients has been shown to improve survival. Furthermore, patients with soft tissue sarcoma treated at high-volume centers have been shown to have improved survival and functional outcomes. Care at such centers is particularly important for patients with high-risk and advanced disease.

The overall 5-year survival rate for patients with all stages of soft tissue sarcoma is 50% to 60%. For patients with extremity sarcomas, a multidisciplinary treatment approach has resulted in local control rates exceeding 90% and 5-year survival rates exceeding 70%. Most patients who die of soft tissue sarcoma die of metastatic disease, which becomes evident within 2 to 3 years of initial diagnosis in 80% of cases.

Recommendations for evaluation and treatment of patients presenting with soft tissue masses are summarized in Table 36-3.
SOFT TISSUE SARCOMAS

CHAPTER 36

Table 36-3
Recommendations for the management of soft tissue masses

1. Soft tissue tumors that are enlarging or greater than 3 cm should be evaluated with radiologic imaging (ultrasonography or computed tomography [CT]), and a tissue diagnosis should be made using core needle biopsy.
2. Once a sarcoma diagnosis is established, obtain imaging (magnetic resonance imaging for extremity lesions and CT for other anatomic locations) and evaluate for metastatic disease with chest CT for intermediate- or high-grade (grade 2 or 3) or large (T2) tumors.
3. A wide local excision with 1- to 2-cm margins is adequate therapy for low-grade lesions and T1 tumors.
4. Radiation therapy plays a critical role in the management of large (T2), intermediate- or high-grade tumors.
5. Patients with locally advanced high-grade sarcomas or distant metastases should be evaluated for chemotherapy.
6. An aggressive surgical approach should be taken in the treatment of patients with an isolated local recurrence or resectable distant metastases.

Surgery

Primary tumors with no evidence of distant metastasis are managed with surgery alone or, when wide pathologic margins cannot be achieved because of anatomic constraints and/or the grade is high, surgery plus radiation therapy. The type of surgical resection is determined by several factors, including tumor location, tumor size, depth of invasion, involvement of nearby structures, need for skin grafting or autogenous tissue reconstruction, and the patient’s performance status. In 1985, the National Institutes of Health developed a consensus statement recommending limb-sparing surgery for most patients with high-grade extremity sarcomas. However, for patients with primary or recurrent tumors that cannot be grossly resected with a limb-sparing procedure and preservation of function (<5% of patients), amputation remains the treatment of choice.

Margin status after surgical resection has been shown to be an independent prognostic factor. The goal of surgical resection is to achieve a complete resection because microscopically positive or grossly positive resection margins are associated with increased risk of local recurrence and death. If an unexpected positive margin is found on pathologic examination of the resection specimen, reexcision should be performed if feasible. In patients with a positive margin, particularly in patients with macroscopic residual disease, local control is unlikely even with the addition of postoperative radiation therapy, emphasizing the importance of a well-planned initial operation.

Wide Local Excision. The preferred treatment for extremity sarcomas is wide local excision that includes resection of the biopsy site. The goal of wide local excision is to remove the tumor with approximately 1 to 2 cm of surrounding normal soft tissue, but narrower margins may be necessary to preserve uninvolved critical neurovascular structures and may be adequate for patients undergoing radiation therapy. Dissection should proceed through grossly normal tissue planes not abutting the tumor. Soft tissue sarcomas are generally surrounded by a zone of compressed reactive tissue that forms a pseudocapsule; this pseudocapsule should not be used to guide resection (enucleation) as microscopic disease exists within this reactive zone. If the tumor is adjacent to or displacing major neurovascular structures, these do not need to be resected, but the adventitia or perineurium should be removed. For some massive tumors of the extremities, wide local excision entails a radical or complete anatomic compartment resection. Surgical clips should be placed to delineate the extent of the resection bed for patients likely to require postoperative radiation therapy.

Recent reports demonstrate encouraging results following radical en bloc resection with vascular reconstruction in the lower extremities. While en bloc resection with vascular reconstruction has been associated with increased rates of postoperative complications, reported local recurrence and 5-year survival rates are similar to those for patients not requiring vessel resection. Similarly, studies have shown acceptable functional outcomes with resection of the sciatic, tibial, and peroneal nerves with appropriate reconstruction and rehabilitation.

Bone invasion from extremity soft tissue sarcoma, which can generally be identified using high-quality cross-sectional imaging such as MRI, has been estimated to occur in about 5% of patients and is associated with reduced overall survival. In cases of bone invasion, bone resection is required to obtain an adequate surgical margin and to achieve local control. Although tumor resection and repair of skeletal defects are possible, the likelihood of postoperative complications may be increased, and functional outcomes may be less favorable. Lin and colleagues recently analyzed 55 patients with soft tissue sarcomas abutting bone and reported that in the absence of frank cortical bone penetration, periosseous was an adequate surgical margin in patients treated with wide local excision and radiation.

Soft tissue sarcomas arising in the distal extremities, particularly the hands and feet, present unique technical challenges. While distal-extremity tumors are often detected at a smaller size (<5 cm) than proximal-extremity tumors, resection and reconstruction techniques are often more complex for distal-extremity tumors, and preoperative planning is critical to obtain favorable functional outcomes. Identifying the proximity of the tumor to underlying critical structures (e.g., bone, tendon, or neurovascular structures) using MRI is essential for surgical planning. In a reported series of patients with sarcomas of the hands or feet treated with limited surgery only, 32% of patients had local recurrences. Preservation of function and acceptable recurrence rates with limited surgery and adjuvant radiation therapy for soft tissue sarcomas of the distal extremities have been reported. For locally advanced tumors, repair of bone defects, vascular reconstruction, tendon transfers, and soft tissue reconstruction using regional or free flaps have resulted in good functional outcomes. Amputation remains a reasonable option for patients with soft tissue sarcomas of the distal extremities when acceptable oncologic or functional outcomes cannot be achieved using available limb salvage techniques.

In an interesting study conducted in Ontario and Quebec, investigators found patients expecting a difficult recovery and patients with uncertain expectations had worse functional outcomes than patients anticipating an easy recovery, indicating that preoperative education including consultation with rehabilitation services may optimize outcomes. Furthermore, all patients undergoing resection of extremity sarcomas should undergo physical therapy beginning immediately after surgery and continuing until maximum function is achieved.
Locoregional Lymphadenectomy. Several studies have reported improved survival for patients with isolated regional lymph node metastases treated with radical lymphadenectomy.²⁶,₆₃-₆₅ Patients with clinically or radiologically suspicious regional nodes should have metastases confirmed by biopsy before radical lymphadenectomy. An ultrasound-guided fine-needle aspiration or core biopsy of lymph nodes in selected patients with suspicious clinical or radiologic findings. The utility of sentinel lymph node biopsy has remained controversial despite the recognition that several histologic subtypes of high-grade sarcoma are known to have a propensity for lymph node metastasis. However, there have been no prospective studies of the sensitivity and specificity of sentinel lymph node biopsy for such tumors, and as such, sentinel node biopsy for sarcoma should be performed in either highly selected patients or in the setting of a clinical trial.

Amputation. Amputation is the treatment of choice for the 5% of patients with primary or recurrent extremity tumors whose tumors cannot be grossly resected with limb-sparing procedures and preservation of function. Historically, local excision of large, high-grade soft tissue sarcomas resulted in local failure rates of 50% to 70%, even when a margin of normal tissue around the tumor was excised; consequently, radical resection or amputation was recommended. Today, however, the addition of radiation therapy to less radical surgical resection has made limb salvage possible in most cases.

A comparison of amputation versus limb-sparing surgery followed by adjuvant radiation therapy performed by the National Cancer Institute between 1975 and 1981 demonstrated no significant difference between the two groups in local recurrence or overall survival rate.⁹³ Potter and colleagues⁵⁰ later reviewed the entire National Cancer Institute experience with 123 patients treated with conservative surgery plus radiation therapy and 83 treated with amputation. The local recurrence rate was significantly higher in the surgery and adjuvant radiation therapy group: 8% versus 0% in the amputation group. However, survival rates did not differ between the groups. Several large single-institution studies have since also reported favorable local control rates with conservative resection plus radiation therapy.⁹⁴-⁹⁶

Isolated Regional Perfusion. Isolated regional perfusion is a limb-sparing technique in which a soft tissue sarcoma is perfused with high concentrations of tumor necrosis factor-alpha (TNF-α) and melphalan under hyperthermic conditions. The use of TNF-α is not approved by the U.S. Food and Drug Administration (FDA) and is used only in European countries. The technique is generally used for locally advanced, multifocal, or locally recurrent disease; it has also served as a palliative treatment to achieve local control for patients with distant metastases.

Limb perfusion requires isolating the main artery and vein of the perfused limb from the systemic circulation. The anatomic approach is determined by tumor site: external iliac vessels are used for thigh tumors, femoral or popliteal vessels for calf tumors, and axillary vessels for upper extremity tumors. The vessels are dissected, and all collateral vessels are ligated. The main artery and vein are then cannulated and connected to a pump oxygenator similar to that used in cardiopulmonary bypass. Either a tourniquet or an Esmarch band is applied to the limb to achieve complete vascular isolation. Chemotherapeutic agents are then added to the perfusion circuit and circulated for 90 minutes. Systemic leakage from the perfused limb is monitored continuously with Tc-radiolabeled human serum albumin injected into the perfusate, and radioactivity above the precordial area is recorded with a Geiger counter. During the entire procedure, hyperthermia of the perfused limb is maintained by external heating and by warming the perfusate to 40°C. At the end of the procedure, the limb is washed out, the cannulas are extracted, and the blood vessels are repaired.

Despite the 40-year history of using isolated limb perfusion to treat extremity sarcomas, many questions about this technique remain to be answered. The optimal chemotherapeutic agent in the perfusion circuit, the benefits of hyperthermia, and the effectiveness of hyperthermic perfusion as neoadjuvant or adjuvant treatment remain to be elucidated. Studies published to date have involved heterogeneous patient groups and various chemotherapeutic agents. Despite these limitations, response rates from 18% to 80% and overall 5-year survival rates from 50% to 70% have been reported.⁹⁷,⁹¹ However, survival outcomes following isolated limb perfusion have not yet been directly compared with survival outcomes after more conventional treatment approaches.

In the initial report of isolated regional perfusion for extremity sarcomas, published in 1974, McBride reported results in 79 patients with extremity sarcomas who had been treated with isolated limb perfusion during the previous 14 years.⁹⁷ All patients received melphalan and dactinomycin. The overall 5-year survival rate was 57%, and only 13 patients had subsequent amputation for recurrent disease. Over the next 20 years, isolated perfusion for treatment of extremity sarcoma fell out of favor for several reasons. Most notably, improved survival and decreased local recurrence rates could be obtained with less radical therapy, including conservative surgical excision combined with radiation to allow limb sparing in patients who were previously thought to require amputation.

A 1992 report by Lienard and colleagues¹⁰¹ renewed interest in isolated limb perfusion for extremity tumors. Those investigators reported a 100% response rate among patients with extremity melanomas and sarcomas treated with high-dose recombinant TNF-α plus interferon-γ and melphalan in an isolated perfusion circuit. This report led to larger studies geared specifically to patients with sarcoma. The largest of these studies, the European Multicenter Study, was reported by Eggermont and colleagues in 1996.⁹⁹ In that study of 186 patients, the overall tumor response rate was 82%, and the clinical and pathologic complete response rate was 29%. Although all of the study participants were reported to initially be candidates for amputation, the rate of limb salvage following isolated limb perfusion was 82%.⁹⁹ Subsequent studies have shown high local response and limb salvage rates and acceptable local and systemic toxic effects.¹⁰²

However, results in the United States have been inferior to those reported in Europe. In a study by Fraker and colleagues, the complete response rate was 26%, and an additional 30% of patients had a partial response. Fourteen patients (32%) underwent amputation for progressive tumors, while the remaining 30 patients (68%) were able to undergo limb-sparing surgery after isolated limb perfusion.¹⁰⁰ The inferior results in the U.S.-based studies are thought to be due to patient selection biases and the degree of treatment before limb perfusion.

While isolated limb perfusion for extremity sarcoma has fallen out of favor, recent reports of isolated limb infusion from the H. Lee Moffitt Cancer Center have shown promising
Patients with extremity sarcoma and who are considered for amputation are offered the option of isolated limb infusion with high-dose melphalan and actinomycin-D on protocol. Isolated limb infusion is a less invasive technique that can be repeated. Percutaneous cannulas are placed prior to infusion, the extremity is isolated similar to limb perfusion with an Esmarch band or tourniquet, and the perfusion is normothermic and acidic. Results from a multicenter retrospective study have demonstrated an overall response rate of 58%, and after a median follow-up of 21 months, there was an overall limb salvage rate of 78%. The benefits over limb perfusion remain the ability to repeat the technique in patients with disease response and less operative morbidity and risk of vascular injury from open surgery and cannulation of the iliac vessels. Although to date the technique has been well established for patients with locally advanced extremity disease for melanoma, its application for advanced, locally recurrent extremity sarcoma deserves further study.

**Radiation Therapy**

Radiation therapy is part of the standard treatment for high-grade extremity and trunk wall soft tissue sarcomas either in the pre- or postoperative setting. Patients with low-grade tumors or small, superficial high-grade tumors that have been resected with adequate margins may safely avoid radiation therapy.

The evidence supporting adjuvant radiation therapy for patients eligible for conservative surgical resection comes from two randomized trials104,105 and three large single-institution reports.106-108 In a randomized trial by the National Cancer Institute, 91 patients with high-grade extremity tumors were treated with limb-sparing surgery followed by chemotherapy alone or radiation therapy plus chemotherapy. The 10-year local control rate was 98% for patients receiving radiation therapy compared with 70% for those not receiving radiation therapy ($P = .0001$).104 Similarly, in a randomized trial from Memorial Sloan-Kettering Cancer Center, 164 patients underwent conservative surgery followed by observation or brachytherapy. For patients with high-grade tumors, the 5-year local control rate was 66% in the observation group and 89% in the brachytherapy group ($P = .003$).105 For patients with low-grade tumors, no significant difference was observed between treatment groups.109

Until recently, the standard treatment guidelines required radiation therapy after surgery for all patients with intermediate- or high-grade tumors of any size. However, small tumors (≤5 cm) have not generally been associated with local recurrence, and radiation therapy for such tumors may not be necessary.105 In a series of 174 patients reported by Geer and colleagues, postoperative radiation therapy did not improve 5-year local recurrence or overall survival rates for patients with small soft tissue sarcomas.109 Karakousis and colleagues reported a 5-year local recurrence rate of 6% for 80 patients with extremity sarcomas treated with wide local excision and observation, a rate similar to that for the 64 patients who underwent resection with narrower surgical margins and postoperative radiation therapy.110

The optimal mode of radiation therapy (external-beam radiation therapy, brachytherapy, or intensity-modulated radiation therapy [IMRT]) and timing of radiation therapy (preoperative, intraoperative, or postoperative) have yet to be defined. External-beam radiation therapy can be delivered using photons or particle beams (electrons, protons, pions, or neutrons). Conventional fractionation is usually 1.8 to 2 Gy per day. CT is an integral part of radiation therapy, used to define the gross tumor volume and to estimate the margin of tissue at risk for microscopic tumor involvement. The optimal radiation margin is not well defined: a margin of 5 to 7 cm is standard, but some centers advocate wider margins for tumors larger than 15 cm. At most institutions, the typical preoperative dose is 50 Gy given in 25 fractions, and resection is performed 4 to 8 weeks after completion of radiation therapy to allow acute radiation changes to subside. Postoperative radiation therapy planning is based on tumor site, tumor grade, surgical margins, and institutional preferences. The entire surgical scar and drain sites should be included in the field so that a near-full dose can be administered to the superficial skin. Metallic clips placed in the tumor bed during surgery can help define the limits of the resection and aid in radiation therapy planning. Doses of 60 to 70 Gy are usually necessary for postoperative treatment.

No consensus exists on the optimal sequence of radiation therapy and surgery. The available data come largely from single-institution, nonrandomized studies. Proponents of preoperative radiation therapy note that multidisciplinary planning with radiation oncologists, medical oncologists, and surgeons is easier early in the course of therapy. In addition, for some radiosensitive histologic subtypes, such as myxoid liposarcoma, preoperative radiation therapy may shrink the tumor, facilitating resection with negative margins. Furthermore, a tissue bed undisturbed by resection has better tissue oxygenation and can be successfully treated with lower doses of radiation. In addition, Nielsen and colleagues112 demonstrated that preoperative radiation fields are smaller than postoperative radiation fields and that the average number of joints included in the field is lower with preoperative than postoperative radiation therapy, which may result in improved functional outcome. Critics of preoperative radiation therapy cite the difficulty of pathologic assessment of margins and the increased rate of postoperative wound complications.113 However, reconstructive surgical techniques with advanced tissue transfer procedures are being used more often in these high-risk wounds and reportedly result in better outcomes. The higher doses generally required for postoperative radiation therapy have also been shown to be associated with greater long-term functional impairment.

The only randomized comparison of preoperative and postoperative radiation therapy to date was performed by the National Cancer Institute of Canada Clinical Trials--Canadian Sarcoma Group.114 This trial was designed to examine complications and functional outcome. The 190 patients enrolled from October 1994 to December 1997 were randomized to preoperative radiation therapy (50 Gy) or postoperative radiation therapy (66 Gy). With a median follow-up time of 3.3 years, the recurrence and progression-free survival rates were similar in the two groups. The incidence of wound complications was higher in the preoperative group versus the postoperative group (35% vs. 17%), and the incidence of wound complications was significantly higher for tumors of the lower extremity (43%) than for those of the upper extremity (5%).114 Late radiation toxic effects (e.g., fibrosis, joint stiffness, and edema) were more common with postoperative than preoperative radiation therapy (48% vs. 32%) because of higher postoperative radiation doses and larger treatment field sizes.115

Brachytherapy involves the placement of multiple radioactive seeds through catheters inserted in the tumor resection bed. The primary benefit of brachytherapy is the shorter overall treatment time of 4 to 6 days, compared to the 4 to 6 weeks generally required for preoperative or postoperative...
radiation therapy regimens. A cost-analysis comparison of adjuvant brachytherapy versus adjuvant external-beam irradiation for soft tissue sarcomas showed that costs were lower with brachytherapy.\textsuperscript{116} The implications of cost have been studied after radical resections and immediate adjuvant brachytherapy with either staged or immediate reconstruction noting a lower cost with staged reconstruction and tissue transfer techniques.\textsuperscript{117} Brachytherapy can also be used for recurrent disease previously treated with external-beam radiation. Guidelines established at Memorial Sloan-Kettering Cancer Center recommend spacing the afterloading catheters in 1-cm increments while leaving a 2-cm margin around the surgical bed.\textsuperscript{105} After adequate wound healing is confirmed, usually after the fifth postoperative day, the catheters are loaded with seeds containing iridium-192 that deliver 42 to 45 Gy of radiation to the tumor bed over 4 to 6 days. Subsequent studies at the H. Lee Moffitt Cancer Center that sought to determine outcomes between staged immediate and delayed reconstruction noted advantages in improved local control, wound healing, and less radiation-associated toxicity with staged reconstruction.\textsuperscript{118} The primary disadvantage of brachytherapy is that it requires significant expertise, extended inpatient hospital stays, and bed rest.

IMRT delivers radiation more precisely to the tumor than external-beam irradiation while minimizing the volume of surrounding tissues exposed to high radiation doses. The proposed benefits of preoperative IMRT include reduced risk of postoperative wound infections because of minimization of the dose to the skin\textsuperscript{119} and protection of underlying bone (e.g., femur) as a result of concave dose distributions.\textsuperscript{120} There have been no prospective randomized trials comparing the long-term outcomes following IMRT versus other types of radiation therapy. In a retrospective analysis of IMRT, patients with negative and positive/close (within 1 mm) margins were found to have 5-year local control rates of 94%.\textsuperscript{121} In addition, the rates of posttreatment edema and joint stiffness with IMRT were lower than the expected rates with conventional radiation therapy.

Local toxic effects of radiation therapy vary according to radiation dose, field size, and timing (preoperative or postoperative). With preoperative radiation therapy, the most frequent wound complications are wound dehiscence, wound necrosis, persistent drainage, infection, seroma formation, ulceration, and cellulitis.\textsuperscript{114} Postoperative irradiation of free flaps is often associated with wound complications, and patients should be advised that secondary surgical repair may be necessary; therefore, consideration for preoperative radiation rather than postoperative radiation for larger tumors requiring flap reconstruction is a logical and sound approach. Wound complication rates of 13% to 37% have been reported for preoperative radiation therapy, compared to 5% to 20% for postoperative radiation therapy.\textsuperscript{121} If catheters are loaded after the fifth postoperative day and/or if staged reconstruction is used, rates of wound complications after brachytherapy are improved if not similar to those after postoperative radiation therapy.\textsuperscript{118}

Long-term (chronic) effects of radiation therapy (those occurring >1 year after completion of therapy) are generally related to fibrosis/contractures, lymphedema, neurologic injury, osteitis, and fractures, all of which can cause substantial functional impairment.\textsuperscript{122} Variables associated with poorer functional outcome after radiation therapy include larger tumors, higher doses of radiation (>63 Gy), longer radiation fields (>35 cm), poor radiation technique, neural sacrifice, postoperative fractures, and wound complications.\textsuperscript{115,121} Additionally, complications of any kind are less likely after treatment for upper extremity sarcoma than after treatment for lower extremity sarcoma.\textsuperscript{113,114}

Definitive radiation therapy that delivers maximal-tissue-tolerance doses of radiation may be appropriate for selected patients with unresectable soft tissue sarcomas. In a study of 112 patients with unresectable soft tissue sarcomas, tumor size and radiation dose were found to influence local control and survival.\textsuperscript{124} The local control rate was 51% for tumors smaller than 5 cm and 9% for tumors larger than 10 cm, and patients who received at least 64 Gy had better local control and survival.

**Systemic Therapy**

Despite improvements in local control rates, metastasis and death remain significant problems for patients with high-risk soft tissue sarcomas. Patients considered at high risk of death from sarcoma include those presenting with metastatic disease, localized sarcomas at nonextremity sites, or sarcomas of intermediate- or high-grade histology larger than 5 cm.\textsuperscript{59,105}

**Standard Chemotherapy.** For most patients with sarcoma, results of conventional chemotherapy regimens have been poor. The chemosensitivity of soft tissue sarcoma varies by histologic subtype.\textsuperscript{30} Synovial sarcoma, myxoid/round cell liposarcoma, and uterine leiomyosarcoma are sensitive to chemotherapy,\textsuperscript{125} whereas pleomorphic liposarcoma, myxofibrosarcoma, epithelioid sarcoma, leiomyosarcoma, MPNSTs, angiosarcoma, and desmoplastic round cell tumors have intermediate sensitivity to chemotherapy. Relatively chemoresistant histologic subtypes include clear cell sarcoma, endometrial stromal sarcoma, alveolar soft part sarcoma, and extraskeletal myxoid chondrosarcoma. Considering the variability of responses by histologic subtype, it is not surprising that clinical trials of standard chemotherapy, which often include heterogeneous populations with respect to tumor grade and histology, have demonstrated no overall survival benefit.

Doxorubicin and ifosfamide are the two most active agents against soft tissue sarcoma, with consistently reported response rates of 20% or greater and positive dose-response curves.\textsuperscript{126,127} The European guidelines recommend doxorubicin 75 mg/m\textsuperscript{2} every 3 weeks as first-line treatment for advanced disease.\textsuperscript{30} Treatment duration is based on response, but a maximum of six cycles is generally recommended because of the risk of cumulative cardiotoxicity. Ifosfamide is the recommended second-line treatment and is recommended for first-line treatment in patients with cardiac morbidity. The standard dose of ifosfamide is 9 to 10 g/m\textsuperscript{2}; however, single-institution series using higher-dose regimens (>10 g/m\textsuperscript{2}) or standard-dose ifosfamide combined with doxorubicin have shown response rates of 20% to 60%.\textsuperscript{127} Synovial sarcomas have been shown to be particularly sensitive to ifosfamide. Ifosfamide-associated toxic effects include hemorrhagic cystitis, neurotoxicity, and renal tubular acidosis. Historically, combination therapy with doxorubicin plus ifosfamide, dacarbazine, or both has resulted in increased response rates but no improvement in overall survival.\textsuperscript{128} Dacarbazine as a single agent has also demonstrated activity in clinical trials.

Over the past decade, several additional chemotherapeutic agents, including gemcitabine, taxanes, and trabectedin, have been noted to be active against soft tissue sarcomas. Gemcitabine as a single agent was reported to produce responses in 18% of patients with advanced sarcoma.\textsuperscript{129} Gemcitabine combined with docetaxel has been reported to produce response rates as high as 53% in patients with uterine leiomyosarcoma.\textsuperscript{129,130} Gemcitabine
combined with vinorelbine has also been associated with clinical benefit in patients with advanced sarcomas.\textsuperscript{131} The taxanes (docetaxel and paclitaxel) have been found to be active against angiosarcomas, particularly of the face and scalp, likely because of their potent antiangiogenic effects.\textsuperscript{122,133}

**Novel Chemotherapeutic Agents.** Aldoxorubicin is a doxorubicin derivative that serves as a produg of doxorubicin that covalently binds to albumin in the blood until reaching the acidic tumor environment releasing doxorubicin into the tissue. A recent international, multicenter, phase 2b, open-label, randomized study enrolled 126 patients from 2012 to 2013. Single-agent aldoxorubicin therapy showed superior efficacy over doxorubicin by prolonging progression-free survival and improving rates of 6-month progression-free survival and tumor response, warranting further study.\textsuperscript{134}

Trabectedin, a marine-derived alkaloid that binds DNA, affecting transcription and inducing the formation of DNA double-strand breaks, has shown benefit in the treatment of advanced soft tissue sarcomas, particularly leiomyosarcoma, myxoid liposarcoma, and other translocation-related sarcomas.\textsuperscript{135} Trabectedin is generally well tolerated but can be associated with prolonged and severe neutropenia, thrombocytopenia, and hepatic toxic effects.

Palifosfamide is a stabilized formulation of the active metabolite of ifosfamide that has been reported to be better tolerated than ifosfamide.\textsuperscript{136} Early trials have suggested anti-tumor activity comparable or superior to that of ifosfamide without nephrotoxicity; however, recent negative results of the PICASSO III Trial, a phase 3, placebo-controlled study of doxorubicin with or without palifosfamide in patients with metastatic soft tissue sarcoma, have neatly secured the fate of palifosfamide in the treatment of soft tissue sarcoma.\textsuperscript{137}

**Targeted Therapies.** Several targeted agents are being investigated for the treatment of soft tissue sarcomas. Among these are tyrosine kinase inhibitors (e.g., imatinib, sunitinib, sorafenib, and dasatinib) that have been developed and approved for treatment of GIST. Clinical data accumulated in phase 2 trials also support the use of tyrosine kinase inhibitors (e.g., imatinib, sorafenib, and sunitinib) in the management of other advanced sarcomas.\textsuperscript{138} Anti-vascular endothelial growth factor antibodies such as bevacizumab have demonstrated activity in patients with metastatic or unresectable angiosarcoma, solitary fibrous tumor, and epithelioid hemangioendothelioma.\textsuperscript{139} Pazopanib is an oral angiogenesis inhibitor that targets vascular endothelial growth factor receptors, platelet-derived growth factor receptor (PDGFR), and c-kit. In a recent phase 3 study, pazopanib showed efficacy against placebo in second or further line of therapy in patients with advanced soft tissue sarcoma.\textsuperscript{139} Inhibitors of the mammalian target of rapamycin pathway, including temsirolimus, everolimus, and ridaforolimus, have also shown activity against some soft tissue sarcomas (i.e., PEComas).\textsuperscript{140}

Olaratumab is a human antiplatelet-derived growth factor receptor α monoclonal antibody that has antitumor activity in human sarcoma xenografts. Recently, a phase 1b and randomized phase 2 study of olaratumab and doxorubicin versus doxorubicin alone has demonstrated improvements in both objective response rates (18.2% vs. 11.9%, $P = 0.34$) and median overall survival (26.5 vs. 14.7 months [stratified hazard ratio 0.46, 0.30–0.71, $P = 0.0003$]). Additional studies are warranted for this promising combination of agents.\textsuperscript{141}

**Benefits of Systemic Therapy.** The use of adjuvant and neoadjuvant chemotherapy for soft tissue sarcomas remains controversial. More than a dozen individual randomized trials of adjuvant chemotherapy have failed to demonstrate improvement in disease-free or overall survival for patients with soft tissue sarcoma. However, several limitations of these individual trials may explain the lack of observed improvement. First, the chemotherapy regimens used were suboptimal, consisting of single-agent therapy (most commonly with doxorubicin) and insufficiently intensive dosing schedules. Second, the patient groups were not large enough to reveal clinically significant differences in survival rates. Finally, most studies included patients at low risk of metastasis and death, namely those with small (≤10 cm) and low-grade tumors.

The Sarcoma Meta-Analysis Collaboration analyzed 1568 patients from 14 trials of doxorubicin-based adjuvant chemotherapy to evaluate the effect of adjuvant chemotherapy on localized, resectable soft tissue sarcomas.\textsuperscript{142} At a median follow-up time of 9.4 years, doxorubicin-based chemotherapy significantly improved the time to local and distant recurrence and recurrence-free survival rates. However, the absolute benefit in overall survival was only 4%, which was not significant ($P = .12$). In a subset analysis, patients with extremity tumors had a 7% benefit in terms of overall survival ($P = .029$).\textsuperscript{142}

After this meta-analysis, randomized controlled trials of more contemporary anthracycline/ifosfamide dosing combinations with relatively small numbers of patients have yielded conflicting results. In an Italian cooperative trial, adjuvant chemotherapy improved median disease-free and overall survival times in patients with high-risk extremity soft tissue sarcomas.\textsuperscript{143} In that study, 104 patients with high-grade tumors 5 cm or larger were randomized to definitive surgery or surgery plus adjuvant chemotherapy consisting of epirubicin (60 mg/m$^2$ per day on days 1 and 2) and ifosfamide (1.8 g/m$^2$ per day on days 1 through 5) for five cycles. With a median follow-up time of almost 5 years, disease-free survival times were 16 months in the surgery-alone group and 48 months in the combined-treatment group ($P = .04$), and median overall survival times were 46 months in the surgery-alone group and 75 months in the combined-treatment group ($P = .03$).\textsuperscript{143} However, several years later, the surgery-alone and combined-treatment groups had equivalent relapse rates and deaths, which resulted in statistically similar overall survival.\textsuperscript{144}

In an effort to further assess the role of chemotherapy in patients with stage III extremity sarcoma, a cohort analysis of the combined databases of The University of Texas MD Anderson Cancer Center and Memorial Sloan-Kettering Cancer Center was performed. Data on 674 patients with stage III extremity sarcoma who received either preoperative or postoperative doxorubicin-based chemotherapy were reviewed. The 5-year disease-specific survival rate was 61%.\textsuperscript{145} Cox regression analysis showed a time-varying effect of chemotherapy with an associated benefit during the first year while receiving chemotherapy. However, the clinical benefits of chemotherapy in patients with stage III sarcomas were not sustained beyond 1 year. Grobmyer and colleagues compared the outcomes of patients treated at two institutions (1990–2001) with surgery only or surgery plus preoperative chemotherapy containing doxorubicin and ifosfamide. In this analysis, chemotherapy was associated with an improvement in the 3-year disease-specific survival rate that was most pronounced in patients with tumors larger than 10 cm (62% for surgery alone vs. 83% for neoadjuvant chemotherapy and surgery).\textsuperscript{146}
More recently, the European Organization for Research and Treatment of Cancer (EORTC) completed a phase 3 randomized study (trial EORTC-62931; conducted from 1995 through 2003) comparing surgery alone versus surgery plus adjuvant ifosfamide (5 g/m²) plus doxorubicin (75 mg/m²) with growth factor support (lenograstim) every 21 days for five cycles in 351 patients with resected grade II or III soft tissue sarcoma at any site. The estimated relapse-free survival rate was 52% in both arms, and the overall survival rate was better in the control arm (69% vs. 64%). Although most individual studies are underpowered, data from all of these studies suggest that chemotherapy regimens that incorporate ifosfamide may provide some disease-free survival benefit but do not improve long-term overall survival for the majority of patients with soft tissue sarcoma.

In 2008, two updates to the 1997 Sarcoma Meta-Analysis Collaboration were published. O’Connor and colleagues included all of the trials in the original meta-analysis and added data from four additional trials, for a total of 18 trials with 2170 patients. The results showed a benefit of chemotherapy in terms of disease-free survival at 5 years and recurrence-free survival at 10 years but again failed to demonstrate a benefit in terms of long-term overall survival. The second update, by Pervaiz and colleagues, which did not include the EORTC-62931 trial, showed that adjuvant chemotherapy was associated with a significant decrease in the risk of death (hazard ratio, 0.77; P = .01).

Because the evidence regarding adjuvant systemic therapy for stage III soft tissue sarcoma is inconclusive, considerable variation still exists in treatment recommendations even though patients with large, stage II or stage III soft tissue sarcomas are at high risk for recurrence and metastasis. Chemotherapy may be considered to downstage large tumors to enable limb-sparing at high risk for recurrence and metastasis. Chemotherapy may be spared the toxic effects of prolonged adjuvant chemotherapy. The theoretical advantages notwithstanding, concurrent chemoradiation therapy decreases the total treatment time for patients with high-risk sarcoma. This decrease represents a substantial advantage over current sequential combined-modality treatment approaches, for which the total duration of radiation therapy, chemotherapy, surgery, and rehabilitation frequently exceeds 6 to 9 months.

**Concurrent Chemoradiation Therapy**

Treatment approaches that combine systemic chemotherapy with radiosensitizers and concurrent external-beam radiation therapy may improve disease-free survival by treating microscopic disease and enhancing the treatment of macroscopic disease. Concurrent chemoradiation therapy with doxorubicin-based regimens reportedly produces favorable local control rates for patients with sarcoma. Since those findings were published, several groups have evaluated routes of administration, alternative chemotherapeutic agents, and the toxicity of combined therapies.

The National Comprehensive Cancer Network (NCCN) recommends a history and physical and chest CT or radiography every 3 to 6 months for 2 to 3 years after completion of treatment. Because most cases of distant metastasis occur within 2 to 3 years of initial diagnosis, the NCCN guidelines indicate that follow-up intervals can be lengthened to every 6 months, and imaging can be done annually during years 2 through 5. Consideration should also be given to imaging the primary tumor site; most experts recommend that the tumor site be evaluated every 6 months with MRI for extremity tumors or CT for intra-abdominal or retroperitoneal tumors. Guidelines have been established for using MRI to distinguish recurrences from typical postsurgical changes: a discrete nodule with low signal intensity on T1-weighted images and higher signal intensity on T2-weighted images that enhances after administration of intravenous contrast material is strongly suggestive of recurrence and should be biopsied. Ultrasonography may be an alternative to MRI or CT for assessing for recurrence in the extremities.
Recurrence is common after surgery for abdominal soft tissue sarcomas. CT is useful for detecting recurrences at primary and distant anatomic sites in the abdomen and pelvis. After surgery, CT every 3 to 6 months during the first 2 years and every 6 months for 3 years thereafter has been recommended. However, today many experienced surgeons are advocating less aggressive imaging for asymptomatic patients, particularly after a second recurrence of retroperitoneal sarcoma, arguing that there is insufficient evidence to suggest that survival is improved by earlier detection.

Whooley and colleagues reviewed the efficacy of the surveillance strategy used at Roswell Park Cancer Institute for 174 patients with soft tissue sarcomas of the extremities.¹⁶⁰ Patients were evaluated every 3 months for the first 2 years, every 4 to 6 months during year 3, and every 6 months during years 4 and 5. Local recurrence occurred in 18% of patients at a median time after completion of treatment of 14 months, and all but one of the recurrences were detected with physical examination alone. Fifty-seven patients had distant recurrences (at a median of 18 months after treatment), of which 36 were asymptomatic and diagnosed by surveillance imaging. The investigators determined that the positive predictive value of chest radiography during follow-up was 92%.¹⁶⁰ However, evaluation of the primary tumor site by CT or MRI was ineffective in detecting recurrences. The authors recommended that patient characteristics, location of the primary tumor, previous treatment, and physician familiarity with changes after surgery and radiation therapy should all be considered in determining the need for radiographic imaging.

Management of Recurrent Sarcoma

Up to 20% of patients with extremity sarcoma develop locally recurrent disease, which is often accompanied by distant metastases; thus, all patients with recurrent extremity sarcoma should undergo a full staging assessment. Patients with microscopically positive surgical margins are at increased risk of local recurrence. In a series of 179 patients with locally recurrent extremity soft tissue sarcoma at Memorial Sloan-Kettering Cancer Center, the median interval to local recurrence was 16 months; 65% of patients developed a local recurrence by 2 years, and 90% by 4 years.¹⁵⁹ The majority of patients (89%) were treated with additional limb-sparing surgery, and 73% received additional adjuvant therapy; the disease-specific survival after treatment of first local recurrence was 55% at 4 years. Independent prognostic factors for disease-specific survival after local recurrence included tumor grade, local recurrence size, and local recurrence-free interval. These data indicate that an isolated local recurrence should be treated aggressively with resection with negative margins.

For patients with extremity sarcomas, achieving negative margins on resection of recurrent disease frequently requires amputation. However, in some patients with recurrent extremity sarcoma, function-preserving resection combined with additional radiation therapy, with or without chemotherapy, can produce acceptable rates of local control.¹⁶¹-¹⁶³ Nori and colleagues reported a local control rate of 69% among 40 patients with recurrent tumors treated with reexcision and brachytherapy to a median dose of 45 Gy.¹⁶³ In a similar series, Midis and colleagues reported that limb-sparing surgery was possible in 66% of patients, and the 5-year local recurrence-free survival rate was 72% in those patients.¹⁶⁰

The primary determinant of survival in patients with soft tissue sarcoma is the development of distant metastases.

Patients with extremity sarcomas generally develop pulmonary metastases.¹⁶⁰ Less common sites of metastasis for soft tissue sarcomas include bone (7%), liver (4%),⁴⁰ and lymph nodes (5–7%).²⁸ Myxoid liposarcoma of the extremity is known to metastasize to the abdomen and pelvis; therefore, staging CT of these regions must be performed before definitive local therapy is administered.³²

Management of Recurrent and Distant Metastatic Sarcoma.

In selected individuals with distant metastatic disease, surgical resection of a primary soft tissue sarcoma may be appropriate as a palliative procedure. The decision should be based on the patient’s symptoms, which often include pain; ability to achieve local tumor control; comorbidities; anticipated morbidity of the surgical procedure; and the extent of metastases.

The most common initial site of distant metastasis of soft tissue sarcomas is the lung. Selected patients with a limited number of pulmonary nodules (less than four nodules), long disease-free intervals, and no endobronchial invasion may become long-term survivors after pulmonary resection (Fig. 36-8); 15% to 40% of patients with complete resection of metastatic disease confined to the lung are long-term survivors.¹⁵⁹,¹⁶⁰,¹⁶⁴ In a retrospective multi-institutional study of 255 patients with lung metastases, the 5-year overall survival rate after metastasectomy was 38%.¹⁵⁷ Favorable prognostic factors in that study included microscopically tumor-free margins, age younger than 40 years, and grade 1 or 2 tumor.¹⁵⁷ For patients who are surgical candidates, pulmonary resection alone can be more cost-effective than watchful waiting, chemotherapy, or chemotherapy plus surgery.¹⁵⁸

Chemotherapy for Distant Metastatic Sarcoma.

Doxorubicin, either alone or combined with other agents, has been the primary treatment modality for patients with advanced or distant metastatic sarcomas for several decades.¹²⁸ Although most patients with metastatic disease are not curable, some
patients with limited disease experience stabilization of disease with multidisciplinary treatment, which often includes surgery and radiation therapy in addition to chemotherapy. Several factors predict better outcome for patients with recurrent metastatic sarcoma undergoing chemotherapy, including good performance status, previous response to chemotherapy, younger age, absence of hepatic metastases, low-grade tumor, and long disease-free interval.\textsuperscript{163} Isolated liver metastases, if stable over several months, may be amenable to resection,\textsuperscript{166} radiofrequency ablation,\textsuperscript{167} or chemoembolization.\textsuperscript{168}

As data accumulate regarding the sensitivity of sarcoma subtypes to particular chemotherapies, it is critical that histology-driven treatment approaches be used. New therapies are also being identified based on the unique molecular signatures of sarcomas.\textsuperscript{128}

**Palliative Radiation Therapy.** Definitive radiation therapy can be considered when no acceptable surgical option is available (e.g., in patients with significant medical comorbidities). In this setting, radiation doses greater than 63 Gy yielded superior tumor control, but doses greater than 68 Gy resulted in increased rates of major complications.\textsuperscript{169}

**SPECIAL CLINICAL SITUATIONS**

**Myxoid Liposarcoma**

Myxoid liposarcomas belong to the group of soft tissue sarcomas with lipomatous differentiation. However, myxoid liposarcomas differ from the other liposarcoma subtypes with respect to morphology (i.e., myxoid stroma and lipomatous differentiation) and clinical behavior. Myxoid liposarcomas frequently present as slow-growing, deep tumors in the lower extremity and can metastasize to other soft tissue locations, including the retroperitoneum and extremities.\textsuperscript{170,171} For this reason, CT of the chest, abdomen, and pelvis is recommended for adequate staging and surveillance of myxoid liposarcoma.

**Retroperitoneal Sarcoma**

Most retroperitoneal tumors are malignant, and about one-third are soft tissue sarcomas. Also to be considered in the differential diagnosis of a retroperitoneal tumor are primary germ cell tumors, lymphoma, and metastatic testicular cancer. Approximately 1000 new cases of retroperitoneal sarcoma are diagnosed annually in the United States, and these tumors account for 10% to 15% of all adult tissue sarcomas. Approximately two-thirds of retroperitoneal sarcomas are high grade (either grade 2 or 3), and liposarcoma and leiomyosarcoma are the most common histologies.

Retroperitoneal sarcomas generally present as large masses: 70% are larger than 10 cm at diagnosis.\textsuperscript{172} They typically do not produce symptoms until they grow large enough to compress or invade contiguous structures, although pain, early satiety, and obstructive gastrointestinal symptoms may occur early in the disease course in some patients. Evaluation of a patient with a retroperitoneal mass begins with an accurate history that should exclude signs and symptoms associated with lymphoma (e.g., fever and night sweats). A complete physical examination, with particular attention to all nodal basins and with a testicular examination in men, is critically important. Laboratory assessment can be helpful; elevated lactate dehydrogenase levels may suggest lymphoma, and elevated β-human chorionic gonadotropin levels or α-fetoprotein levels may indicate a germ cell tumor.

Although the general principles of evaluation and management for retroperitoneal sarcomas are similar to those for extremity sarcomas, there are some differences. Contrast-enhanced CT of the abdomen and pelvis is used to define the extent of the tumor and its relationship to surrounding structures, particularly vascular structures, for surgical planning; contrast-enhanced CT can also often distinguish between well-differentiated and dedifferentiated liposarcoma. CT imaging is also done to evaluate the liver for the evidence of metastases, the peritoneal cavity for evidence of discontiguous disease, and the kidneys for assessment of function. Angiography or magnetic resonance arteriography/venography can also be used to delineate vascular anatomy when involvement of critical vascular structures is suspected. Thoracic CT should be performed to evaluate for potential lung metastases because 11% of patients with retroperitoneal sarcoma present with synchronous metastatic disease. CT-guided core needle biopsy is appropriate to provide a tissue diagnosis; however, well-differentiated liposarcoma may be diagnosed with CT imaging alone, and negative biopsy findings should not delay operative intervention.

Complete surgical resection is the most effective treatment for primary or recurrent retroperitoneal sarcoma (Fig. 36-9). En bloc resection often necessitates sacrificing contiguous structures such as the colon, kidney, spleen, pancreas, psoas muscle, small bowel, inferior vena cava, and aorta.\textsuperscript{173} In a review of 25 patients who underwent resection of retroperitoneal sarcoma with major blood vessel involvement in a 16-year time span, postoperative morbidity and mortality rates were 36% and 4%, respectively. Vessel patency rates were greater than 88% with a median follow-up time of 19.3 months.\textsuperscript{173,174} Local control and survival rates were favorable in patients with tumor-free resection margins. The authors concluded that vascular resection is the treatment of choice in sarcomas that involve major blood vessels in the retroperitoneum.\textsuperscript{83} Similar considerations were made by other groups reporting specifically on inferior vena cava resection in the context of multivisceral resection for retroperitoneal sarcoma and on surgical morbidity after extended surgical resection of retroperitoneal sarcoma. Extended procedures, including also vessels, are feasible and safe if carried out in experienced centers. While the goal of sarcoma resection is

![Figure 36-9. A 50-year-old man with a large right dedifferentiated liposarcoma. Note the atypical fat surrounding the right kidney and displacing the viscera to the left hemiabdomen and the large dedifferentiated mineralized solid nodule lateral to the right kidney.](image-url)
wide excision, this is unlikely to be achievable in most patients with retroperitoneal sarcomas. Surgery is considered marginal in most cases, even when macroscopically complete, but every attempt should be made to minimize this marginality by liberally resecting surrounding organs when involved. The extension of surgery should then take into consideration a trade-off between expected morbidity and benefit and should be best carried out at high-volume centers, where technical skills and knowledge of the natural history of this very rare disease can be found.

In an analysis of 500 patients with retroperitoneal soft tissue sarcoma treated at Memorial Sloan-Kettering Cancer Center, the median survival time was 103 months for those who underwent complete resection versus 18 months for those who underwent incomplete resection or observation without resection.172 In general, surgical resection should not be offered unless radiographic evidence indicates the potential for complete resection; however, palliative surgical resection may be considered to reduce symptoms of intestinal obstruction, pain, or bleeding.173 In particular, in patients with atypical lipomatous tumors, an aggressive surgical approach including incomplete resection or debulking is justified to palliate symptoms and may provide a potential survival benefit.174 Such an approach is not justified for dedifferentiated liposarcomas or other high-grade retroperitoneal sarcomas because these tumors have high rates of distant metastasis and local recurrence.

Adjuvant Therapy. Most studies have failed to show a survival benefit from adjuvant chemotherapy for retroperitoneal sarcoma.177-179 Because of the high rates of local recurrence, radiation therapy has been proposed for treating microscopic residual disease as an adjunct to surgical resection. However, the optimal technique and timing of radiation therapy have not been established, and the potential benefits of radiation therapy must be weighed against the increased risk of treatment-related toxic effects.

Radiation treatment of retroperitoneal sarcomas is complex because tumors are usually large, which necessitates large treatment fields close to radiosensitive structures (e.g., bowel). Several techniques have been used, including preoperative and postoperative external-beam radiation therapy, intraoperative radiation therapy, and brachytherapy.180 Preoperative radiation therapy is feasible and well tolerated. Toxic effects may be less severe with preoperative radiation therapy given that the tumor borders are definable, the tumor displaces radiosensitive viscera away from the treatment field, and effective doses of radiation may be lower preoperatively.181

Several studies have shown favorable local control rates for intermediate- and high-grade retroperitoneal sarcoma treated with preoperative radiation therapy and complete resection.182 However, most studies have failed to show a survival benefit.183 This situation prompted the initiation of a multicenter, randomized trial sponsored by the American College of Surgeons Oncology Group (ACOSOG) comparing surgery to surgery with preoperative radiation (ACOSOG Z9031). Unfortunately, the study was closed prematurely in 2006 because of low patient accrual. A similar study is now ongoing in Europe, sponsored by the Soft Tissue and Bone Sarcoma Group (STBSG) of the EORTC.

Current recommendations for radiation therapy for patients with retroperitoneal sarcoma at high volumes centers are based on disease characteristics at presentation.184 For high-risk patients, defined as those with large, high-grade tumors or recurrent low-grade tumors, preoperative radiation therapy to a total dose of 50 Gy followed by surgical resection is considered. Postoperative radiation is discouraged unless the resected tumor bed is clearly away from dose-limiting structures.

Treatment of Recurrence. Retroperitoneal sarcomas recur more often than extremity and trunk wall ones. Retroperitoneal leiomyosarcomas, in addition to recurring locally in the tumor bed and metastasizing to the lungs, frequently spread to the liver. Retroperitoneal sarcomas can also recur diffusely throughout the peritoneal cavity (sarcomatosis). Resection of recurrent retroperitoneal sarcoma is similar to resection of recurrent extremity sarcoma. However, the likelihood that a recurrent retroperitoneal sarcoma will be resectable declines precipitously with each recurrence. In a large series of patients treated at Memorial Sloan-Kettering Cancer Center, the authors were able to resect recurrent tumors in 57% of patients with a first recurrence but only 20% of patients with a second recurrence and 10% of patients with a third recurrence.185 In up to 25% of patients, well-differentiated retroperitoneal liposarcoma recurs in a poorly differentiated form or recurs with areas of dedifferentiation. Dedifferentiated retroperitoneal liposarcoma is more aggressive than its well-differentiated precursor and has a greater propensity for distant metastasis.

Gastrointestinal Sarcoma

Patients with gastrointestinal sarcoma most often present with nonspecific gastrointestinal symptoms that are determined by the site of the primary tumor. In a series from Memorial Sloan-Kettering Cancer Center, early satiety and dyspepsia were noted in patients with tumors of the upper gastrointestinal tract, whereas tenesmus and changes in bowel habits were common in patients with tumors of the lower gastrointestinal tract.184 In a series of 80 patients with various smooth-muscle tumors of the gastrointestinal tract, Chou and colleagues185 identified the most common presenting symptoms and signs as gastrointestinal bleeding (44%), abdominal mass (38%), and abdominal pain (21%).

Establishing the diagnosis of a gastrointestinal sarcoma preoperatively is often difficult. Radiologic assessment, including CT of the abdomen or pelvis, is sometimes useful to determine the anatomic location, size, and extent of disease. Patients with localized disease frequently present with a large intra-abdominal mass. However, there is no radiographic evidence of regional lymph node metastases, which would be typical of an adenocarcinoma of similar size and anatomic location. In patients with advanced gastrointestinal sarcoma, CT may demonstrate disseminated intra-abdominal masses with or without concomitant ascites and invasion of tissue planes.

Endoscopy (esophagogastroduodenoscopy or colonoscopy) has become the mainstay for evaluating symptoms related to the gastrointestinal tract. For tumors involving the stomach, upper endoscopy with endoscopic ultrasonography and biopsy are important diagnostic tests used to distinguish gastrointestinal sarcoma from adenocarcinoma of the stomach. Endoscopic biopsy of these tumors is preferred over CT-guided biopsy if feasible. This distinction is clinically significant because the extent of resection (local excision versus gastrectomy) and the role of regional lymphadenectomy differ for these two conditions. For gastrointestinal sarcomas, lymphatic spread is not the primary route of metastasis; consequently, lymphadenectomy is not routinely performed as part of resection. The general recommendation for gastrointestinal sarcoma, based on published data and the primary pattern of distant (vs. local) failure, is to
resect the tumor with a 2- to 4-cm margin of normal tissue. However, some cases may be technically challenging because of the tumor’s anatomic location or size. For example, for gastric tumors located near the gastroesophageal junction, achieving adequate surgical margins may not be possible without a total or proximal subtotal gastrectomy. This recommendation is much different when considering resection of gastrointestinal stromal tumors (GIST) where a gross margin negative resection is recommended are rarely is a total gastrectomy required. Similarly, large leiomyosarcomas arising from the stomach with invasion of adjacent organs should be resected together with the adjacent involved viscera en bloc.

For sarcomas of the small or large intestine, segmental bowel resection is the standard treatment. For sarcomas of the jejunum, ileum, and colon, the tumor is excised en bloc with the involved segment of intestine and its mesentery; radical mesenteric lymphadenectomy is not attempted. For sarcomas originating in the rectum, the tumor resection technique is based on the anatomic location and size of the tumor. For small, low rectal lesions, clear margins may be achievable with a transanal excision. Large or locally invasive lesions may require more extensive operations for complete tumor extirpation.\textsuperscript{186,187}

**Breast Sarcoma**

Sarcomas of the breast are rare tumors, accounting for less than 1% of all breast malignancies and less than 5% of all soft tissue sarcomas. A variety of histologic subtypes have been reported within the breast, including angiosarcoma, stromal sarcoma, fibrosarcoma, and malignant fibrous histiocytoma.

Angiosarcoma of the breast accounts for about 50\% of all sarcomas of the breast and has increasingly been associated with radiation therapy for treatment of primary breast cancer.\textsuperscript{10} The period between radiation therapy and diagnosis of radiation-associated breast sarcoma has been reported to range from 3 to 20 years, with an incidence of 0.3\% at 10 years and 0.5\% at 15 years.\textsuperscript{188} In a retrospective study of 55 patients with angiosarcoma of the breast, patients with radiation-associated angiosarcoma were on average 30 years older and were less likely to present with distant metastases than radiation-naive patients. Clinically, radiation-associated angiosarcoma of the breast may occur in the irradiated chest wall after mastectomy or in the irradiated breast following segmental resection. The findings at presentation of a patient with cutaneous angiosarcoma often include an expanding erythematous patch, red papular eruptions, bluish-black lesions, or bruise-like discoloration overlying an area of induration. Mammography is often nonspecific, and diagnosis requires punch or incisional biopsy.

Cystosarcoma phylloides are generally not considered to be sarcomas because these tumors are thought to originate from hormonally responsive stromal cells of the breast and are usually benign. In patients with these tumors, infiltrating tumor margins, severe stromal overgrowth, atypia, and cellularity have all been identified as risk factors for metastases.\textsuperscript{189}

As with sarcomas at other anatomic sites, histopathologic grade and tumor size are important prognostic factors for sarcomas of the breast. The likelihood of local recurrence increases as tumor size increases; tumors smaller than 5 cm are associated with better overall survival. Local and distant recurrences are more common in patients with high-grade lesions. Complete excision with negative margins is the primary therapy. Simple mastectomy confers no additional benefit if complete excision can be accomplished by segmental mastectomy. Because of low rates of regional lymphatic spread, axillary dissection is not routinely indicated. Neoadjuvant chemotherapy or radiation therapy may be considered for patients with large, high-risk tumors.

**Uterine Sarcoma**

Sarcomas account for less than 5\% of uterine malignancies. Uterine sarcomas have been classified into four histologic subgroups: uterine leiomyosarcoma, endometrial stromal sarcoma, malignant mixed Müllerian tumor (carcinosarcoma), and undifferentiated endometrial sarcoma. Five-year overall survival rates for patients with uterine sarcoma are 30\% to 50\%.\textsuperscript{190} Total abdominal hysterectomy (TAH) is recommended for localized disease. Bilateral salpingo-oophorectomy is mandatory only in endometrial stromal sarcoma. Because uterine sarcomas are rare, the benefits of adjuvant therapy (e.g., chemotherapy, hormonal therapy) have not been adequately evaluated. Pelvic postoperative irradiation has been studied instead in a randomized fashion. The results of such study have been reported, showing no benefit in survival in favor of radiation therapy.\textsuperscript{191}

Uterine leiomyosarcomas are smooth-muscle tumors and account for 35\% to 40\% of uterine sarcomas. Leiomyosarcoma can affect women in their twenties, although it is more commonly diagnosed between 50 and 60 years of age. Standard treatment is TAH with or without ovarian preservation depending on the patient’s wishes and menopausal status. Lymph node metastasis is present in less than 5\% of patients at diagnosis, and lymphadenectomy is not recommended. Adjuvant pelvic radiation therapy can be considered for selected high-risk patients. Adjuvant chemotherapy is controversial. Gemcitabine plus docetaxel has been noted to be well tolerated and highly active, with a response rate of 53\% in patients with unresectable uterine leiomyosarcoma.\textsuperscript{180} Doxorubicin and trabectedin have also demonstrated activity when used as first- or second-line therapy.

Endometrial stromal sarcomas account for approximately 7\% to 10\% of uterine sarcomas. Mitotic count is used to classify endometrial stromal sarcomas as low grade (<10 mitoses per 10 high-power fields) or high-grade (>10 mitoses per 10 high-power fields). In general, low-grade tumors demonstrate an indolent clinical course, while high-grade tumors are more aggressive with a poorer prognosis. Unlike other uterine sarcomas subtypes, endometrial stromal sarcomas express progesterone receptors and have been found to be responsive to hormonal manipulation as an adjuvant therapy or for treatment of recurrent disease.\textsuperscript{192,193} Surgical treatment for these tumors includes TAH and bilateral salpingo-oophorectomy in premenopausal women; postoperative hormone replacement therapy is contraindicated.\textsuperscript{194} Recurrent or advanced disease may respond to antiestrogen therapy. Tamoxifen is not recommended because it may be proestrogenic in this setting.

Malignant mixed müllerian tumor accounts for 50\% of uterine sarcomas and arises predominantly in postmenopausal women. This tumor is regarded as epithelial and is treated not with agents typically used to treat sarcoma but with agents used to treat ovarian and endometrial cancers.

Undifferentiated endometrial sarcoma is an aggressive malignancy that does not express estrogen or progesterone receptors. It is associated with a poor prognosis even in patients presenting with localized disease. TAH with or without preservation of the ovaries is recommended; postoperative pelvic radiation therapy may also be administered. Systemic agents for other soft tissue sarcomas are used for recurrent and/or metastatic disease.
GASTROINTESTINAL STROMAL TUMORS

GISTs, which account for the majority of gastrointestinal sarcomas, have distinctive molecular features that have been characterized over the last decade. These tumors share phenotypic similarities with the intestinal pacemaker cells known as the interstitial cells of Cajal; interstitial cells of Cajal and GIST cells express the hematopoietic progenitor cell marker CD34 and the growth factor receptor c-Kit. Expression of the c-Kit gene product, CD117, has emerged as an important defining feature of GISTs. Using these diagnostic criteria, the incidence of GIST has been estimated to be 6 to 15 cases per million individuals per year. Until recently, systemic treatment for patients with unresectable or metastatic GIST was of little benefit because these tumors were resistant to conventional chemotherapy. Since the recognition that KIT activation occurs in most GISTs, KIT inhibition has emerged as an adjunct to surgery in select patients with resectable disease and as a primary treatment modality for patients with stage IV disease.

Approximately 80% of GISTs have a mutation in the gene encoding the KIT receptor tyrosine kinase, and 5% to 10% have a mutation in the gene encoding the related PDGFRA receptor tyrosine kinase; such mutations result in the expression of mutant proteins with constitutive tyrosine kinase activity. The remaining GISTs do not have a detectable mutation, but lack of a mutation does not preclude a diagnosis of GIST if the tumor is morphologically typical of GIST. The presence and type of KIT (exon 11 or exon 9) or PDGFRA (exon 18) mutation has been found to predict tumor response to imatinib. In a phase 2 trial, patients with KIT exon 11 mutations had better response rates (83.5% vs. 47.8%) and survival than those with KIT exon 9 mutations or those without KIT or PDGFRA mutation. These findings have subsequently been confirmed in two additional phase 3 trials conducted by the EORTC–Italian Sarcoma Group–Australasian Gastrointestinal Trials Group (EORTC-62005). The most common locations for GISTs are the stomach (60%) and small intestine (30%), but GISTs can arise anywhere along the gastrointestinal tract. Gastric GISTs have been shown to be associated with a more favorable prognosis than GISTs at other sites. GISTs are most commonly diagnosed by upper endoscopy and/or CT of the abdomen as an incidental finding in an asymptomatic patient or in a patient being evaluated for symptoms of early satiety, abdominal pain, or gastrointestinal bleeding. GIST most frequently metastasizes to the liver and/or abdominal cavity.

**Radiologic Assessment**

Standard imaging techniques apply for GIST as for other intraabdominal sarcomas. In general, oral and IV contrast enhanced spiral CT is the staging modality of choice for GIST. CT scan of the abdomen and pelvis allows for assessment of the primary lesion and the presence or absence of intraabdominal disseminated disease or metastatic disease to the liver (the two most common locations for distant metastasis of GIST). FDG-PET has been reported to be useful for preoperative staging of GISTs because it may reveal early metastases and establish baseline metabolic activity and may be considered in select patients where equivocal findings are identified on CT or in the setting of following metabolic response to therapy. PET has been shown to be highly sensitive in detecting early response to imatinib treatment and in predicting long-term response in patients with metastatic GIST. If PET is to be used for monitoring response to therapy, baseline PET should be performed before initiation of treatment. Useful and effective CT-based criteria by Choi et al for detection of GIST and for predicting prognosis of GIST have also been proposed and may be used readily without incurring the cost and radiation exposure of PET/CT.

**Management of Localized Disease**

Complete surgical resection with negative margins is the recommended treatment for localized GISTs. Extended anatomic resection, wide margins, and lymphadenectomy are not required; therefore, total gastrectomy for gastric primaries is rarely required even with the largest of lesions. Resection of even locally advanced tumors is associated with improved survival. The 5-year survival rate for all patients with GISTs ranges from 20% to 44%, and the 5-year survival rate for patients with completely excised early-stage tumors is up to 75%. An analysis of 200 patients by DeMatteo and colleagues found a disease-specific survival rate of 54% for patients with grossly complete resection of primary GIST, and the median survival duration for patients with metastatic disease was only 20 months.

As for other soft tissue sarcomas, tumor size has consistently been identified as an important prognostic factor for GIST. Mitotic activity has also been identified as an important prognostic factor and is generally categorized as fewer than 5, 5 to 10, or more than 10 mitoses per high-power field. The National Institutes of Health and the Armed Forces Institute of Pathology have proposed prognostic criteria for risk stratification of surgically treated, localized primary GIST. Both groups take into account tumor size and mitotic count; the Armed Forces Institute of Pathology also includes tumor site as a prognostic variable. Accurate risk stratification is essential for selecting patients most likely to benefit from adjuvant treatment.

**Management of Locally Advanced or Metastatic Disease**

Treatment with imatinib mesylate (Gleevec, ST1571), a selective inhibitor of the KIT protein tyrosine kinase, has resulted in impressive clinical responses in a large percentage of patients with unresectable or metastatic GISTs. On the basis of the initial results in a single patient with metastatic GIST, the EORTC Soft Tissue and Bone Sarcoma Group initiated a phase 1 study to test the safety and efficacy of imatinib. In that study, 53% of patients with GISTs had confirmed partial responses; investigators concluded that imatinib is safe and effective against this disease. A multicenter, international trial of imatinib for GIST was begun in July 2000 at four treatment centers: Dana-Farber Cancer Institute, Oregon Health Sciences University, Fox Chase Cancer Center, and University Hospital of Helsinki, Finland. A total of 147 patients with unresectable or metastatic GISTs were randomized to 400 or 600 mg of imatinib daily for up to 24 months. Objective response was demonstrated in 79 patients (54%); all had partial responses, and there was no significant difference in response rate between imatinib doses. Fourteen percent of patients experienced disease progression. The toxicity profile was acceptable; the predominant effects were gastrointestinal effects (diarrhea, nausea), periorbital edema, muscle cramps, and fatigue. However, 21% of patients experienced serious (grade 3 or 4) adverse events, including gastrointestinal bleeding in 5% of patients, most likely related to the rapid tumor response of mural lesions.
A phase 3 randomized Intergroup trial was simultaneously performed to assess the clinical activity of imatinib at two dose levels for patients with unresectable or metastatic GIST expressing the c-Kit tyrosine kinase. From December 15, 2000, to September 1, 2001, 746 patients were accrued and randomized to low-dose (400 mg/d) or high-dose (800 mg/d) imatinib. The primary endpoint of the trial was survival. Preliminary toxicity data from 325 patients revealed a 23% incidence of grade 3 or 4 adverse events, including nausea and vomiting, gastrointestinal bleeding, abdominal pain, edema, fatigue, and rash.

In February 2002, the FDA approved imatinib for treatment of GIST based on the results of these promising clinical trials. Both the Intergroup trial mentioned in the preceding paragraph and a separate phase 3 trial compared the efficacy of low-dose (400 mg/d) and high-dose (800 mg/d) imatinib in patients with metastatic or unresectable GISTs. Both studies showed equivalent response rates and overall survival for the two doses but increased toxicity for the 800-mg/d dose. Current recommendations include consideration of dose escalation to 800 mg/d for patients who experience disease progression at a dose of 400 mg/d and for patients with advanced GIST and KIT exon 9 mutations.

The optimal duration of imatinib treatment, the duration of benefit from imatinib, and the long-term toxicity of imatinib have not been established. When feasible, imatinib should be continued in the absence of disease progression. A randomized trial reported worse median progression-free survival in patients who stopped imatinib after 1 year than in patients who continued beyond 1 year (progression-free survival of 6 months vs. 18 months). Less than 4% of patients with GISTs have experienced serious adverse events with imatinib. Mild gastrointestinal toxicity is the most frequently reported adverse event, but gastrointestinal tract hemorrhage, presumably from rapid tumor necrosis, has also been reported. Thus, all patients with GISTs treated on clinical protocols should be evaluated and followed by a team of medical professionals that includes a surgeon.

Many patients with GIST develop resistance to imatinib. Primary resistance is defined as clinical progression that develops during the first 6 months of treatment and is most commonly seen in patients with KIT exon 9 mutation, PDGFRα exon 18 mutation, or no mutations. Secondary resistance is defined as progression that develops more than 6 months after the start of treatment in a patient with an initial response. Imatinib resistance should be managed by either dose escalation or transition to treatment with sunitinib.

In 2006, sunitinib malate (SU11248, Sutent, Pfizer) emerged as an alternative systemic treatment for patients unable to tolerate imatinib and patients with imatinib-refractory GIST. Sunitinib is a tyrosine kinase inhibitor that targets multiple kinases, including the vascular endothelial growth factor receptors, PDGFRα, KIT, and FLT3. Sunitinib has both antiangiogenic and antiproliferative activity. In a phase 3, randomized, placebo-controlled trial, sunitinib was associated with a significant improvement in median time to progression (27.3 weeks vs. 6.4 weeks with placebo) in patients with imatinib-resistant GIST. In addition, sunitinib therapy was well tolerated; diarrhea, fatigue, and nausea were the most common adverse effects. Sunitinib has also been associated with hand-foot skin reaction, hypertension, cardiotoxicity, and hypothyroidism.

In 2006, sunitinib was approved by the FDA for treatment of patients with resistance or intolerance to imatinib.

The third FDA-approved drug recently made available for treatment of patients with imatinib- and sunitinib-resistant GIST is regorafenib. Regorafenib is a structurally unique inhibitor of multiple cancer-associated kinases, including KIT and PDGFRα, with broad-spectrum anticancer activity in preclinical and early-phase trials. Because KIT and PDGFRα remain drivers of GIST after resistance to imatinib and sunitinib, a multicenter, single-stage phase 2 trial examined regorafenib in patients with advanced GIST after failure of at least imatinib and sunitinib.

Thirty-four patients were enrolled from February to December 2010 and given regorafenib orally, 160 mg daily, on days 1 to 21 of a 28-day cycle. Clinical benefit was noted in 79% of patients with a median progression-free survival of 10 months. This trial was then followed by a phase 3, international, placebo-controlled, randomized trial of regorafenib for metastatic GIST after failure of imatinib and sunitinib. Patients with progression of disease on the placebo arm were crossed to the treatment arm of the study. Patients treated with regorafenib had a median progression-free survival of 4.8 months compared to 0.9 months on the placebo arm. Other tyrosine kinase inhibitors have demonstrated modest activity against GIST and target more than one family of protein kinases.

Among these are sorafenib, dasatinib, and nilotinib for the treatment of imatinib-resistant GIST, and these are now generally reserved for therapy after progression with regorafenib.

**Multidisciplinary Treatment**

Although imatinib has improved survival of patients with advanced GIST, most patients with advanced GIST are not cured with imatinib. Some patients develop secondary resistance to imatinib with one or more sites of disease progression after 6 months of clinical response (Fig. 36-10A [before imatinib], Fig. 36-10B [after imatinib]). The mechanisms of imatinib resistance are currently being investigated. Surgery has been shown to be beneficial for selected patients with isolated disease progression during imatinib therapy. Surgical resection of residual metastatic disease responding to imatinib-sensitive GIST has also been shown to result in progression-free survival in 70% to 96% of patients with imatinib- or sunitinib-sensitive GISTs.

The optimal timing of surgery in relation to imatinib therapy for patients with metastatic disease remains to be determined. It is not possible to compare outcomes for patients treated with kinase inhibitors alone and patients treated with kinase inhibitors plus surgical resection outside the context of randomized trials given the heterogeneity of patients and biases associated with selection of patients for surgical resection.

**Postoperative Imatinib**

Given the promising results of imatinib therapy for metastatic and locally advanced GIST, the next step was to study the efficacy of imatinib as adjuvant (postoperative) treatment in patients with surgically resectable disease, particularly those at high risk for recurrence because of large tumor size or high mitotic count. The ACOSOG first evaluated the efficacy of 1 year of postoperative imatinib in a single-arm phase 2 trial with 106 patients with high-risk GIST and compared the results with historical controls. Adjuvant treatment with imatinib for GIST patients was then examined in two key trials. In the ACOSOG randomized, double-blind, phase 3 Z9001 study, treatment with 12 months of imatinib was compared with placebo, following complete resection of a primary GIST smaller than 3 cm. Primary and secondary endpoints were recurrence-free survival.
intermediate or high risk of recurrence after resection and that at least 36 months of adjuvant imatinib be considered for patients at high risk of recurrence. Further, both the FDA and EMA updated the label, extending the duration of adjuvant therapy to at least 36 months in patients at high risk of recurrence.

Whether longer treatment durations may be of further benefit is still an open question that will be addressed by future studies. However, paralleling what is commonly done in the metastatic setting, many investigators believe that even adjuvant imatinib should become a chronic therapy. While moving toward more prolonged adjuvant treatment durations, it is all the more essential to identify the appropriate patients to treat to avoid the burden of adverse events or increased financial liability for patients who will not derive therapeutic benefit from imatinib. Risk stratification based on patients’ risk of recurrence is a key component to optimizing adjuvant treatment. The most practical stratification scheme to use for making a decision for adjuvant therapy is the modified National Institutes of Health consensus criteria. High-risk GIST patients, whose tumor harbors a sensitive genotype, should be treated by adjuvant imatinib because they have a poor prognosis. On the contrary, neither low-risk nor intermediate-risk GIST patients need adjuvant therapy, even if their tumor carries a sensitive genotype. In fact, evidence has been provided that the outcome of these patients with intermediate- or low-risk GIST is good. When using other risk stratification schemes, such as the Armed Forces Institute of Pathology table, Memorial Sloan-Kettering Cancer Center nomogram, or the heat map, there is a consensus to treat all patients having 30% or higher risk of recurrence, if their tumor carries a sensitive genotype. There is also a consensus not to treat patients having 10% or less risk of recurrence, even if their tumor carries a sensitive genotype. All patients having a risk between 10% and 30% should be evaluated on a case-by-case basis, and advantages/disadvantages of treatment should be made clear and discussed with the patient. Whenever a decision for adjuvant therapy is made, treatment duration of at least 36 months should be considered independently from the risk.

Beside the risk of recurrence, the other important factor to consider is the tumor genotype. In other words, as found in both the metastatic and adjuvant settings, GIST tumors with \textit{KIT} exon 11 and \textit{PDGFRA} non-D842V mutations are sensitive to imatinib. Patients with these mutations are suitable for adjuvant imatinib if the risk determined by stratification tools is significant. Patients with \textit{KIT} exon 9 mutations should also be treated; a higher dose (800 mg/d) may be more appropriate but remains to be studied clinically. Patients with \textit{PDGFRA} D842V–mutated tumors should not be treated with adjuvant imatinib, nor should patients with \textit{KIT} and \textit{PDGFRA} wild-type tumors associated with neurofibromatosis type 1 or the pediatric GIST/Carney-Stratakis syndromes, whatever the risk. Patients with sporadic wild-type GIST could be treated on an individual basis.

**Preoperative Imatinib**

Patients with marginally resectable GIST or at significant risk for operative morbidity should be considered for preoperative imatinib with close monitoring. Since the optimal duration of preoperative therapy is unknown, imatinib should be continued until maximal response is achieved or until there is evidence of progression. Preoperative imatinib can be stopped immediately before surgery and resumed when oral medications are restarted.
Preoperative imatinib in patients with primary GIST or resectable metastatic GIST has been evaluated in the context of two randomized phase 2 studies. The Radiologic Treatment Oncology Group (RTOG 0132/ACRIN 6665) evaluated the efficacy of preoperative imatinib (600 mg/d) for 8 to 10 weeks before surgery and 24 months after surgery in patients with primary (n = 30) or potentially resectable recurrent or metastatic (n = 22) tumors. Primarily stable disease was noted during imatinib treatment, and the 2-year progression-free survival rates were 83% for primary GIST and 77% for recurrent or metastatic GIST. In another study, 19 patients undergoing surgical resection at a single institution were randomized to preoperative imatinib (600 mg/d) for 3, 5, or 7 days followed by surgical resection and postoperative imatinib for 24 months. The response rate assessed using FDG-PET was 69%, and the median disease-free survival time following treatment with surgery and imatinib was 46 months. Similar results were observed in a prospective series of patients treated at a major institution.

All of these studies show that neoadjuvant treatment is feasible, but to maximize the benefit of preoperative therapy, the following factors need to be considered. First, the patient should in principle have a favorable mutational status; otherwise, the treatment would be in vain, allowing the tumor to continue growing. Fortunately, the majority of GISTs will respond, but it should not be forgotten that, especially in gastric location, the amount of insensitive mutations in the localized setting is less uncommon than what has been previously reported. However, we do not absolutely need to know the mutational status in advance, but we should be aware that mutation is an issue. Alternatively, if mutation status is not determined prior to treatment, we may also check response very early, either by CT, PET, or contrast-enhanced ultrasound. If a radiographic response is detected within a month, then the mutation status is likely favorable, and the treatment could be continued without necessarily pursuing mutation testing. If not, then mutation status should be investigated before continuing the treatment.

Second, the resectability of the tumor and the extent of resection necessary should be considered. Other than presentations of clearly inoperable tumors (which are usually treated with imatinib upfront) or symptomatic tumors requiring urgent intervention (hemorrhage, perforation, etc), there are few reasons today to perform extended procedures (i.e., multivisceral resections or formal organ resections) without first attempting preoperative therapy. For instance, patients with large GISTs who may require a long midline incision for resection may benefit from neoadjuvant imatinib to downstage the operation, potentially converting an open laparotomy approach to a laparoscopic one. Another typical circumstance in which neoadjuvant therapy may be beneficial is in patients with GISTs arising in the esophagus, gastroesophageal junction, duodenum, or distal rectum. Preoperative treatment may shrink the tumor and allow a more conservative local excision. In general, such patients would normally undergo postoperative adjuvant treatment as well because of the expected recurrence risk. The chance of obtaining a response is high, and the benefit for tumor shrinkage obvious, so this approach should always be discussed with patients affected by bulky and/or poorly located disease (esophagus, gastroesophageal junction, duodenum, distal rectum) as well as for those who would be candidates for an adjuvant treatment anyway.

Third, in the studies mentioned earlier, patients underwent surgery after a limited treatment duration (3 months at best). It is now well known that the preoperative treatment may result in sustained tumor shrinkage if given for a longer duration. Surgical resection may then be performed between 6 and 12 months or sooner if treatment effect plateaus. This allows for optimal tumor shrinkage, or at least shrinkage to the point where there is no further benefit to be gained by further neoadjuvant therapy without the risk of developing secondary resistance.

**DESMOIDS**

Desmoid tumors are not low-grade sarcomas but can be locally aggressive, although they do not metastasize. Approximately half of these tumors arise in the extremities; the remaining lesions are located on the trunk or in the retroperitoneum. Abdominal wall desmoids are associated with pregnancy and are thought to be the result of hormonal influence. Although usually sporadic, desmoids may occur in association with familial adenomatous polyposis, a presentation that is referred to as Gardner’s syndrome and is linked to germline mutations in the APC gene. Sporadic cases of desmoid fibromatosis are commonly linked to mutations in CTNNB1, the gene for β-catenin.

The primary therapy for desmoid tumors has long been considered surgical resection with wide local excision to achieve negative margins. However, local recurrence occurs in up to one-third of patients independently of the quality of surgical margins. Up to two-thirds of the patients operated on with positive margins do not recur. This is why there is growing evidence that the primary approach could be more conservative. Function-sparing operations should be the goal, even if a positive margin is left on a critical structure. Moreover, some authors advocate the possibility to observe patients at presentation, limiting surgery to those who progress or fail medical therapies. It has in fact been reported that by this approach, up to 50% of patients skip surgical resection.

Radiation therapy may be effective in patients with unresectable tumors or as adjuvant therapy following surgery for recurrent disease, although long-term side effects and the risk of radiation-induced sarcoma should always be considered. When used, a dose of 50 to 54 Gy is usually recommended. Systemic treatment is another option when surgery is not indicated. Hormonal therapies such as tamoxifen have been reported to be beneficial, as have nonsteroidal anti-inflammatory drugs, which are known to affect the β-catenin signaling pathways. Chemotherapy is also effective, although usually reserved for patients with tumor-associated symptoms who have not responded to other interventions. Combinations of methotrexate and vinblastine have been shown to have activity, as have single-agent pegylated liposomal doxorubicin and sorafenib.

Imatinib has also been studied with unconvincing results.

**DERMATOFIBROSARCOMA PROTUBERANS**

Dermatofibrosarcoma protuberans is a rare low-grade sarcoma arising in the dermis that rarely metastasizes but is locally aggressive. The overall annual incidence has been estimated at 4.2 cases per million individuals, and the incidence is higher among blacks than whites (6.5 vs. 3.9 per million per year). Approximately 40% of cases arise on the trunk, and most of the remaining tumors are distributed between the head and neck and the extremities. Dermatofibrosarcoma protuberans presents as a nodular, cutaneous mass that grows slowly and persistently. Satellite lesions may be found in patients with larger tumors.
Standard treatment is wide local excision, which generally results in local recurrence rates of less than 10%. Although local recurrence rates as high as 30% to 50% have been reported in population-based series, the associated 5-year survival rate is greater than 99%. Dermatofibrosarcoma protuberans arises from a specific chromosomal translocation involving chromosomes 17 and 22, in which the collagen 1 gene is fused to the gene for PDGF β-chain (PDGFB). The resultant deregulated expression of PDGFB leads to continuous activation of the PDGFR protein tyrosine kinase, which promotes tumor cell growth. The identification of this chromosomal translocation in more than 90% of cases of dermatofibrosarcoma protuberans has led to the development of targeted therapy. Inhibiting PDGFR with imatinib has been shown to induce clinical and radiologic improvement in patients with unresectable dermatofibrosarcoma protuberans. These data have resulted in the approval by the FDA of imatinib for treatment of patients with locally advanced dermatofibrosarcoma protuberans.

**PEDIATRIC SARCOMAS**

Soft tissue sarcomas in children are relatively rare, accounting for 7% to 8% of all pediatric cancers and totaling approximately 600 new cases per year. Pediatric sarcomas have traditionally been divided into two groups: rhabdomyosarcoma and nonrhabdomyosarcoma soft tissue sarcomas.

**Rhabdomyosarcoma**

Associated with skeletal muscle, rhabdomyosarcomas are the most common soft tissue tumors among children younger than 15 years and can occur at any site comprised of striated muscle. Patients with these tumors generally present with a painless enlarging mass; about 24% of tumors are located in the genitourinary system, 20% in the extremities, 20% in the head and neck, 16% in the parameningeal region, and 22% in other sites. Rhabdomyosarcoma is a small round cell tumor that demonstrates muscle differentiation upon light microscopy and immunohistochemical analysis. Two primary histologic subtypes account for 90% of cases: embryonal (70%) and alveolar (20%). Alveolar rhabdomyosarcoma is associated with cytogenetic translocation [t(2:13)(q35;q14)] in 85% to 90% of cases and [t(1:13)(p36;q14)] in 10% of cases. These translocations affect biologic activity at the levels of protein function and gene expression, thereby affecting the control of cell growth, apoptosis, differentiation, and motility and ultimately contributing to tumorigenic behavior. Whereas alveolar rhabdomyosarcomas often have translocations, most embryonal rhabdomyosarcomas have an allelic loss at chromosome 11p15.5 that is thought to inactivate a tumor suppressor gene. Both of these distinct molecular subtypes of rhabdomyosarcoma are thought to have similar alterations in downstream targets such as the p53 and Rb pathways. Further insight into these genetic alterations may lead to a better understanding of the pathogenesis of rhabdomyosarcoma and provide novel targets for therapeutic approaches.

Extent of disease is the strongest predictor of long-term outcome. Several staging systems for rhabdomyosarcoma are available. The Intergroup Rhabdomyosarcoma Study Group system is based on surgical-pathologic groupings. Multidisciplinary evaluation including pediatric oncologists, surgical subspecialists, and radiation oncologists is critical to plan the best treatment approach to maximize local tumor control while minimizing long-term treatment effects.

Complete surgical resection is the treatment of choice for rhabdomyosarcoma when function and cosmesis can be preserved. Patients who are able to undergo a complete tumor resection with negative (group I) or microscopic surgical margins (group II) are able to undergo less intensive systemic therapy and still have overall survival rates approaching 90%. At some anatomic sites, in particular the head and neck and genitourinary system, surgery is often avoided because the associated morbidity would be substantial. Recent findings suggest that chemotherapy alone can adequately control many such tumors. In the second International Society of Paediatric Oncology study of rhabdomyosarcoma (MMT84), the choice of local treatment was based on response to initial chemotherapy such that radical surgery and radiation therapy were avoided in 66% of patients. Among the patients who subsequently developed local relapse, the 5-year overall survival rate after salvage therapy was 46%.

Unlike other soft tissue sarcomas, rhabdomyosarcomas have a high propensity for lymph node metastasis, with rates up to 20% to 30% for sites such as the extremities, paratesticular nodes, and prostate. Lymph node sampling and, more recently, sentinel lymph node mapping have been used to evaluate regional node status in children with rhabdomyosarcoma. About 15% to 20% of patients with rhabdomyosarcoma have distant metastasis at presentation, most commonly (40–50% of cases) to the lungs, followed by bone marrow and bone. However, all patients with rhabdomyosarcoma are assumed to have micrometastatic disease at presentation. Therefore, multigent chemotherapy is recommended for all patients with rhabdomyosarcoma. Combination regimens including vincristine, dactinomycin, and cyclophosphamide continue to be the basis of effective curative therapy. Although various combinations including doxorubicin, ifosfamide, cisplatin, and etoposide have been shown to be active against rhabdomyosarcoma, they have not improved outcomes. Radiation therapy is given to most patients with microscopic residual disease (group II) after resection.

The prognosis for children with rhabdomyosarcomas is related to tumor site, surgical-pathologic grouping, and tumor histology. The 5-year disease-free survival rate for all patients has been reported to be 65%. Five-year disease-free survival rates for patients in groups I, II, III, and IV have been reported to be 84%, 74%, 62%, and 23%, respectively (see Table 36-3).

**Nonrhabdomyosarcoma Soft Tissue Sarcomas**

Approximately 60% of soft tissue sarcomas in children are nonrhabdomyosarcomas. These include numerous histologic subtypes, which are generally categorized into four groups: (a) fibrosarcoma, (b) Kaposi’s sarcoma, (c) other “specified” soft tissue sarcomas (e.g., synovial, angiosarcoma, hemangiopericytoma, leiomyosarcoma, liposarcoma, and extraosseous Ewing’s sarcoma), and (d) “unspecified” soft tissue sarcoma. The most common subtypes are synovial sarcoma, MPNST, and fibrosarcoma. No single histology accounts for more than 15% of all cases.

As with adult tumors, the evaluation of the soft tissue mass begins with a history and physical examination followed by imaging, which usually includes MRI. A CT scan of the chest is important for evaluation of metastatic disease. A core needle biopsy is generally required to establish a diagnosis. Surgery remains the primary treatment of nonrhabdomyosarcoma, and...
local control of large, high-grade tumors is improved with radiation therapy. The prognostic factors for children with nonrhabdomyosarcoma are similar to those for adults, and the role of chemotherapy for high-risk tumors is unclear, as for adults.

RESEARCH PERSPECTIVES

As the molecular alterations associated with various sarcoma subtypes are elucidated, many new potential targets for therapeutic intervention will be identified. A wide variety of DNA alterations have been observed in sarcomas that result in mutated genes encoding proteins ranging from transcription factors to tyrosine kinases to cytokines. The challenge in identifying therapeutic targets in sarcoma is to identify those that are specifically important to cellular function. The ideal therapeutic target has been described as a single molecule that is critical for pathogenesis, is expressed and active, is involved in a single pathway amenable to blockade (i.e., no alternative bypass pathways exist), and is critical for sarcoma cell survival.25

CONCLUSIONS

Soft tissue sarcomas are a heterogeneous family of rare tumors, accounting for approximately 1% of malignancies in adults. The etiology in the vast majority of patients is sporadic, and the management of such diverse tumors is complex. Diagnosis by light microscopy is inexact, but molecular diagnosis, although still in its infancy, holds great promise. The natural history of soft tissue sarcomas is well established. Approximately two-thirds of cases arise in the extremities, and the remaining one-third are distributed between the retroperitoneum, trunk, abdomen, and head and neck. The management algorithm for soft tissue sarcomas is complex and depends on tumor stage, site, and histology.

The most common site of metastasis is the lungs, and metastasis generally occurs within 3 years of diagnosis. Soft tissue sarcomas have unique molecular profiles that contribute to varying responses to systemic therapy. Doxorubicin-based regimens have been the mainstay of treatment for the past two decades; however, it is now clear that specific histologic subtypes have increased sensitivity to specific agents. For example, angiosarcomas are more sensitive to paclitaxel, while leiomyosarcoma is sensitive to gemcitabine and docetaxel.

Progress in understanding of soft tissue sarcoma biology is crucial for the development of additional therapeutic targets. Drug engineering will enable molecular-based therapies to become increasingly incorporated into clinical trials and, with success, into standard treatment strategies for soft tissue sarcomas in the near future.

INTRODUCTION

Inguinal herniorrhaphy is one of the most commonly performed operations in the United States. Based on estimates made by the National Center for Health Statistics, in 2010 nearly 515,000 inguinal hernia operations were performed in hospitals, and an additional 450,000 were performed in ambulatory surgery centers.

Approximately 75% of abdominal wall hernias occur in the groin. Of inguinal hernia repairs, 90% are performed in men, and 10% are performed in women. This is thought to be because the lifetime risk of inguinal hernia is 27% in men and 3% in women. The incidence of inguinal hernia in men has a bimodal distribution, with peaks before the first year of age and after age 40. Abramson demonstrated the age-dependence of inguinal hernias in 1978. Those age 25 to 34 years had a lifetime prevalence rate of 15%, whereas those age 75 years and over had a rate of 47% (Table 37-1). Approximately 70% of femoral hernia repairs are performed in women; however, the most common subtype of groin hernia in men and women is still the indirect inguinal hernia. Inguinal hernias are five times more common than femoral hernias.

Globally, the inguinal hernia repair has become one of the most important procedures in improving quality of life and preventing disability. In one study, an international cooperative organization performed over 1033 hernia repairs on 926 patients, and their impact was measured in disability adjusted life years (DALYs). They were able to avoid 5014 DALYs or 5.41 DALYs per patient.

History

Surgical repair of hernias has been documented as far back as in ancient Egyptian and Greek civilizations. In the past, early management of inguinal hernias often involved a conservative approach with operative management reserved only for complications. Surgery often involved routine excision of the testicle, and wounds were closed with cautery or allowed to close by secondary intention. These procedures were performed without aseptic technique, and infection and recurrence rates were high.

From the late 1700s to the early 1800s, physicians including Hesselbach, Cooper, Camper, Scarpa, Richter, and Gimbernat identified vital components of the inguinal region from cadaveric dissection. This improved understanding of the anatomy and pathophysiology of inguinal hernias. These findings, coupled with the development of aseptic technique, led surgeons such as Marcy, Kocher, and Lucas-Championnière to perform sac dissection, high ligation, and closure of the internal ring. This led to improved outcomes, but recurrence rates remained unacceptably high.

At around this time, Bassini (1844–1924) pioneered a new method that transformed inguinal hernia repair into a successful venture with minimal morbidity. The success of the Bassini repair over its predecessors ushered in an era of tissue-based repairs. The Bassini repair was then modified into the McVay and Shouldice repairs. All three of these techniques, as well as modern variations such as the Desarda operation, are currently practiced.

The next major advancement in inguinal hernia repair was in the 1980s. At this time, Lichtenstein applied a piece of mesh to the floor of the inguinal canal, allowing for a truly tension-free repair. This technique demonstrated superior outcomes compared to previous tissue-based repairs. There were several other advantages of this process. In addition to being truly tension-free, the mesh could restore the strength of the transversalis fascia, and importantly, the technique had a very short learning curve. The superior outcomes have been widely reproduced regardless of hernia size and type, and they were achievable among both expert and nonexpert hernia surgeons.

With the advent of minimally invasive surgery, inguinal hernia repair underwent its most recent transformation. Laparoscopic inguinal hernia repair offers an alternative approach, minimizes postoperative pain, and improves recovery. Since the initial description by Ger, the laparoscopic method has become more sophisticated. Refinements in approach and technique have performed without aseptic technique, and infection and recurrence rates were high.

Refinements in approach and technique have performed without aseptic technique, and infection and recurrence rates were high.
Key Points

1. Conservative management of asymptomatic inguinal hernias is recommended.
2. A thorough understanding of groin anatomy is essential to successful surgical treatment of inguinal hernias.
3. Elective repair of inguinal hernias can be undertaken using a laparoscopic, robotic, or open approach.
4. Robotic-assisted hernia surgery is quickly becoming adopted by general surgeons because of its better ergonomics and visualization.
5. The use of prosthetic mesh as a reinforcement significantly improves recurrence rates, whether the repair is open or laparoscopic.
6. Recurrence, pain, and quality of life are the metrics by which hernia repair outcomes are measured.
7. Laparoscopic inguinal hernia repair results in less pain; however, mastery of this technique has a longer learning curve.

Anatomy

The inguinal canal is an approximately 4- to 6-cm long cone-shaped region situated in the anterior portion of the pelvic basin (Fig. 37-1). The canal begins on the posterior abdominal wall, where the spermatic cord passes through a hiatus in the transversalis fascia also known as the deep (internal) inguinal ring. The canal concludes medially at the superficial (external) inguinal ring, the point at which the spermatic cord crosses a defect in the external oblique aponeurosis. The boundaries of the inguinal canal are the external oblique aponeurosis anteriorly, the internal oblique muscle laterally, the transversalis fascia and transversus abdominis muscle posteriorly, the internal oblique and transversus abdominis muscle superiorly, and the inguinal (Poupart’s) ligament inferiorly. The spermatic cord traverses the inguinal canal, and it contains three arteries, three veins, two nerves, the pampiniform venous plexus, and the vas deferens. It is enveloped in three layers of spermatic fascia.

Additional important structures surrounding the inguinal canal include the iliopubic tract, the lacunar ligament, Cooper’s ligament, and the conjoined tendon (Fig. 37-2). The iliopubic tract is an aponeurotic band that begins at the anterior superior iliac spine and inserts into Cooper’s ligament from above. It forms on the deep inferior margin of the transversus abdominis and transversalis fascia. The shelving edge of the inguinal ligament is a structure that connects the iliopubic tract to the inguinal ligament. The iliopubic tract helps form the inferior margin of the internal inguinal ring as it courses medially, where it continues as the anteromedial border of the femoral canal. The lacunar ligament, or ligament of Gimbert, is the triangular fanning of the inguinal ligament as it joins the pubic tubercle. Cooper’s (pectineal) ligament is the lateral portion of the lacunar ligament that is fused to the periosteum of the pubic tubercle. The conjoined tendon is commonly described as the fusion of the inferior fibers of the internal oblique and transversus abdominis aponeurosis at the point where they insert on the pubic tubercle.

Inguinal hernias are generally classified as direct, indirect, or femoral based upon the site of herniation relative to surrounding structures. Indirect hernias protrude lateral to the inferior epigastric vessels, through the deep inguinal ring. Direct hernias protrude medial to the inferior epigastric vessels, within Hesselbach’s triangle. The borders of the triangle are the inguinal ligament inferiorly, the lateral edge of rectus sheath medially, and the inferior epigastric vessels superolaterally. Femoral hernias protrude through the small and inflexible femoral ring. They traverse the empty space between the femoral vein and the lymphatic channels. The borders of the femoral ring include the iliopubic tract and inguinal ligament anteriorly, Cooper’s ligament posteriorly, the lacunar ligament medially, and the femoral vein laterally. The Nyhus classification categorizes hernia defects by location, size, and type (Table 37-2).

Laparoscopic inguinal hernia repair requires a thorough knowledge of inguinal anatomy from a posterior perspective (Fig. 37-3). Intraperitoneal points of reference are the five peritoneal folds, bladder, inferior epigastric vessels, and psoas muscle (Fig. 37-4). Two potential spaces exist within the preperitoneum. Between the peritoneum and the posterior lamina of the transversalis fascia is Bogros’s (preperitoneal) space. This area contains preperitoneal fat and areolar tissue. The most medial aspect of the preperitoneal space, that which lies superior to the bladder, is known as the space of Retzius. The posterior perspective also allows visualization of the myopectineal orifice of Fruchaud, a relatively weak portion of the abdominal wall that is divided by the inguinal ligament (Fig. 37-5).

The vascular space is situated between the posterior and anterior laminae of the transversalis fascia, and it houses the

in inferior epigastric vessels. The inferior epigastric artery supplies the rectus abdominis. It is derived from the external iliac artery, and it anastomoses with the superior epigastric, a continuation of the internal thoracic artery. The epigastric veins course parallel to the arteries within the rectus sheath, posterior to the rectus muscles. Inspection of the internal inguinal ring will reveal the deep location of the inferior epigastric vessels.

Nerves of interest in the inguinal region are the ilioinguinal, iliohypogastric, genitofemoral, and lateral femoral cutaneous nerves (Figs. 37-6 and 37-7). The ilioinguinal and iliohypogastric nerves arise together from the first lumbar nerve (L1). The ilioinguinal nerve emerges from the lateral border of the psoas major and passes obliquely across the quadratus lumborum. At a point just medial to the anterior

superior iliac spine, it pierces the transversus and internal oblique muscles to enter the inguinal canal and exits through the superficial inguinal ring. It supplies somatic sensation to the skin of the upper and medial thigh. In males, it also innervates the base of the penis and upper scrotum. In females, it innervates the mons pubis and labium majus. The iliohypogastric nerve arises from T12–L1. After it pierces the deep abdominal wall, it courses between the internal oblique and transversus abdominis, supplying both. It then divides into lateral and anterior cutaneous branches. A common variant is for the iliohypogastric and ilioinguinal nerves to exit around the superficial inguinal ring as a single entity. The genitofemoral nerve arises from L1 to L2, courses along the retroperitoneum, and emerges on the anterior aspect of the psoas. It then divides into genital and femoral branches. The genital branch enters the inguinal canal lateral to the inferior epigastric vessels, and it courses ventral to the iliac vessels and iliopubic tract. In males, it travels through the superficial inguinal ring and supplies the ipsilateral scrotum and cremaster muscle. In females, it supplies the ipsilateral mons pubis and labium majus. The

Figure 37-3. Anatomy of the groin region from the posterior perspective.

femoral branch courses along the femoral sheath, supplying the skin of the upper anterior thigh. The lateral femoral cutaneous nerve arises from L2 to L3, emerges lateral to the psoas muscle at the level of L4, and crosses the iliacus muscle obliquely toward the anterior superior iliac spine. It then passes inferiorly to the inguinal ligament where it divides to supply the lateral thigh (Fig. 37-8).

The preperitoneal anatomy seen in laparoscopic hernia repair led to characterization of important anatomic areas of interest, known as the triangle of doom, the triangle of pain, and the circle of death (Fig. 37-9). The triangle of doom is bordered medially by the vas deferens and laterally by the vessels of the spermatic cord. The contents of the space include the external iliac vessels, deep circumflex iliac vein, femoral nerve, and genital branch of the genitofemoral nerve. The triangle of pain is a region bordered by the iliopubic tract and gonadal vessels, and it encompasses the lateral femoral cutaneous, femoral branch of the genitofemoral and femoral nerves. The circle of death is a vascular continuation formed by the common iliac, internal iliac, obturator, inferior epigastric, and external iliac vessels.

Pathophysiology

Inguinal hernias may be congenital or acquired. Most adult inguinal hernias are considered acquired defects in the abdominal wall. There is however, a known hereditary association that is not well understood. The most likely risk factor for inguinal hernia is weakness in the abdominal wall musculature; however, there are several other risk-factors that have been studied (Table 37-3). Congenital hernias, which make up the majority of pediatric hernias, can be considered a developmental defect rather than an acquired weakness. During the normal course of development, the testes descend from the intra-abdominal space into the scrotum in the third trimester. Their descent is guided by the gubernaculum through an evagination of the peritoneum, which protrudes through the inguinal canal and becomes the processus vaginalis. Between 36 and 40 weeks’ gestation, the processus vaginalis closes and eliminates the peritoneal opening at the internal inguinal ring. Failure of the peritoneum to close results in a patent processus vaginalis (PPV). In preterm babies, indirect inguinal hernias as a result of PPV is very high. Overall, the risk of developing a symptomatic hernia during childhood in the presence of a known PPV is relatively low.

Overall, there is limited data regarding the etiology of inguinal hernia development. Several studies have documented strenuous physical activity as a risk factor for acquired inguinal hernia. A case-controlled study of over 1400 male patients with inguinal hernia revealed that a positive family history was associated with an eightfold lifetime incidence of

Epidemiologic studies have identified risk factors that may predispose to a hernia. Microscopic examination of skin of inguinal hernia patients demonstrated significantly decreased ratios of type I to type III collagen. Type III collagen does not contribute to wound tensile strength as significantly as type I collagen. Additional analyses of similar skin revealed disaggregated collagen tracts with decreased collagen fiber density. Collagen disorders such as Ehlers-Danlos syndrome are also associated with an increased incidence of hernia formation (Table 37-4). Recent studies have found an association between concentrations of extracellular matrix...

DIAGNOSIS

History

Workup for inguinal hernia begins with a detailed history. The most common symptom of inguinal hernia is a groin mass that protrudes while standing, coughing, or straining. It is sometimes described as reducible while lying down. Symptoms that are extrainguinal such as a change in bowel habits or urinary symptoms are far less common but should be recognized as having the potential to be ominous. The pain is thought to be due to compression of the nerves by the sac, causing generalized pressure, localized sharp pain, or referred pain. Referred pain may involve the scrotum, testicle, or inner thigh.

Important considerations of the patient’s history include the duration and timing of symptoms. Sudden onset symptoms are more concerning. Questions should also be directed to characterize whether the hernia is reducible. Patients will often reduce the hernia by pushing the contents back into the abdomen, thereby providing temporary relief. As the defect size increases and more intra-abdominal contents fill the hernia sac, the hernia may become harder to reduce and incarcerate, prompting urgent surgical intervention.

Certain elements of the review of systems such as chronic constipation, cough, or urinary retention should prompt the surgeon to perform a thorough workup to rule out any underlying malignancy.
Physical Examination
Physical examination is essential to the diagnosis of inguinal hernia. The patient should be examined in a standing position to increase intra-abdominal pressure, with the groin and scrotum fully exposed. Inspection is performed first, with the goal of identifying an abnormal bulge along the groin or within the scrotum. If an obvious bulge is not detected, palpation is performed to confirm the presence of the hernia.

Palpation is performed by advancing the index finger through the scrotum towards the external inguinal ring (Fig. 37-11). This allows the inguinal canal to be explored. The patient is then asked to perform a Valsalva maneuver to increase intra-abdominal pressure. These maneuvers will reveal an abnormal bulge and allow the clinician to determine whether the hernia is reducible or not. Examination of the contralateral side affords the clinician the opportunity to compare the presence and extent of herniation between sides. This is especially useful in the case of a small hernia. In addition to inguinal hernia, a number of other diagnoses may be considered in the differential of a groin bulge (Table 37-5).

While very difficult to ascertain, there are certain physical examination maneuvers that can be performed to help distinguish direct vs. indirect inguinal hernias. The inguinal occlusion test entails the examiner blocking the internal inguinal ring with a finger as the patient is instructed to cough. A controlled impulse suggests an indirect hernia, while persistent herniation suggests a direct hernia. Transmission of the cough impulse to the tip of the finger implies an indirect hernia, while an impulse palpated on the dorsum of the finger implies a direct hernia. When results of physical examination are compared against operative findings, there is a probability somewhat higher than chance (i.e., 50%) of correctly diagnosing the type of hernia.21,22

External groin anatomy is difficult to assess in obese patients, making the physical diagnosis of inguinal hernia challenging. A further challenge to the physical examination is the identification of a femoral hernia. Femoral hernias should be palpable below the inguinal ligament, lateral to the pubic tubercle. In obese patients, a femoral hernia may be missed or misdiagnosed as a hernia of the inguinal canal. In contrast, a prominent inguinal fat pad in a thin patient, otherwise known as a femoral pseudohernia, may prompt an erroneous diagnosis of femoral hernia.

Imaging
In the case of an ambiguous diagnosis, radiologic investigations may be used as an adjunct to history and physical examination. Imaging in obvious cases is unnecessary. The most common radiologic modalities include ultrasonography (US), computed tomography (CT), and magnetic resonance imaging (MRI). Each technique has certain advantages over physical examination alone; however, each modality is associated with potential limitations.

US is the least invasive technique and does not impart any radiation to the patient. Anatomic structures can be more easily identified by the presence of bony landmarks; however, because there are few bones in the inguinal canal, other structures such as the inferior epigastric vessels are used to define groin anatomy. Positive intra-abdominal pressure is used to elicit the herniation of abdominal contents. Movement of these contents through the canal is essential to making the diagnosis with US.
and lack of this movement may lead to a false negative. A recent meta-analysis demonstrated that ultrasound detects inguinal hernia with a sensitivity of 86%, specificity of 77%. In thin patients, normal movement of the spermatic cord and posterior abdominal wall against the anterior abdominal wall may lead to false-positive diagnoses of hernia.

CT and MRI provide static images that are able to delineate groin anatomy, to detect groin hernias, and to exclude potentially confounding diagnoses (Fig. 37-12). Meta-analysis determined standard CT detects inguinal hernia with a sensitivity of 80%, specificity of 65%. Although direct herniography has a higher sensitivity and specificity than CT, its invasiveness and limited availability restrict its routine use. As CT imaging increases in resolution, its sensitivity in detecting inguinal hernia is expected to expand; however, this has yet to be clinically confirmed by surgical correlation.

MRI is most commonly utilized in cases where physical examination detects a groin bulge, but where ultrasonography is inconclusive. In a 1999 study of 41 patients with clinical findings of inguinal hernia, laparoscopy revealed that MRI was an effective diagnostic test with a sensitivity of 95%, specificity of 96%. The expense of MRI precludes its routine use to diagnose inguinal hernias.

**TREATMENT**

Surgical repair of hernias can be performed open, laparoscopic, or with robotic assistance. Surgical repair is the definitive treatment of inguinal hernias. The most common reason for elective repair is pain. Incarceration and strangulation are the primary indications for urgent repair. Symptomatic hernias should be operated on electively, and minimally symptomatic or asymptomatic hernias should undergo watchful waiting. Repair of minimally symptomatic inguinal hernia in patients with significant medical comorbidities surgery should be deferred and the patient medically optimized. If despite optimal management of comorbidities, the patient remains high-risk, open repair under local anesthesia can be safely performed. Although the natural history of untreated inguinal hernias is poorly defined, the rates of incarceration and strangulation are low in the asymptomatic population. As a result, nonoperative management is an appropriate consideration in minimally symptomatic patients. Prospective studies and meta-analyses have demonstrated no difference in intention-to-treat outcomes, quality of life, or cost-effectiveness between watchful waiting and elective repair among healthy inguinal hernia patients. A 2012 systematic review found that 72% of asymptomatic inguinal hernia patients developed symptoms and had surgical repair within 7.5 years of diagnosis. Nevertheless, the complication rates of immediate and delayed elective repair are equivalent. A nonoperative strategy is safe for minimally symptomatic inguinal hernia patients.

Nonoperative inguinal hernia treatment targets pain, pressure, and protrusion of abdominal contents in the symptomatic patient population. The recumbent position aids in hernia reduction via the effects of gravity and a relaxed abdominal wall. Trusses externally confine hernias to a reduced state and intermittently relieve symptoms in up to 65% of patients; however, they do not prevent complications, and they may be associated with an increased rate of incarceration. The risks of incarceration and strangulation appear to decrease over the first year, likely because gradual enlargement of the abdominal wall defect facilitates spontaneous reduction of hernia contents. The sheer volume of protruding tissue in an inguinal hernia does not necessarily signify severe morbidity.

Femoral and symptomatic inguinal hernias carry higher complication risks, and so surgical repair is performed earlier for these patients. Irrespective of symptoms, one study found the 3-month and 2-year cumulative incidences of strangulation were 2.8% and 4.5%, respectively, for inguinal hernias and 22% and 45%, respectively, for femoral hernias. Data from the Swedish Hernia Registry demonstrates that emergent operation is associated with a sevenfold increase in all-cause mortality over that of elective surgery among 107,838 groin hernia repairs. For this reason, it is recommended that femoral hernias and symptomatic inguinal hernias be electively repaired, when possible.

Incarceration occurs when hernia contents fail to reduce; however, a minimally symptomatic, chronically incarcerated hernia may also be treated nonoperatively. Taxis should be attempted for incarcerated hernias without sequelae of strangulation, and the option of surgical repair should be discussed prior to the maneuver. To perform taxis, analgesics and light sedatives are administered, and the patient is placed in the Trendelenburg position. The hernia bulge is elongated with both hands, and while slight countertraction is maintained, reduction of the contents is attempted circumferentially in a small stepwise fashion to ease their reduction into the abdomen.

The indication for emergent inguinal hernia repair is impending compromise of intestinal contents. As such, strangulation of hernia contents is a surgical emergency. Clinical signs that indicate strangulation include tenderness, fever, leukocytosis, and hemodynamic instability. The hernia bulge is usually warm, tender, and the overlying skin is often erythematos or discolored. Symptoms of bowel obstruction in patients with sliding or incarcerated inguinal hernias may also indicate strangulation. Taxis should not be performed when strangulation is suspected, as reduction of potentially gangrenous tissue into the abdomen may result in an intra-abdominal catastrophe. Preoperatively, the patient should receive fluid resuscitation, nasogastric decompression, and prophylactic intravenous antibiotics.
Prophylactic Antibiotics

The debate as to whether or not to administer preoperative prophylactic antibiotics in elective inguinal hernia repair still remains controversial as elective hernia repair is considered a clean procedure and as such are exempt from SCIP surgical prophylaxis guidelines. A Cochrane review of 17 randomized controlled trials in 2012 revealed an overall decrease in infection rates (3.1% vs. 4.5%, odds ratio [OR] 0.64, 95% confidence interval [CI] 0.50–0.82) when prophylactic antibiotics are administered in patients. In subgroup analyses, the difference was smaller in patients without mesh placement (3.5% vs. 4.9%, OR 0.71, 95% CI 0.51–1.00) than in those with mesh placement (2.4% vs. 4.2%, OR 0.56, 95% CI 0.38–0.81). However, with inguinal hernia repair, overall wound infection rates were higher than those expected for clean operations, as a result, they were unable to definitively recommend for or against antimicrobial prophylaxis.36,37 Although there is no universal guideline regarding the administration of prophylactic antibiotics for open elective hernia repair, the routine indexing of cases for quality improvement databases have resulted in the routine administration of prophylactic perioperative antibiotics in inguinal hernia repairs.

Open Approach

The most commonly performed type of hernia operation still remains the open inguinal hernia repair. These repairs can be performed tension-free with mesh or by reconstruction of the floor with tissue. Tissue repairs are less common and are primarily indicated in infected fields.

Exposure of the anterior inguinal region is common to the open approaches. An oblique or horizontal incision is performed over the groin (Fig. 37-13). The incision begins two fingerbreadths inferior and medial to the anterior superior iliac spine. It is then extended medially for approximately 6 to 8 cm. The subcutaneous tissue is dissected using electrocautery. Scarpa’s fascia is divided to expose the external oblique aponeurosis. A small incision is made in the external oblique aponeurosis parallel to the direction of the muscle fibers.
Specific Considerations

Figure 37-14. Anterior open exposure of the inguinal canal. m. = muscle; n. = nerve; v. = vein.

1. Metzenbaum scissors are introduced and spread beneath the fibers to sweep away the underlying ilioinguinal nerve. The scissors are then used to incise the aponeurosis superior to the inguinal ligament, splitting the external inguinal ring.

2. The flaps of the external oblique aponeurosis are elevated with Hemostat clamps. The internal oblique fibers are dissected bluntly from the overlying external oblique flaps. Dissection of the inferior flap reveals the shelving edge of the inguinal ligament. The iliohypogastric and ilioinguinal nerves are identified and preserved. Effort should be made to avoid removing nerves from their natural bed and disrupting the protective investing fascia. The pubic tubercle is identified, and the cord structures are dissected off of the pubis, encircled, and elevated with a Penrose drain. The cord is elevated 2 cm over the pubic symphysis in an avascular plane, and csematic fibers are preserved to avoid injuring cord structures (Fig. 37-14).

3. An indirect hernia sac will generally be found on the anteromedial surface of the spermatic cord after division of the cremasteric muscle in the direction of its fibers. The genital nerve is visualized along the inferolateral surface of the cord adjacent to the external spermatic vein. The floor of the inguinal canal is fully assessed for direct hernias. If a hernia is not visualized upon entry into the inguinal canal, the preperitoneal space should be explored for a femoral hernia. In addition to sac identification, the vas deferens and vessels of the spermatic cord must be identified to allow dissection of the sac from the cord. Blunt dissection facilitates dissection of the sac from the cord. The dissection is carried proximally toward the deep inguinal ring.

4. In cases where the viability of sac contents is in question, the sac should be incised, and hernia contents should be evaluated for signs of ischemia. The defect should be enlarged to augment blood flow to the sac contents. Viable contents may be reduced into the peritoneal cavity, while nonviable contents resected. In elective cases, the sac may be amputated at the internal inguinal ring. Care is taken to avoid injury to the preperitoneal structures, which are bluntly dissected to mobilize the upper and lower fascial flaps. At the pubic tubercle, the iliopubic tract is sutured to the lateral edge of the rectus sheath using a synthetic, nonabsorbable, monofilament suture. This continuous suture progresses laterally, approximating the edge of the inferior transversalis fascia flap to the posterior portion of the inguinal canal. The suture is tied to the tail of the original stitch. The next suture begins at the internal inguinal ring, and it continues medially, apposing the aponeuroses of the external oblique and transversus abdominis to the external oblique aponeurotic fibers. At the pubic tubercle, the suture doubles back through the same structures laterally toward the tightened internal ring.

5. Tissue Repairs. Tissue-based herniorrhaphy is a suitable alternative when prosthetic materials cannot be used safely. Indications for tissue repairs include operative field contamination, emergency surgery, and when the viability of hernia contents is uncertain.

6. Bassini Repair The Bassini repair was a historic advancement in operative technique. Its current use is limited as modern techniques reduce recurrence. The original repair includes dissection of the spermatic cord, dissection of the hernia sac with high ligation, and extensive reconstruction of the floor of the inguinal canal (Fig. 37-15). After exposing the inguinal floor, the transversalis fascia is incised from the pubic tubercle to the internal inguinal ring. Preperitoneal fat is bluntly dissected from the upper margin of the posterior side of the transversalis fascia to permit adequate tissue mobilization. A triple-layer repair is then performed. The internal oblique, transversus abdominis, and transversalis fascia are fixed to the shelving edge of the inguinal ligament and pubic periosteum with interrupted sutures. The lateral aspect of the repair reinforces the medial border of the internal inguinal ring.

7. Shouldice Repair The Shouldice repair recapitulates principles of the Bassini repair, and its distribution of tension over several tissue layers results in lower recurrence rates (Fig. 37-16). During dissection of the cord, the genital branch of the genitofemoral nerve is routinely divided, resulting in ipsilateral loss of sensation to the scrotum in men or the mons pubis and labium majus in women. With the posterior inguinal floor exposed, an incision in the transversalis fascia is made between the pubic tubercle and internal ring. Care is taken to avoid injury to preperitoneal structures, which are bluntly dissected to stabilize the upper and lower fascial flaps. At the pubic tubercle, the iliopubic tract is sutured to the lateral edge of the rectus sheath using a synthetic, nonabsorbable, monofilament suture. This continuous suture progresses laterally, approximating the edge of the inferior transversalis fascia flap to the posterior portion of the inguinal canal. The suture is tied to the tail of the original stitch. The next suture begins at the internal inguinal ring, and it continues medially, apposing the aponeuroses of the external oblique and transversus abdominis to the external oblique aponeurotic fibers. At the pubic tubercle, the suture doubles back through the same structures laterally toward the tightened internal ring.

8. McVay Repair The McVay repair addresses both inguinal and femoral ring defects. This technique is indicated for femoral hernias and in cases where the use of prosthetic material is contraindicated (Fig. 37-17). Once the spermatic cord has been isolated, an incision in the transversalis fascia permits entry into the preperitoneal space. The upper flap is mobilized by gentle blunt dissection of underlying tissue. Cooper’s ligament is bluntly dissected to expose its surface. A 2 to 4 cm relaxing incision is made in the anterior rectus sheath vertically from the...
**Figure 37-15.** Bassini repair. A. The transversalis fascia is opened. B. Reconstruction of the posterior wall by suturing the transversalis fascia (TF), the transversus abdominis muscle (TA), and the internal oblique muscle (IO) medially to the inguinal ligament (IL) laterally. EO = external oblique aponeurosis.

**Figure 37-16.** Shouldice repair. A. The iliopubic tract is sutured to the medial flap of the transversalis fascia and the internal oblique and transverse abdominis muscles. B. The second of the four suture lines, reversing toward the pubic tubercle approximating the internal oblique and transversus muscles to the inguinal ligament. Two more suture lines affix the internal oblique and transversus muscles mediadly.

The medial leaf of the external oblique aponeurosis is sutured to the inguinal ligament from the pubic tubercle to the abdominal ring using 1–0 Ethilon or Prolene interrupted sutures. The first two sutures are taken at the junction of the anterior rectus sheath and EOA. The last suture is taken so as to sufficiently close the transversus fascia to the inguinal ligament.

The pubic tubercle. This incision is essential to reduce tension on the repair; however, it may result in increased postoperative pain and higher risk of ventral abdominal herniation. Using either interrupted or continuous suture, the superior transversalis flap is then fastened to Cooper’s ligament, and the repair is continued laterally along Cooper’s ligament to occlude the femoral ring. Lateral to the femoral ring, a transition stitch is placed, affixing the transversalis fascia to the inguinal ligament. The transversalis is then sutured to the inguinal ligament laterally to the internal ring.

**Desarda Repair** The Desarda hernia repair was recently described in 2001, and it consists of a mesh-free repair utilizing a strip of external oblique aponeurosis.

An oblique skin incision is made, and dissection is carried down to the external oblique fascia. The integrity of the fascia is preserved as much as possible. The cremasteric muscle is then incised, and the spermatic cord along with the cremasteric muscle is separated from the inguinal floor. Excision of the sac is done in all cases except in small direct hernias, where it is inverted.
narrow the abdominal ring without constricting the spermatic cord (Fig. 37-18). Each suture is passed first through the inguinal ligament, then the transversalis fascia, and then the EOA. The index finger of the left hand is used to protect the femoral vessels and retract the cord structures laterally while taking lateral sutures. A splitting incision is then taken in the EOA, partially separating a strip. This splitting incision is extended medially up to the pubic symphysis and laterally 1 to 2 cm beyond the reconstructed abdominal ring.

The free border of the strip of the EOA is now sutured to the internal oblique or conjoined tendon lying close to it with 1–0 Ethilon or Prolene interrupted sutures. This is followed by closure of the superficial fascia and the skin as usual.39-41

Prosthetic Repairs. The popularization of tension-free prosthetic mesh repairs signified a paradigm shift in the surgical concept of inguinal hernia pathophysiology. Mesh-based hernioplasty is the most commonly performed general surgical procedure, owing to the technique’s efficacy and improved outcomes. The techniques of the most commonly performed prosthetic repairs are presented in this section.

Lichtenstein Tension-Free Repair The Lichtenstein technique allows for a tension-free repair of the inguinal floor by buttressing the floor with a prosthetic mesh (Fig. 37-18). Initial exposure and mobilization of cord structures is identical to other open approaches. The inguinal canal is dissected to expose the shelving edge of the inguinal ligament, the pubic tubercle, and sufficient area for mesh. The most commonly used mesh is “flat iron” shaped with a keyhole for cord egress, it is available in several sizes. It should be noted that when selecting the size, it must be large enough to extend 2 to 3 cm superior to Hesselbach’s Triangle. The medial edge of the mesh is affixed to the anterior rectus sheath such that it overlaps the pubic tubercle by 1.5 to 2 cm. This refinement to the original Lichtenstein technique minimizes medial recurrence.42

For fixation of the inferior margin of the mesh, a permanent, synthetic, monofilament suture is used taking care to avoid placing sutures directly into the periosteum of the pubic tubercle. Fixation is continued along the shelving edge of the inguinal ligament from medial to lateral, ending at the internal ring. The upper tail of the mesh is then fixed to the internal oblique aponeurosis and the medial edge to the rectus sheath using a synthetic, absorbable suture.

In the case of a femoral hernia, a triangular extension of the inferior aspect of the mesh is sutured to Cooper’s ligament medially and to the inguinal ligament laterally. The lateral tails of the mesh are tailored to fit snugly around the cord at the internal ring, but not too tight to strangulate it. The tails are then sutured to the inguinal ligament with an interrupted stitch and placed beneath the external oblique aponeurosis.

Plug and Patch Technique. A modification of the Lichtenstein repair, the Plug and Patch technique was developed by Gilbert and later popularized by Rutkow and Robbins.43 Prior to placing the prosthetic mesh patch over the inguinal floor, a three-dimensional prosthetic plug is placed in the space previously occupied by the hernia sac (Fig. 37-19). In the case of an indirect hernia, the plug is sutured to Cooper’s ligament and the inguinal ligament with interrupted sutures.44 For direct hernias, the sac is reduced, and the plug is sutured to Cooper’s ligament, the inguinal ligament, and
the internal oblique aponeurosis. While the technique has good overall outcomes, there have been some isolated case report series of complications involving the presence of the plug, including bowel obstruction and chronic pain.

**Wound Closure** Once the reconstruction of the inguinal canal is complete, the cord contents are returned to their anatomic position. The external oblique aponeurosis is then reapproximated continuously from medial to lateral using an absorbable suture. The external ring should be reconstructed in close apposition to the spermatic cord to avoid the appearance of recurrence on future examination. Scarpa’s fascia and skin are appropriately closed.

**Laparoscopic Approach**

Laparoscopic inguinal hernia repairs have become increasingly popular given the noninferiority studies, improved aesthetics, and increased surgeon experience with the procedure. Principal endoscopic methods include the transabdominal preperitoneal (TAPP) repair, the totally extraperitoneal (TEP) repair, and the less-commonly performed intraperitoneal onlay mesh (IPOM) repair.

Of note, awake patients do not tolerate abdominal insufflation well; therefore, laparoscopic repair necessitates the administration of general anesthesia and its inherent risks. Any patient with a contraindication to the use of general anesthesia should not undergo laparoscopic hernia repair. Occasionally, induction of general anesthesia may result in reduction of an incarcerated or strangulated inguinal hernia. If the surgeon suspects this might have occurred, the abdomen should be explored for non-viable tissue either via laparoscopy or upon conversion to an open laparotomy.

The indications for laparoscopic inguinal hernia repair are similar to those for open repair. Most surgeons would agree that the endoscopic approach to bilateral or recurrent inguinal hernias is superior to the open approach. Concurrent inguinal hernia repair can be considered if a hernia patient is scheduled to undergo another laparoscopic procedure without gross contamination, such as prostatectomy. International Endohernia Society (IEHS) guidelines offer a grade A recommendation that TEP and TAPP are preferred alternatives to Lichtenstein repair for recurrent hernias after open anterior repair. The possibility of bilateral repair should be discussed with all patients undergoing endoscopic inguinal hernia surgery.

The operating room configuration is identical for TAPP, TEP, and IPOM procedures. The patient is placed in the Trendelenburg position, and video screens are placed at the foot of the bed. The surgeon stands contralateral to the hernia, and the assistant stands opposite the surgeon. The patient’s arms are tucked to the sides. Figure 37-20 demonstrates a typical operating room setup for endoscopic inguinal hernia repair. The following sections outline the most commonly performed endoscopic inguinal hernia repair techniques.

**Transabdominal Preperitoneal Procedure.** The transabdominal approach confers the advantage of an intraperitoneal perspective, which is useful for bilateral hernias, large hernia defects, and scarring from previous lower abdominal surgery. The abdominal cavity is accessed using a dissecting trocar or open Hasson technique. Pneumoperitoneum to a level of 15 mmHg is achieved. Two 5-mm trocars are placed lateral and slightly inferior to the umbilical trocar, avoiding injury to the inferior epigastric vessels (Fig. 37-21). The patient is then placed in the Trendelenburg position, and the pelvis is inspected.

The bladder, median and medial umbilical ligaments, external iliac, and inferior epigastric vessels are visualized. An incision is made in the peritoneum at the medial umbilical liga ment, 3 to 4 cm superior to the hernia defect, and it is carried laterally to the anterior superior iliac spine. For bilateral inguinal hernia repair, bilateral peritoneal incisions are advisable, leaving a midline bridge of tissue to avoid injuring a potential patent urachus. The inferior edge of incised peritoneum is retracted, and the preperitoneum is dissected to expose the spermatic cord. If a direct hernia is encountered, the sac is inverted and fixed to Cooper’s ligament to prevent development of hematoma or seroma. An indirect hernia sac will usually protrude anterior to the spermatic cord. In this case, the sac is grasped and elevated superiorly from the cord and the space below is developed bluntly to allow for mesh placement. The sac is dissected from its adhesions, and the cord is skeletonized.

The mesh usually measures 10 × 15 cm to completely cover the myopectineal orifice (Fig. 37-22). It is rolled lengthwise and placed through the 12-mm trocar. It is unrolled in the preperitoneal space and secured medially to Cooper’s ligament using an endoscopic tacker. During this fixation, the surgeon palpates the end of the tacker from the abdominal surface to ensure its proper angle and to stabilize the mesh. The mesh is then pulled taut and fixed laterally to the anterior superior iliac spine. Tacks are placed above the iliopubic tract to avoid injury to the lateral cutaneous nerve of the thigh and the femoral branch of the genitofemoral nerve. The peritoneal edges are reapproximated using tacks or intracorporeal sutures as the mesh is stabilized. The peritoneum should be closed completely to avoid contact between the mesh and the intestine. The abdomen is desufflated, and the trocars are removed. The fascial defect of the 12-mm port and the skin incisions are appropriately closed.

**Totally Extraperitoneal Procedure.** The advantage of the TEP repair is the access to the preperitoneal space without intraperitoneal infiltration. Consequently, this approach minimizes the risk of injury to intra-abdominal organs and port site herniation through an iatrogenic defect in the abdominal wall. As with TAPP, TEP is indicated for repair of bilateral inguinal hernias or
for unilateral hernias when scarring makes the anterior approach challenging.

A small horizontal incision is made inferior to the umbilicus. Subcutaneous tissue is dissected to the level of the anterior rectus sheath, which is then incised lateral to the linea alba. The rectus muscle is retracted superolaterally, and a dissecting balloon is advanced through the incision toward the pubic symphysis. Under direct visualization with a 30° laparoscope, the balloon is inflated slowly to bluntly dissect the preperitoneal space (Fig. 37-23). The dissecting balloon is replaced with a 12-mm balloon trocar, and pneumoperitoneum is achieved by insufflation to 15 mmHg. A 5-mm trocar is placed suprapublically in the midline, and another is placed inferior to the insufflation port (see Fig. 37-21). The patient is placed in the Trendelenburg position, and the operation proceeds in an identical fashion to TAPP. No modifications are necessary to repair bilateral inguinal hernias with the TEP approach. Any peritoneal rents should be repaired prior to desufflation to prevent mesh from contacting intraperitoneal structures. Following mesh placement, the preperitoneal space is desufflated slowly under direct vision to ensure proper mesh positioning. Trocars are removed, and the anterior rectus sheath is closed with an interrupted suture. If there

is violation of the peritoneum during insufflation of the dissection balloon and subsequent pneumoperitoneum, visualization can be compromised. To address this, a Veress needle or angiocatheter can be placed in the LUQ, which will allow desufflation of the peritoneum and restore visualization.

**Intraperitoneal Onlay Mesh Procedure.** In contrast to TAPP and TEP, the IPOM procedure permits the posterior approach without preperitoneal dissection. It is an attractive procedure in cases where the anterior approach is unfeasible, in recurrent hernias that are refractory to other approaches, or where extensive preperitoneal scarring would make TEP or TAPP challenging. Port placement and inguinal hernia identification are identical to TAPP. Hernia sac contents are reduced; however, the sac itself is not inverted from the preperitoneal space. Instead, mesh is placed directly over the defect and fixed in place with sutures or spiral tacks. Because these anchors are placed through the peritoneum without preperitoneal inspection, the lateral cutaneous nerve of the thigh and the genitofemoral nerve are especially prone to injury. Furthermore, intraperitoneal mesh migration is a documented phenomenon that can lead to postoperative morbidity, recurrence, and reoperation.

**Robot-Assisted Inguinal Hernia Repair**

Application of a robotic platform to hernia repair has been adapted by general surgeons across the country. The endorobot capabilities provide greatly improved manual dexterity and a relatively short learning curve. Though both total extraperitoneal repair and transabdominal preperitoneal repair can be adapted to a robotic platform, the latter has gained more traction among surgeons.

Many papers have explored the efficacy and cost-effectiveness of robot-assisted herniorrhaphy. Retrospective data have had mixed results when comparing robot-assisted surgery vs. laparoscopy. One recent study has shown longer operative time, another analysis has shown increased cost. It should be noted, however, that there is a decrease in cost with robotic surgery as the volume of procedures increases at each center, though it is still unlikely that the costs will ever converge to that of laparoscopic surgery. A retrospective, single-institution study has shown greatly reduced complication rates with robotic assisted surgery in obese patients; however, this was compared against open inguinal hernia repair (10.8% vs. 3.2%, \( P = 0.047 \)), the two groups were covariate matched for preoperative risk. Studies have also shown excellent long-term (36-month) quality of life indicators in robot-assisted TAPP, though this was a single surgeon survey. Further randomized trials will shed more light into cost issues as surgeons gain more experience with robotic application that would lead to shorter operative time and minimize additional instrument use.

Similar to laparoscopy, robot-assisted repair is ideal for recurrent inguinal hernia patients who had previous anterior repair and bilateral hernias. Contraindications to robotic hernia repair are the same as for laparoscopic repair and include coagulopathy and/or severe cardiopulmonary disease precluding induction of general anesthesia and pneumoperitoneum. Previous preperitoneal repair is a relative contraindication along with the presence of a large incarcerated inguinal hernia.

Patient evaluation should proceed similarly to workup for laparoscopic inguinal herniorrhaphy.

**Technique.** Patients are instructed to void in the preoperative area to avoid Foley catheter placement, though some surgeons advocate routine Foley catheter placement. Ideally, the operating table should have capability of synchronization with robotic arms to prevent injury to the patient during repositioning during the procedure. The patient is placed in supine position with arms tucked at both sides. Appropriate padding of extremities is important to avoid neuropraxia and trauma from robotic arm movements. Three trocars are typically used for TAPP repair. Open Hasson technique is employed for initial trocar placement at umbilicus; this can be an 8-mm trocar or alternatively a 12-mm with a telescoped 8-mm trochar. Additionally, two 8-mm trocars are placed in each side of the mid-abdomen, slightly above the level of umbilicus. After trocar placement, the robot is docked and targeted, and the patient is placed in Trendelenburg position. Typically, the surgeon will use robotic shears attached to electrocautery, Cadiere forceps, and a needle holder as the primary instruments. This combination provides optimal cost-effectiveness because the majority of the cost associated with robotic application is due to disposable instruments. Exposure starts with incising the parietal peritoneum from the medial umbilical ligament to the anterior superior iliac spine. A peritoneal flap is developed by blunt and sharp dissection with robotic shears in the preperitoneal space. Special care is taken to leave the preperitoneal fat pad containing nerves and vessels with the anterior abdominal wall. Small vessels can be coagulated with application of electrocautery with scissors. With the aid of pneumoperitoneum, the preference is first to perform a lateral dissection in the space of Bogros. Dissection continues in this plane laterally towards the anterior superior iliac spine. The generous development of a peritoneal flap will ensure successful mesh placement at the end. Then the space of Retzius is entered medially exposing the pubic symphysis. In the absence of haptic feedback, visual recognition of the pubic symphysis is crucial as this serves as an important landmark for further dissection. Inferior epigastric vessels are readily identified. Next, an inferior peritoneal flap is developed to avoid rolling of mesh during closure. Direct, indirect, and femoral spaces are carefully examined. Cadiere forceps are then used to grasp the hernia sac to provide traction. Any cord lipoma is carefully dissected free from the cord structures, and the testicular vessels, pampiniform plexus, and ductus deferens are separated from hernia sac. These structures can usually be identified at the neck of sac. Reduction is successful when the sac stays reduced after traction is released. The next step is placement of the mesh. Lightweight barbed mesh and anatomically preshaped mesh are routinely used. Mesh should be an appropriate size to cover the myopectineal orifice entirely, and the peritoneal dissection will need to be large enough to accommodate this size mesh. It is rolled and placed through one of the ports by the bedside assistant. Then it is unrolled and placed in the pelvis overlapping the pubic symphysis by several centimeters medially; this is essential as the majority of recurrences occur in this area. Utilization of tacking devices are not necessary, which helps to reduce procedural cost; however, this is surgeon preference. Finally, the peritoneal flap is placed back over the mesh layer and sutured back into place with a running locking suture that is facilitated by the increased intracorporeal dexterity of the robotic instruments. Then the fascia of the umbilical trochar site is closed with 0-absorbable suture (Fig 37-24), and the skin is closed with absorbable monofilament suture.

**Prosthesis Considerations**

The success of prosthetic repairs has generated considerable debate about the desirable physical attributes of mesh and their fixation. An ideal mesh should be easy to handle, flexible,
Figure 37-24. Steps in robotic TAPP repair. A. Image of a direct inguinal hernia. B. There is no visible hernia on the contralateral side. C. Hernia contents and sac are dissected and cleared for mesh placement. D. Unrolling and placement of mesh. E. Satisfactory placement of mesh. F. Closure of peritoneum. G. Completed repair of hernia with comparison to contralateral side.
strong, immunologically inert, contraction-resistant, infection-resistant, and inexpensive to manufacture. The following section reviews the most common types of mesh and fixatives currently available.

**Synthetic Mesh Material.** Polypropylene and polyester are the most common synthetic prosthetic materials used in hernia repair. These materials are permanent and hydrophobic, and they promote a local inflammatory response that results in cellular infiltration and scarring with slight contraction in size. Other synthetic mesh materials are under investigation with the goals of minimizing postoperative pain and preventing infection or recurrence. In selecting mesh material, considerations include mesh absorbability, thickness, weight, porosity, and strength.

Variations in the fiber diameter and fiber count of mesh materials categorize them as heavyweight or lightweight in density, though there does not seem to be a universally agreed upon set of criteria for either. Commonly used lightweight mesh materials include β-d-glucan, titanium-coated polypropylene, and polypropylene–poliglecaprone. These materials have greater elasticity and less theoretical surface area contact with surrounding tissues than their heavyweight counterparts. They are hypothesized to reduce scarring and chronic pain without compromising the strength of the repair. The use of lightweight mesh use in TEP and TAPP repairs is associated with fewer 3-month cumulative mesh-related complications. A 2012 meta-analysis of 2310 patients undergoing open or laparoscopic hernia repairs found a lower incidence of chronic pain (relative risk [RR] 0.61, CI 0.50–0.74) following use of lightweight mesh versus heavyweight mesh and no significant difference in rates of recurrence.

When available, lightweight mesh should be considered for all prosthetic repairs to minimize postoperative chronic pain.

A disadvantage of currently available commercial prostheses is their high cost. In settings where resources are limited, prosthetic repairs are performed using alternative materials. Polypropylene and polyethylene mosquito nets are inexpensive and ubiquitous in sub-Saharan Africa and India, and they have similar mechanical properties to commercially available hernioplasty meshes. Meta-analysis of 577 hernioplasties performed using sterilized mosquito nets demonstrated similar rates of short-term mesh-related complications (6.1%) and recurrence (0.17%) to those using commercial meshes. Furthermore, the disability-adjusted life years (DALYs) prevented by inguinal hernia repair signify a comparable impact to that of vaccination in sub-Saharan Africa. Expensive prostheses are not necessarily needed for hernia surgery, whether in resource-limited or in resource-abundant settings, and the anticipated benefits should be evaluated with consideration of increased costs.

**Biologic Mesh.** Although indications for the use of biologic prostheses have not been absolutely defined, they are commonly reserved for contaminated cases or when domain expansion is necessary in the face of high infection risk. This is partially on account of their high cost and high recurrence rates. There are numerous biologic materials available with differing properties, but in general, they have a lower tensile strength and subsequently higher rates of rupture than synthetic prostheses. They also have varying degrees of tensile strength and tissue biocompatibility between them. In ventral hernia repairs, xenograft material was associated with a lower rate of recurrence than allograft material. A review of biologic materials concludes cross-linked graft materials are more durable and less prone to failure than non–cross-linked grafts. Nevertheless, their diminished ability to remodel adversely affects rates of infection and incorporation. While new prosthetic materials continue to be developed, no single biologic warrants routine use. These materials will continue to evolve, and they remain an important tool for challenging cases when used judiciously.

**Fixation Technique.** Independent of prosthesis material, the method of its fixation remains disputed. Suturing, stapling, and tack ing prostheses entail tissue perforation, which may cause inflammation, neurovascular injury, and chronic pain development. Conversely, improper prosthesis fixation may result in mesh migration, repair failure, meshoma pain, and hernia recurrence. Mesh may be fixed with fibrin-derived glue, and self-gripping mesh has been developed to minimize trauma to surrounding tissues and to reduce the risk for entrapment neuropathy. For hernias repaired via a strictly preperitoneal approach, prosthesis fixation may not be necessary at all.

Fibrin glue fixation is a successful alternative to tackle fixation in hernia repair with a synthetic prosthesis. Recent studies comparing fibrin glue fixation and suture fixation in open hernia repair showed superior rates of chronic pain with both Lichtenstein and Plug and Patch techniques. Meta-analyses of endoscopic hernia repair determined the incidence of chronic postoperative pain after tacker fixation was significantly higher than after fibrin glue fixation, with one showing a relative risk of 4.64 (CI 1.9–11.7). Rates of other postoperative complications and recurrence were similar between both fixation methods. Glue fixation is a promising technical refinement, and several studies have shown long-term benefit; however, its questionable efficacy in larger hernias and cost remain considerations.

In TEP repairs, fixation of mesh may not be compulsory. A prospective randomized trial comparing fixation and no fixation in TEP repairs found a significant increase in new pain and equivalent recurrence rates in the fixation group several months after repair. A 2012 meta-analysis comparing laparoscopic tacker mesh fixation to no mesh fixation found no statistically significant differences in operative duration, pain, mesh-related complications, recurrence, or length of stay between the two methods. Studies of three-dimensional, ergonomically contoured mesh without fixation, as well as self-gripping meshes, have yielded similar results. In the preperitoneal approach, the reapproximation of surrounding tissues and physiologic intra-abdominal pressure hypothetically prevent mesh migration. Due to higher theoretical risk of mesh migration, repair without fixation is not recommended for anterior or transperitoneal approaches.

**COMPLICATIONS**

As with other clean operations, the most common complications of inguinal hernia repair include bleeding, infection, seroma, urinary retention, ileus, and injury to adjacent structures (Table 37-6). Complications specific to herniorrhaphy include hernia recurrence, chronic inguinal and pubic pain, and injury to the spermatic cord or testis. The incidence, prevention, and treatment of these complications are discussed in the ensuing section.

**Hernia Recurrence**

When a patient develops pain, bulging, or a mass at the site of an inguinal hernia repair, clinical entities such as seroma, persistent cord lipoma, and hernia recurrence should be considered. Common medical issues associated with recurrence include malnutrition, immunosuppression, diabetes, steroid use, and smoking. Technical causes of recurrence include improper mesh size, tissue

Other chronic pain syndromes include local nerve entrapment, meralgia paresthesia, and osteitis pubis. At greatest ischemia, infection, and tension in the reconstruction. A focused physical examination should be performed. As with primary hernias, US, CT, or MRI can elucidate ambiguous physical findings. When a recurrent hernia is discovered and warrants reoperation, an approach through a virgin plane facilitates its dissection and exposure. Extensive dissection of the scarred field and mesh may result in injury to cord structures, viscera, large blood vessels, and nerves. After an initial anterior approach, the posterior endoscopic approach will usually be easier and more effective than another anterior dissection. Conversely, failed preperitoneal repairs should be approached using an open anterior repair.

### Pain

Pain after inguinal hernia repair is classified into acute or chronic manifestations of three mechanisms: nociceptive (somatic), neuropathic, and visceral pain. Nociceptive pain is the most common of the three. Because it is usually a result of ligamentous or muscular trauma and inflammation, nociceptive pain is reproduced with abdominal muscle contraction. Treatment consists of rest, nonsteroidal anti-inflammatory drugs (NSAIDs), and reassurance as it resolves spontaneously in most cases. Neuropathic pain occurs as a result of direct nerve damage or entrapment. It may present early or late, and it manifests as a localized, sharp, burning, or tearing sensation. It may respond to pharmacologic therapy and to local steroid or anesthetic injections when indicated. Visceral pain refers to pain conveyed through afferent autonomic pain fibers. It is usually poorly localized and may occur during ejaculation as a result of sympathetic plexus injury.

Chronic postoperative pain remains an important measure of clinical outcome that has been reported in as many as 63% of inguinal hernia repair cases. Despite the significant anatomic variation in the three inguinal nerves, literature reviews suggest identification of all three nerves is possible in 70% to 90% of cases. Meticulous nerve identification may prevent injury that results in debilitating chronic postoperative pain syndromes. Notwithstanding, moderate-to-severe pain adversely affects physical activity, social interactions, health care utilization, employment, and productivity in 6% to 8% of patients. Pain in this subset of patients comprises a tremendous individual and societal burden.

Postherniorrhaphy inguinodynia is a debilitating chronic complication. Its incidence is independent of the method of hernia repair. Selective ilioinguinal, iliohypogastric, and genitofemoral nerve injury/myectomy, removal of mesh and fixation material, and revision of the repair are the three most common options for treatment. Nevertheless, anatomic variation and cross-innervation of the inguinal nerves in the retroperitoneum and inguinal canal make selective myectomy less reliable. When inguinodynia is refractory to pharmacologic and interventional measures, triple myectomy with removal of meshoma is routinely performed with acceptable outcomes in the majority of patients. Refractory inguinodynia with concurrent orchialgia also requires resection of the paravasal nerves.

A relatively newly described technique that has cited good outcomes is the laparoscopic triple myectomy. This involves laparoscopic approach to and division of the main trunks of the ilioinguinal and iliohypogastric nerves and additional division of the genitofemoral nerve in the lumbar plexus. Several studies with moderate numbers of patients treated showed durable reduction in pain scores.

Other chronic pain syndromes include local nerve entrapment, meralgia paresthesia, and osteitis pubis.
risk of entrapment are the ilioinguinal and iliohypogastric nerves in anterior repairs and the genitofemoral and lateral femoral cutaneous nerves in endoscopic repairs. Clinical manifestations of nerve entrapment mimic acute neuropathic pain, and they occur with a dermatomal distribution. Injury to the lateral femoral cutaneous nerve results in meralgia paresthetica, a condition characterized by persistent paresthesia of the lateral thigh. Initial treatment of nerve entrapment consists of rest, ice, NSAIDs, physical therapy, and possible local corticosteroid and anesthetic injection. This can be followed by a trial of gabapentin or its analogues. Osteitis pubis is characterized by inflammation of the pubic symphysis and usually presents as medial groin or symphyseal pain that is reproduced by thigh adduction. Avoiding the pubic periosteum when placing sutures and tacks reduces the risk of developing osteitis pubis. CT scan or MRI excludes hernia recurrence, and bone scan is confirmatory for the diagnosis. Initial treatment is identical to that of nerve entrapment; however, if pain remains intractable, orthopedic surgery consultation should be sought for possible bone resection and curettage. Irrespective of treatment, the condition often takes six months to resolve.

**Cord and Testes Injury**

Injury to spermatic cord structures may result in ischemic orchitis or testicular atrophy. Ischemic orchitis is most commonly caused by injury to the pampiniform plexus and not to the testicular artery. It usually manifests within 1 week of inguinal hernia repair as an enlarged, indurated, and painful testis, and it is almost certainly self-limited. It occurs in <1% of primary hernia repairs; however, this figure is larger for recurrent inguinal hernia repairs. US will demonstrate testicular blood flow to differentiate between ischemia and necrosis. Emergent orchiectomy is only necessary in the case of necrosis. Injury to the testicular artery itself may lead to testicular atrophy, which is manifest over a protracted period but does not always lead to testicular necrosis. This is because despite compromise of the artery, there is collateral flow from the inferior epigastric, vesical, prostatic, and scrotal arteries that supply the testes, and in the case of insufficiency, there is atrophy. Treatment for ischemic orchitis most frequently consists of reassurance, NSAIDs, and comfort measures. Intraoperatively, proximal ligation of large hernia sacs to avoid cord manipulation minimizes the risk of injury.

Injury to the vas deferens within the cord may lead to infertility. In open inguinal hernia repairs, isolating the vas deferens along with the cord structures using digital manipulation may cause injury or disruption. In endoscopic approach, grasping the vas may result in a crush injury. Transections of the vas deferens should be addressed with a urologic consult and early anastomosis, if possible. Historically, surgeons and their patients speculated that synthetic material would increase the risks of mesh rejection, carcinogenesis, and inflammation; however, as mesh became used more frequently, these concerns did not manifest. Nevertheless, one study found prosthetic mesh may exert long-term deleterious effects upon the vas deferens, causing azoospermia. Similar studies report varied results, though. A recent prospective study from the Swedish Hernia Registry discovered no difference in rates of patient-reported infertility between the general population and patients who underwent either mesh or tissue-based inguinal hernia repair. Chronic scarring may lead to vas deferens obstruction, resulting in decreased fertility rates and a dysejaculation syndrome. Pain and burning during ejaculation are usually self-limited, and more common causes, such as sexually transmitted diseases, should be excluded.

In females, the round ligament is the analog to the spermatic cord, and it maintains uterine antversion. Injury to the artery of the round ligament does not result in clinically significant morbidity.

**Laparoscopic Complications**

In general, the risks of the TEP technique mirror those of open anterior repairs, as the peritoneal space is not violated. Complications of transabdominal laparoscopy include urinai retention, paralytic ileus, visceral injuries, vascular injuries, and less commonly, bowel obstruction, hypercapnia, gas embolism, and pneumothorax. The most common complications of endoscopic inguinal hernia repair are presented in this section.

**Urinary Retention.** The most common cause of urinary retention after hernia repair is general anesthesia, which is routine in endoscopic hernia repairs. Among 880 patients undergoing inguinal hernia repair with local anesthesia only, 0.2% developed urinary retention, while the rate of urinary retention was 13% among 200 patients undergoing repair with general or spinal anesthesia. Overall, the risk of development of postoperative urinary retention is 2% to 3%. Other risk factors for postoperative urinary retention include pain, narcotic analgesia, and perioperative bladder distention. Initial treatment of urinary retention requires decompression of the bladder with short-term catheterization. Patients will generally require an overnight admission and trial of normal voiding before discharge. Failure to void normally requires reinsertion of the catheter for up to a week. Chronic requirement of a urinary catheter is rare, though older patients may require prolonged catheterization. Risk of urinary retention can be minimized by ensuring voiding prior to surgery and minimization of perioperative fluid administration.

**Ileus and Bowel Obstruction.** The laparoscopic transabdominal approach is associated with a higher incidence of ileus than other modes of repair. This complication is self-limited; however, it necessitates sustained inpatient observation, intravenous fluid maintenance, and possibly nasogastric decompression. Abdominal imaging may be helpful to confirm the diagnosis and to exclude bowel obstruction. Prolonged absence of bowel function, in conjunction with a suspicious abdominal series, should raise concern for obstruction. In this case, CT of the abdomen is helpful to distinguish anatomic sites of obstruction, inflammation, and ischemia. In TAPP repairs, obstruction occurs most commonly secondary to herniation of bowel loops through peritoneal defects or large trocar insertion sites; however, the use of smaller trocars and the preponderance of TEP repairs have reduced the frequency of this complication. True obstruction warrants reoperation.

**Visceral Injury.** Small bowel, colon, and bladder are at risk for injury in laparoscopic hernia repair. The presence of intraabdominal adhesions from previous surgeries may predispose to visceral injuries. Direct bowel injuries may also result from trocar placement. In reoperative abdominal surgery, open Hasson technique and direct visualization of trocars are recommended to reduce the likelihood of visceral injury. Bowel injury may also occur secondary to electrocautery and instrument trauma outside of the camera field. Missed bowel injuries are associated with increased mortality. If injury to the bowel is suspected, its entire length should be examined, and conversion to open repair may be necessary.
Bladder injuries are less common than visceral injuries, and they are usually associated with perioperative bladder distention or extensive dissection of perivesical adhesions. As with bladder injuries encountered in open surgery, cystotomies must be repaired in several layers with 1 to 2 weeks of Foley catheter decompression. A confirmatory cystogram may be performed before catheter removal to confirm healing of the injury.

**Vascular Injury.** The most severe vascular injuries usually occur in iliac or femoral vessels, either by misplaced sutures in anterior repairs, endoscopic tack use, or by trocar injury or direct dissection in laparoscopic repairs. In these cases, exsanguination may be swift. Conversion to an open approach may be necessary, and bleeding should be temporarily controlled with mechanical compression until vascular control is obtained.

The most commonly injured vessels in laparoscopic hernia repair include the inferior epigastrics and external iliac arteries. Although apparent upon initial approach, these vessels may be obscured during mesh positioning, and tacks or staples may injure them. Oftentimes, due to tamponade effect, injury to the inferior epigastric vessels is not apparent until the adjacent trocar is removed. If injured, the inferior epigastrics may be ligated with a percutaneous suture passer or endoscopic vessel clips.

If the tissue pressure exerted by pneumoperitoneum is greater than an injured vessel’s hydrostatic intraluminal pressure, bleeding will not manifest until pneumoperitoneum is released. The presentation of an inferior epigastric vein injury is often delayed because of this effect, and it may result in a significant rectus sheath hematoma. Accordingly, the surgeon should be aware of this intraoperative consideration.

### Hematomas and Seromas

Hematomas may present as localized collections or as diffuse bruising over the operative site. Injury to spermatic cord vessels may result in a scrotal hematoma. Although they are self-limited, characteristic dark blue discoloration of the entire scrotum may alarm patients. Intermittent warm and cold compression aids in resolution. Hematomas may also develop in the incision, retroperitoneum, rectus sheath, and peritoneal cavity. The latter three sites are more frequently associated with laparoscopic repair. Bleeding within the peritoneum or preperitoneal space may not be readily apparent on physical examination. For this reason, close monitoring of subjective complaints, vital signs, urine output, and physical parameters is necessary.

Seromas are fluid collections that most commonly develop within one week of synthetic mesh repairs. Large hernia sac remnants may fill with physiologic fluid and mimic seromas. Patients often mistake seromas for early recurrence. Treatment consists of reassurance and warm compression to accelerate resolution. To avoid secondary infection, seromas should not be aspirated unless they cause discomfort or they restrict activity for a prolonged time.

### OUTCOMES

The incidence of recurrence is the most-cited measure of postoperative outcome following inguinal hernia repair. In evaluating the various available techniques, other salient signifiers of outcome include complication rates, operative duration, hospital stay, and quality of life. The following section summarizes the evidence-based outcomes of the various approaches to inguinal hernia repair.

Among tissue repairs, the Shouldice operation is the most commonly performed technique, and it is most frequently executed at specialized centers. A 2012 meta-analysis from the Cochrane database demonstrated significantly lower rates of hernia recurrence (OR 0.62, CI 0.45–0.85) in patients undergoing Shouldice operations when compared with other open tissue-based methods.96 In experienced hands, the overall recurrence rate for the Shouldice repair is about 1%.97 Although it is an elegant procedure, its meticulous nature requires significant technical expertise to achieve favorable outcomes, and it is associated with longer operative duration and longer hospital stay. One study found the recurrence rate for Shouldice repairs decreased from 9.4% to 2.5% after surgeons performed the repair six times.99 Compared with mesh repairs, the Shouldice technique resulted in significantly higher rates of recurrence (OR 3.65, CI 1.79–7.47); however, it is the most effective tissue-based repair when mesh is unavailable or contraindicated.97

Hernia recurrence is drastically reduced as a result of the Lichtenstein tension-free repair.100 Compared with open elective tissue-based repairs, mesh repair is associated with fewer recurrences (OR 0.37, CI 0.26–0.51) and with shorter hospital stay and faster return to usual activities,101,102 In a multi-institutional series, 3019 inguinal hernias were repaired using the Lichtenstein technique, with an overall recurrence rate of 0.2%,103 Among other tension-free repairs, the Lichtenstein technique remains the most commonly performed procedure worldwide. Meta-analysis demonstrates no significant differences in outcomes between the Lichtenstein and the Plug and Patch techniques; however, intra-abdominal plug migration and erosion into contiguous structures occurs in approximately 6% of cases.101,104,105 The Stoppa technique results in longer operative duration than the Lichtenstein technique. Nevertheless, postoperative acute pain, chronic pain, and recurrence rates are similar between the two methods.106 Perhaps the most compelling advantage of the Lichtenstein technique is that nonexpert surgeons rapidly achieve similar outcomes to their expert counterparts. Guidelines issued by the European Hernia Society recommend the Lichtenstein repair for adults with either unilateral or bilateral inguinal hernias as the preferred open technique.102 Compared to open approaches, endoscopic primary inguinal hernia repair produces equivalent recurrence rates and improved recovery time, pain prevention, and return to normal activities.107 In a study of 168 patients randomized to either TEP or Lichtenstein repair, the 5-year recurrence rates were extremely low in both groups.108,109 Similarly, a study of 200 male patients randomized to either ambulatory TEP or Lichtenstein repair demonstrated no recurrences in either group after one year.110 Because endoscopic surgery requires specialized instruments and longer operative times, its cost is higher than conventional open repair; however, the potential financial benefit of shorter recovery and decreased pain may offset these costs in the long-term.

Perhaps the most salient difference between open and endoscopic techniques is the number of cases needed to develop technical proficiency. In a randomized controlled trial performed by the VA Cooperative Study, two-year recurrence rates were 10.1% in patients undergoing endoscopic repair and 4.9% in those undergoing open repair, and the outcomes of endoscopic repairs improved after each surgeon performed at least 250 cases.111 More recently, Lal and colleagues found that surgeons sustained a decrease from 9% to 2.9% in postoperative recurrences after performing 100 TEP operations.112 Other studies also suggest surgeons develop proficiency in these endoscopic techniques after performing 30
to 100 cases; however, this estimate has decreased precipitously since laparoscopic technique was first introduced.11,13,14

Although controversy persists regarding the utility of TEP versus TAPP, reviews to date find no significant differences in operative duration, length of stay, time to recovery, or short-term recurrence rate between the two approaches. In TAPP repair, the risk of intra-abdominal injury is higher than in TEP repair. This finding prompted the IEHS to recommend TAPP should only be attempted by surgeons with sufficient experience.12 A Cochrane systematic review found rates of port-site hernias and visceral injuries were higher for the TAPP technique, while TEP may be associated with a higher rate of conversion to an alternative approach; however, neither finding was sufficiently compelling to recommend one technique over the other.14

The frequency with which the aforementioned inguinal hernia repair techniques are performed reinforces the importance of broad experience. The authors recommend that surgeons become proficient in several techniques to address different manifestations of inguinal hernias. Surgeons should tailor this experience to optimize outcomes for each patient.

THYROID

Historical Background

Goiters (from the Latin guttur, throat), defined as an enlargement of the thyroid, have been recognized since 2700 B.C. even though the thyroid gland was not documented as such until the Renaissance period. In 1619, Hieronymus Fabricius ab Aquapendente recognized that goiters arose from the thyroid gland. The term thyroid gland (Greek thyreoïdes, shield-shaped) is, however, attributed to Thomas Wharton in his Adenographia (1656). In 1776, the thyroid was classified as a ductless gland by Albrecht von Haller and was thought to have numerous functions ranging from lubrication of the larynx to acting as a reservoir for blood to provide continuous flow to the brain, and to beautifying women’s necks. Burnt seaweed was considered to be the most effective treatment for goiters.

The first accounts of thyroid surgery for the treatment of goiters were given by Roger Frugardi in 1170. In response to failure of medical treatment, two setons were inserted at right angles into the goiter and tightened twice daily until the goiter separated. The open wound was treated with caustic powder and left to heal. However, thyroid surgery continued to be hazardous with prohibitive mortality rates (>40%) until the latter half of the 19th century, when advances in general anesthesia, antisepsis, and hemostasis enabled surgeons to perform thyroid surgery with significantly reduced mortality and morbidity rates. The most notable thyroid surgeons were Emil Theodor Kocher (1841–1917) and C.A. Theodor Billroth (1829–1894), who performed thousands of operations with increasingly successful results. However, as more patients survived thyroid operations, new problems and issues became apparent. After total thyroidectomy, patients (particularly children) became myxedematous with cretinous features. Myxedema was first effectively treated in 1891 by George Murray using a subcutaneous injection of an extract of sheep’s thyroid, and later, Edward Fox demonstrated that oral therapy was equally effective. In 1909, Kocher was awarded the Nobel Prize for medicine in recognition “for his works on the physiology, pathology, and surgery of the thyroid gland.”

Embryology

The thyroid gland arises as an outpouching of the primitive foregut around the third week of gestation. It originates at the floor of the pharyngeal anlage thicken to form the medial thyroid anlage (Fig. 38-1) that descends in the neck anterior to structures that form the hyoid bone and larynx. During its descent, the anlage remains connected to the foramen cecum via an epithelial-lined tube known as the thyroglossal duct. The epithelial cells making up the anlage give rise to the thyroid follicular cells. The paired lateral anlages originate from the fourth branchial pouch and fuse with the median anlage at approximately the fifth week of gestation. The lateral anlages are neuroectodermal in origin (ultimobranchial bodies) and provide the calcitonin producing parafollicular or C cells, which thus come to lie in the superoposterior region of the gland. Thyroid follicles are initially apparent by 8 weeks, and colloid formation begins by the 11th week of gestation.

Developmental Abnormalities

Thyroglossal Duct Cyst and Sinus. Thyroglossal duct cysts are the most commonly encountered congenital cervical anomalies. During the fifth week of gestation, the thyroglossal duct lumen starts to obliterate, and the duct disappears by the eighth week of gestation. Rarely, the thyroglossal duct may persist in whole or in part. Thyroglossal duct cysts may occur anywhere along the migratory path of the thyroid, although 80% are found in juxtaposition to the hyoid bone. They are usually asymptomatic but occasionally become infected by oral bacteria, prompting the patient to seek medical advice. Thyroglossal duct sinuses
result from infection of the cyst secondary to spontaneous or surgical drainage of the cyst and are accompanied by minor inflammation of the surrounding skin. Histologically, thyroglossal duct cysts are lined by pseudostratified ciliated columnar epithelium and squamous epithelium, with heterotopic thyroid tissue present in 20% of cases.

The diagnosis usually is established by observing a 1- to 2-cm, smooth, well-defined midline neck mass that moves upward with protrusion of the tongue. Routine thyroid imaging is not necessary, although thyroid scintigraphy and ultrasound have been performed to document the presence of normal thyroid tissue in the neck. Treatment involves the “Sistrunk operation,” which consists of en bloc cystectomy and excision of the central hyoid bone to minimize recurrence. Approximately 1% of thyroglossal duct cysts are found to contain cancer, which is usually papillary (85%). The role of total thyroidectomy in this setting is debated, but it is advised in patients with large tumors, particularly if there are additional thyroid nodules and evidence of cyst wall invasion or lymph node metastases. Squamous, Hurthle cell, and anaplastic cancers also have been reported but are rare. Medullary thyroid cancers (MTCs) are, however, not found in thyroglossal duct cysts.

**Lingual Thyroid.** A lingual thyroid represents a failure of the median thyroid anlage to descend normally and may be the only thyroid tissue present. Intervention becomes necessary for obstructive symptoms such as choking, dysphagia, airway obstruction, or hemorrhage. Many of these patients develop hypothyroidism. Medical treatment options include administration of exogenous thyroid hormone to suppress thyroid-stimulating hormone (TSH) and radioactive iodine (RAI) ablation followed by hormone replacement. Surgical excision is rarely needed but, if required, should be preceded by an evaluation of normal thyroid tissue in the neck to avoid inadvertently rendering the patient hypothyroid.

**Ectopic Thyroid.** Normal thyroid tissue may be found anywhere in the central neck compartment, including the esophagus, trachea, and anterior mediastinum. Thyroid tissue has been observed adjacent to the aortic arch, in the aortopulmonary window, within the upper pericardium, or in the interventricular septum. Often, “tongues” of thyroid tissue are seen to extend off the inferior poles of the gland and are particularly apparent in large goiters. Thyroid tissue situated lateral to the carotid sheath and jugular vein, previously termed lateral aberrant thyroid, almost always represents metastatic thyroid cancer in lymph nodes, and not remnants of the lateral anlage that had

---

**Figure 38-1.** Thyroid embryology—early development of the median thyroid anlage as a pharyngeal pouch. *(Reproduced with permission from Cady B, Rossi R: Surgery of the Thyroid and Parathyroid Glands. Philadelphia, PA: WB Saunders; 1991.)*
failed to fuse with the main thyroid, as previously suggested by Crile. Even if not readily apparent on physical examination or ultrasound imaging, the ipsilateral thyroid lobe contains a focus of papillary thyroid cancer (PTC), which may be microscopic.

**Pyramidal Lobe.** Normally the thyroglossal duct atrophies, although it may remain as a fibrous band. In about 50% of individuals, the distal end that connects to the thyroid persists as a pyramidal lobe projecting up from the isthmus, lying just to the left or right of the midline. In the normal individual, the pyramidal lobe is not palpable, but in disorders resulting in thyroid hypertrophy (e.g., Graves’ disease, diffuse nodular goiter, or lymphocytic thyroiditis), the pyramidal lobe usually is enlarged and palpable.

**Thyroid Anatomy**
The anatomic relations of the thyroid gland and surrounding structures are depicted in Fig. 38-2. The adult thyroid gland is brown in color and firm in consistency and is located posterior to the strap muscles. The normal thyroid gland weighs approximately 20 g, but gland weight varies with body weight and iodine intake. The thyroid lobes are located adjacent to the thyroid cartilage and connected in the midline by an isthmus that is located just inferior to the cricoid cartilage. A pyramidal lobe is present in about 50% of patients. The thyroid lobes extend to the midthyroid cartilage superiorly and lie adjacent to the carotid sheaths and sternocleidomastoid muscles laterally. The strap muscles (sternohyoid, sternothyroid, and superior belly of the omohyoid) are located anteriorly and are innervated by the ansa cervicalis (ansa hypoglossi). The thyroid gland is enveloped by a loosely connecting fascia that is formed from the partition of the deep cervical fascia into anterior and posterior divisions. The true capsule of the thyroid is a thin, densely adherent fibrous layer that sends out septa that invaginate into the gland, forming pseudolobules. The thyroid capsule is condensed into the posterior suspensory or Berry’s ligament near the cricoid cartilage and upper tracheal rings.

**Figure 38-2.** Anatomy of the thyroid gland and surrounding structures, viewed anteriorly (A) and in cross-section (B). a. = artery; m. = muscle; n. = nerve; v. = vein.
Blood Supply. The superior thyroid arteries arise from the ipsilateral external carotid arteries and divide into anterior and posterior branches at the apices of the thyroid lobes. The inferior thyroid arteries arise from the thyrocervical trunk shortly after their origin from the subclavian arteries. The inferior thyroid arteries travel upward in the neck posterior to the carotid sheath to enter the thyroid lobes at their midpoint. A thyroidea ima artery arises directly from the aorta or innominate in 1% to 4% of individuals to enter the isthmus or replace a missing inferior thyroid artery. The inferior thyroid artery crosses the recurrent laryngeal nerve (RLN), necessitating identification of the RLN before the arterial branches can be ligated. The venous drainage of the thyroid gland occurs via multiple small surface veins, which coalesce to form three sets of veins—the superior, middle, and inferior thyroid veins. The superior thyroid veins run with the superior thyroid arteries bilaterally. The middle vein or veins are the least consistent. The superior and middle veins drain directly into the internal jugular veins. The inferior veins often form a plexus, which drains into the brachiocephalic veins.

Nerves. The left RLN arises from the vagus nerve where it crosses the aortic arch, loops around the ligamentum arteriosum, and ascends medially in the neck within the tracheoesophageal groove. The right RLN arises from the vagus at its crossing with the right subclavian artery. The nerve usually passes posterior to the artery before ascending in the neck, its course being more oblique than the left RLN. Along their course in the neck, the RLNs may branch, and pass anterior, posterior, or interdigitate with branches of the inferior thyroid artery (Fig. 38-3). The right RLN may be nonrecurrent in 0.5% to 1% of individuals and often is associated with a vascular anomaly. Nonrecurrent left RLNs are rare but have been reported in patients with situs inversus and a right-sided aortic arch. The RLN may branch in its course in the neck, and identification of a small nerve should alert the surgeon to this possibility. Identification of the nerves or their branches often necessitates mobilization of the most lateral and posterior extent of the thyroid gland, the tubercle of Zuckerkandl, at the level of the cricoid cartilage. The last segments of the nerves often course below the tubercle and are closely approximated to the ligament of Berry. Branches of the nerve may traverse the ligament in 25% of individuals and are particularly vulnerable to injury at this junction. The RLNs terminate by entering the larynx posterior to the cricothyroid muscle.

The RLNs innervate all the intrinsic muscles of the larynx, except the cricothyroid muscles, which are innervated by the external laryngeal nerves. Injury to one RLN leads to paralysis of the ipsilateral vocal cord, which comes to lie in the paramedian or the abducted position. The paramedian position results in a normal but weak voice, whereas the abducted position leads to a hoarse voice and an ineffective cough. Bilateral RLN injury may lead to airway obstruction, necessitating emergency tracheostomy, or loss of voice. If both cords come to lie in an abducted position, air movement can occur, but the patient has an ineffective cough and is at increased risk of repeated respiratory tract infections from aspiration.

The superior laryngeal nerves also arise from the vagus nerves. After their origin at the base of the skull, these nerves...
travel along the internal carotid artery and divide into two branches at the level of the hyoid bone. The internal branch of the superior laryngeal nerve is sensory to the supraglottic larynx. Injury to this nerve is rare in thyroid surgery, but its occurrence may result in aspiration. The external branch of the superior laryngeal nerve lies on the inferior pharyngeal constrictor muscle and descends alongside the superior thyroid vessels before innervating the cricothyroid muscle. Cernea and colleagues proposed a classification system to describe the relationship of this nerve to the superior thyroid vessels (Fig. 38-4). The type 2a variant, in which the nerve crosses below the tip of the thyroid superior pole, occurs in up to 20% of individuals and places the nerve at a greater risk of injury. Therefore, the superior pole vessels should not be ligated en masse, but should be individually divided, low on the thyroid gland and dissected lateral to the cricothyroid muscle. Injury to this nerve leads to inability to tense the ipsilateral vocal cord and hence difficulty “hitting high notes,” difficulty projecting the voice, and voice fatigue during prolonged speech.

Sympathetic innervation of the thyroid gland is provided by fibers from the superior and middle cervical sympathetic ganglia. The fibers enter the gland with the blood vessels and are vasomotor in action. Parasympathetic fibers are derived from the vagus nerve and reach the gland via branches of the laryngeal nerves.

**Parathyroid Glands.** The embryology and anatomy of the parathyroid glands are discussed in detail in the “Parathyroid Gland” section of this chapter. About 85% of individuals have four parathyroid glands that can be found within 1 cm of the junction of the inferior thyroid artery and the RLN. The superior glands are usually located dorsal to the RLN, whereas the inferior glands are usually found ventral to the RLN (Fig. 38-5).

**Lymphatic System.** The thyroid gland is endowed with an extensive network of lymphatics. Intraglandular lymphatic vessels connect both thyroid lobes through the isthmus and also drain to perithyroidal structures and lymph nodes. Regional lymph nodes include pretracheal, paratracheal, perithyroidal, RLN, superior mediastinal, retropharyngeal, esophageal, and upper, middle, and lower jugular chain nodes. These lymph nodes can be classified into seven levels as depicted in Fig. 38-6. The central compartment includes nodes located in the area between the two carotid sheaths, whereas nodes lateral to the vessels are present in the lateral compartment. Thyroid cancers may metastasize to any of these regions, although metastases to submaxillary nodes (level I) are rare (<1%). There also can be “skip” metastases to nodes in the lateral ipsilateral neck without central neck nodes.

**Thyroid Histology**

Microscopically, the thyroid is divided into lobules that contain 20 to 40 follicles (Fig. 38-7). There are about $3 \times 10^6$ follicles in the adult male thyroid gland. The follicles are spherical and average 30 μm in diameter. Each follicle is lined by cuboidal epithelial cells and contains a central store of colloid secreted from the epithelial cells under the influence of the pituitary hormone TSH. The second group of thyroid secretory cells is the C cells or parafollicular cells, which contain and secrete the hormone calcitonin. They are found as individual cells or clumped in small groups in the interfollicular stroma and located in the upper poles of the thyroid lobes.

**Thyroid Physiology**

**Iodine Metabolism.** The average daily iodine requirement is 0.1 mg, which can be derived from foods such as fish, milk, and eggs or as additives in bread or salt. In the stomach and jejunum, iodine is rapidly converted to iodide and absorbed into the bloodstream, and from there it is distributed uniformly throughout the extracellular space. Iodide is actively transported into the thyroid follicular cells by an adenosine triphosphate (ATP)–dependent process. The thyroid is the storage site of >90% of the body’s iodine content and accounts for one-third of the plasma iodine loss. The remaining plasma iodine is cleared via renal excretion.

**Thyroid Hormone Synthesis, Secretion, and Transport.** The synthesis of thyroid hormone consists of several steps.

---

**Figure 38-4.** Relationship of the external branch of the superior laryngeal nerve and superior thyroid artery originally described by Cernea and colleagues. In type 1 anatomy, the nerve crosses the artery ≥1 cm above the superior aspect of the thyroid lobe. In type 2 anatomy, the nerve crosses the artery <1 cm above the thyroid pole (2a) or below (2b) it. SPECIFIC CONSIDERATIONS

PART II

(Fig. 38-8). The first, iodide trapping, involves active (ATP-dependent) transport of iodide across the basement membrane of the thyrocyte via an intrinsic membrane protein, the sodium/iodine (Na+/I-) symporter. Thyroglobulin (Tg) is a large (660 kDa) glycoprotein, which is present in thyroid follicles and has four tyrosyl residues. The second step in thyroid hormone synthesis involves oxidation of iodide to iodine and iodination of tyrosine residues on Tg, to form monoiodotyrosines (MIT) and diiodotyrosines (DIT). Both processes are catalyzed by thyroid peroxidase (TPO). A recently identified protein, pendrin, is thought to mediate iodine efflux at the apical membrane. The third step leads to coupling of two DIT molecules to form tetra-iodothyronine or thyroxine (T₄), and one DIT molecule with one MIT molecule to form 3,5,3′-triiodothyronine (T₃) or 3,3′,5′-triiodothyronine reverse (rT₃). When stimulated by TSH, thyrocytes form pseudopodia, which encircle portions of cell membrane containing Tg, which in turn, fuse with enzyme-containing lysosomes. In the fourth step, Tg is hydrolyzed to release free iodotyrosines (T₃ and T₄) and mono- and diiodotyrosines. The latter are deiodinated in the fifth step to yield iodide, which is reused in the thyrocyte. In the euthyroid state, T₄ is produced and released entirely by the thyroid gland, whereas only 20% of the total T₃ is produced by the thyroid. Most of the T₄ is produced by peripheral deiodination (removal of 5′-iodine from the outer ring) of T₃ in the liver, muscles, kidney, and anterior pituitary, a reaction that is catalyzed by 5′-mono-deiodinase. Some T₃ is converted to rT₃, the metabolically inactive compound, by deiodination of the inner ring of T₃. In conditions such as Graves’ disease, toxic multinodular goiter, or a stimulated thyroid gland, the proportion of T₃ released from the thyroid may be dramatically elevated. Thyroid hormones are transported in serum bound to carrier proteins such as T₄-binding globulin, T₃-binding prealbumin, and albumin. Only a small fraction (0.02%) of thyroid hormone (T₃ and T₄) is free (unbound) and is the physiologically active component. T₃ is the more potent of the two thyroid hormones, although its circulating plasma level is much lower than that of T₄. T₃ is less tightly bound to protein in the plasma than T₄, and so it enters tissues more readily. T₃ is three to four times more active than T₄ per unit weight, with a half-life of about 1 day, compared to approximately 7 days for T₄.

The secretion of thyroid hormone is controlled by the hypothalamic-pituitary-thyroid axis (Fig. 38-9). The hypothalamus produces a peptide, the thyrotropin-releasing hormone (TRH), which stimulates the pituitary to release TSH or thyrotropin. TRH reaches the pituitary via the portovenous circulation. TSH, a 28-kDa glycopeptide, mediates iodide trapping, secretion, and release of thyroid hormones, in addition to increasing the cellularity and vascularity of the thyroid gland. The TSH receptor (TSH-R) belongs to a family of G-protein–coupled receptors that have seven transmembrane-spanning domains and use cyclic adenosine monophosphate in the signal-transduction pathway. TSH secretion by the anterior pituitary is also regulated via a negative feedback loop by T₄ and T₃. Because the pituitary has the ability to convert T₃ to T₄, the latter is thought to be more important in this feedback control. T₃ also inhibits the release of TRH.

The thyroid gland also is capable of autoregulation, which allows it to modify its function independent of TSH. As an adaptation to low iodide intake, the gland preferentially synthesizes
T3 rather than T4, thereby increasing the efficiency of secreted hormone. In situations of iodine excess, iodide transport, peroxide generation, and synthesis and secretion of thyroid hormones are inhibited. Excessively large doses of iodide may lead to initial increased organification, followed by suppression, a phenomenon called the Wolff-Chaikoff effect. Epinephrine and human chorionic gonadotropin hormones stimulate thyroid hormone production. Thus, elevated thyroid hormone levels are found in pregnancy and gynecologic malignancies such as hydatidiform mole. In contrast, glucocorticoids inhibit thyroid hormone production. In severely ill patients, peripheral thyroid hormones may be reduced, without a compensatory increase in TSH levels, giving rise to the euthyroid sick syndrome.

**Thyroid Hormone Function.** Free thyroid hormone enters the cell membrane by diffusion or by specific carriers and is carried to the nuclear membrane by binding to specific proteins. T4 is deiodinated to T3 and enters the nucleus via active transport, where it binds to the thyroid hormone receptor. The T3 receptor is similar to the nuclear receptors for glucocorticoids, mineralocorticoids, estrogens, vitamin D, and retinoic acid. In humans, two types of T3 receptor genes (α and β) are located on chromosomes 3 and 17. Thyroid receptor expression depends on peripheral concentrations of thyroid hormones and is tissue specific—the α form is abundant in the central nervous system, whereas the β form predominates in the liver. Each gene product has a ligand-independent, amino-terminal domain;

**Figure 38-6.** A and B. Lymph nodes in the neck can be divided into six regions. Upper mediastinal nodes constitute level VII. m. = muscle; n. = nerve.
The binding of thyroid hormone leads to the transcription and translation of specific hormone-responsive genes.

Thyroid hormones affect almost every system in the body. They are important for fetal brain development and skeletal maturation. T₃ increases oxygen consumption, basal metabolic rate, and heat production by stimulation of Na⁺/K⁺ ATPase in various tissues. It also has positive inotropic and chronotropic effects on the heart by increasing transcription of the Ca²⁺ ATPase in the sarcoplasmic reticulum and increasing levels of β-adrenergic receptors and concentration of G proteins. Myocardial α-receptors are decreased, and actions of catecholamines are amplified. Thyroid hormones are responsible for maintaining the normal hypoxic and hypercapnic drive in the respiratory center of the brain. They also increase gastrointestinal (GI) motility, leading to diarrhea in hyperthyroidism and constipation in hypothyroidism. Thyroid hormones also increase bone and protein turnover.

Figure 38-7. Normal thyroid histology—follicular cells surround colloid.

Figure 38-8. Thyroid follicular cell showing the major signaling pathways involved in thyroid cell growth and function and key steps in thyroid hormone synthesis. The basal membrane of the cell in contact with the circulation and its apical surface contact the thyroid follicle. Thyroid hormone synthesis is initiated by the binding of thyroid-stimulating hormone (TSH) to the TSH receptor (TSHR), a G-protein–coupled transmembrane receptor, on the basal membrane. Activation leads to an increase in cyclic adenosine monophosphate (cAMP), phosphorylation of protein kinase A (PKA), and activation of target cytosolic and nuclear proteins. The protein kinase C (PKC) pathway is stimulated at higher doses of TSH. Iodide is actively transported into the cell via the Na/I symporter (NIS) and flows down an electrical gradient to the apical membrane. There, thyroid peroxidase (TPO) oxidizes iodide and iodinated tyrosyl residues on thyroglobulin (Tg) in the presence of peroxide (H₂O₂). Mono- and diiodotyrosyl (MIT, DIT) residues are also coupled to form T₃ and T₄ by TPO. Thyroglobulin carrying T₃ and T₄ is then internalized by pinocytosis and digested in lysosomes. Thyroid hormone is released into the circulation, while MIT and DIT are deiodinated and recycled. ATP = adenosine triphosphate; CREB = cAMP response element binding protein; CREM = cAMP response element modulator; DAG = diacylglycerol; IGF-1 = insulin-like growth factor 1; IP₃ = inositol-3-phosphate; NADP⁺ = nicotinamide adenine dinucleotide phosphate, oxidized form; NADPH = nicotinamide adenine dinucleotide phosphate; PIP₂ = phosphatidylinositol; PLC = phospholipase C; T₃ = 3,5′,3′-triiodothyronine; T₄ = thyroxine. and the speed of muscle contraction and relaxation. They also increase glycogenolysis, hepatic gluconeogenesis, intestinal glucose absorption, and cholesterol synthesis and degradation.

Evaluation of Patients With Thyroid Disease

Tests of Thyroid Function. A multitude of different tests are available to evaluate thyroid function. No single test is sufficient to assess thyroid function in all situations, and the results must be interpreted in the context of the patient’s clinical condition. TSH is the only test necessary in most patients with thyroid nodules that clinically appear to be euthyroid.

Serum Thyroid-Stimulating Hormone (Normal 0.5–5 μU/mL) The tests for serum TSH are based on the following principle: monoclonal TSH antibodies are bound to a solid matrix and bind serum TSH. A second monoclonal antibody binds to a separate epitope on TSH and is labeled with radioisotope, enzyme, or fluorescent tag. Therefore, the amount of serum TSH is proportional to the amount of bound secondary antibody (immunometric assay). Serum TSH levels reflect the ability of the anterior pituitary to detect free T4 levels. There is an inverse relationship between the free T4 level and the logarithm of the TSH concentration—small changes in free T4 lead to a large shift in TSH levels. The ultrasensitive TSH assay has become the most sensitive and specific test for the diagnosis of hyper- and hypothyroidism and for optimizing T4 therapy.

Total T4 (Reference Range 55–150 nmol/L) and T3 (Reference Range 1.5–3.5 nmol/L) Total T4 and T3 levels are measured by radioimmunoassay and measure both the free and bound components of the hormones. Total T4 levels reflect the output from the thyroid gland, whereas T3 levels in the nonstimulated thyroid gland are more indicative of peripheral thyroid hormone metabolism, and are, therefore, not generally suitable as a general screening test. Total T4 levels are increased not only in hyperthyroid patients, but also in those with elevated Tg levels secondary to pregnancy, estrogen/progesterone use, or congenital diseases. Similarly, total T4 levels decrease in hypothyroidism and in patients with decreased Tg levels due to anabolic steroid use and protein-losing disorders like nephrotic syndrome. Individuals with these latter disorders may be euthyroid if their free T4 levels are normal. Measurement of total T4 levels is important in clinically hyperthyroid patients with normal T3 levels, who may have T3 thyrotoxicosis. As discussed previously in “Thyroid Hormone Synthesis, Secretion, and Transport,” total T4 levels often are increased in early hypothyroidism.

Free T4 (Reference Range 12–28 pmol/L) and Free T3 (3–9 pmol/L) These radioimmunoassay-based tests are a sensitive and accurate measurement of biologically active thyroid hormone. Free T4 estimates are not performed as a routine screening tool in thyroid disease. Use of this test is confined to cases of early hyperthyroidism in which total T4 levels may be normal but free T4 levels are raised. In patients with end-organ resistance to T4 (Refetoff’s syndrome), T4 levels are increased, but TSH levels usually are normal. Free T3 is most useful in confirming the diagnosis of early hyperthyroidism, in which levels of free T3 and free T4 rise before total T4 and T3. Free T3 levels may also be measured indirectly using the T4-resin uptake test. If free T4 levels are increased, fewer hormone binding sites are available for binding radiolabeled T3 that has been added to the patient’s serum. Therefore, more T3 binds with an ion-exchange resin, and the T4-resin uptake is increased.

Thyrotropin-Releasing Hormone This test is useful to evaluate pituitary TSH secretory function and is performed by administering 500 μg of TRH intravenously and measuring TSH levels after 30 and 60 minutes. In a normal individual, TSH levels should increase at least 6 μIU/mL from the baseline. This test also was previously used to assess patients with borderline hyperthyroidism but has largely been replaced by sensitive TSH assays for this purpose.

Thyroid Antibodies Thyroid antibodies include anti-Tg, antimicrosomal, or anti-TPO and thyroid-stimulating immunoglobulin (TSI). Anti-Tg and anti-TPO antibody levels do not determine thyroid function, but rather indicate the underlying disorder, usually an autoimmune thyroiditis. About 80% of patients with Hashimoto’s thyroiditis have elevated thyroid antibody levels; however, levels may also be increased in patients with Graves’ disease, multinodular goiter, and occasionally, thyroid neoplasms.

Serum Thyroglobulin Tg is only made by normal or abnormal thyroid tissue. It normally is not released into the circulation in large amounts but increases dramatically in destructive processes of the thyroid gland, such as thyroiditis, or overactive states such as Graves’ disease and toxic multinodular goiter. The most important use for serum Tg levels is in monitoring patients with differentiated thyroid cancer for recurrence, particularly after total thyroidectomy and RAI ablation. Elevated anti-Tg antibodies can interfere with the accuracy of serum Tg levels and should always be measured when interpreting Tg levels.
**Serum Calcitonin (0–4 pg/mL Basal)** This 32-amino-acid polypeptide is secreted by the C cells and functions to lower serum calcium levels, although in humans, it has only minimal physiologic effects. It is also a sensitive marker of MTC.

**Thyroid Imaging**

**Radionuclide Imaging** Both iodine-123 (\(^{123}\text{I}\)) and iodine-131 (\(^{131}\text{I}\)) are used to image the thyroid gland. The former emits low-dose radiation, has a half-life of 12 to 14 hours, and is used to image lingual thyroids or goiters. In contrast, \(^{131}\text{I}\) has a half-life of 8 to 10 days and leads to higher-dose radiation exposure. Therefore, this isotope is used to screen and treat patients with differentiated thyroid cancers for metastatic disease. The images obtained by these studies provide information not only about the size and shape of the gland, but also the distribution of functional activity. Areas that trap less radioactivity than the surrounding gland are termed **cold** (Fig. 38-10), whereas areas that demonstrate increased activity are termed **hot**. The risk of malignancy is higher in “cold” lesions (20%) compared to “hot” or “warm” lesions (<5%). Technetium Tc 99m pertechnetate (\(^{99m}\text{Tc}\)) is taken up by the thyroid gland and is increasingly being used for thyroid evaluation. This isotope is taken up by the mitochondria, but is not organified. It also has the advantage of having a shorter half-life and minimizes radiation exposure. It is particularly sensitive for nodal metastases. More recently, \(^{18}\text{F}\)-fluorodeoxyglucose (FDG) positron emission tomography (PET) combined with computed tomography (CT) is being increasingly used to screen for metastases in patients with thyroid cancer in whom other imaging studies are negative. PET scans are not routinely used in the evaluation of thyroid nodules; however, they may show clinically occult thyroid lesions. There are several recent reports of rates of malignancy in these lesions ranging from 14% to 63%. These incidentally discovered nodules should be worked up by ultrasound and fine-needle aspiration biopsy (FNAB).

**Ultrasound** Ultrasound is an excellent noninvasive and portable imaging study of the thyroid gland with the added advantage of no radiation exposure. It is helpful in the evaluation of thyroid nodules, distinguishing solid from cystic ones, and providing information about size and multicentricity. In addition, characteristics such as echotexture, shape, borders and presence of calcifications, and vascularity can provide useful information regarding risk of malignancy. Ultrasound is also especially helpful for assessing cervical lymphadenopathy (Fig. 38-11) and to guide FNAB. An experienced ultrasonographer is necessary for the best results.

**Computed Tomography/Magnetic Resonance Imaging Scan** CT and magnetic resonance imaging (MRI) studies provide excellent imaging of the thyroid gland and adjacent nodes and are particularly useful in evaluating the extent of large, fixed, or substernal goiters (which cannot be evaluated by ultrasound) and their relationship to the airway and vascular structures. Noncontrast CT scans should be obtained for patients who are likely to require subsequent RAI therapy. If contrast is necessary, therapy needs to be delayed by several months. Combined PET-CT scans are increasingly being used for Tg-positive, RAI-negative tumors.

**Benign Thyroid Disorders**

**Hyperthyroidism.** The clinical manifestations of hyperthyroidism result from an excess of circulating thyroid hormone. Hyperthyroidism may arise from a number of conditions that are listed in Table 38-1. It is important to distinguish disorders such as Graves’ disease and toxic nodular goiters that result from increased production of thyroid hormone from those disorders that lead to a release of stored hormone from injury to the thyroid gland (thyroiditis) or from other nonthyroid gland–related conditions. The former disorders lead to an increase in RAI uptake (RAIU), whereas the latter group is characterized by low RAIU. Of these disorders, Graves’ disease, toxic multinodular goiter, and solitary toxic nodule are most relevant to the surgeon.

**Diffuse Toxic Goiter (Graves’ Disease)** Although originally described by the Welsh physician Caleb Parry in a posthumous article in 1825, this disorder is known as Graves’ disease after Robert Graves, an Irish physician who described three patients in 1835. Graves’ disease is by far the most common cause of hyperthyroidism in North America, accounting for 60% to 80% of cases. It is an autoimmune disease with a strong familial predisposition, female preponderance (5:1), and peak incidence between the ages of 40 and 60 years. Graves’ disease is characterized by thyrotoxicosis, diffuse goiter, and extrathyroidal conditions including ophthalmopathy, dermopathy (pretibial myxedema), thyroid acropachy, gynecomastia, and other manifestations.

**Etiology, Pathogenesis, and Pathology.** The exact etiology of the initiation of the autoimmune process in Graves’ disease is not known. However, conditions such as the postpartum state, iodine excess, lithium therapy, and bacterial and viral infections have been suggested as possible triggers. Genetic factors also play a role, as haplotyping studies indicate that Graves’ disease is associated with certain human leukocyte antigen (HLA) haplotypes, including HLA-B8, HLA-DR3, and HLA-DR4*0501 in Caucasian patients, whereas HLA-DRB1*0701 is protective.
against it. Polymorphisms of the cytotoxic T-lymphocyte antigen 4 (CTLA-4) gene also have been associated with Graves’ disease development. CD40 has also been recognized as a Graves’ susceptibility gene. It has an important role in B-cell function and its upregulation leads to a lower threshold for B-cell activation. It can also lead to enhanced IL-6 secretion and activation of T-cells in thyrocytes leading to a local inflammatory response. Other susceptibility genes include PTPN22 (encodes the lymphoid tyrosine phosphatase) and CD25, which encodes for the interleukin-2 receptor α-chain (IL-2Rα). Once initiated, the inflammatory process causes sensitized T-helper lymphocytes to stimulate B lymphocytes, which produce antibodies directed against the thyroid hormone receptor. TSIs or antibodies that stimulate the TSH-R, as well as TSH-binding inhibiting immunoglobulins or antibodies, have been described. The thyroid-stimulating antibodies stimulate the thyrocytes to grow and synthesize excess thyroid hormone, which is a hallmark of Graves’ disease. Graves’ disease also is associated with other autoimmune conditions such as type 1 diabetes mellitus, Addison’s disease, pernicious anemia, and myasthenia gravis.

Macroscopically, the thyroid gland in patients with Graves’ disease is diffusely and smoothly enlarged, with a concomitant increase in vascularity. Microscopically, the gland is hyperplastic, and the epithelium is columnar with minimal colloid present. The nuclei exhibit mitosis, and papillary projections of hyperplastic epithelium are common. There may be aggregates of lymphoid tissue, and vascularity is markedly increased.

**Clinical Features.** The clinical manifestations of Graves’ disease can be divided into those related to hyperthyroidism and those specific to Graves’ disease. Hyperthyroid symptoms include heat intolerance, increased sweating and thirst, and weight loss despite adequate caloric intake. Symptoms of increased adrenergic stimulation include palpitations, nervousness, fatigue, emotional lability, hyperkinesis, and tremors. The most common GI symptoms include increased frequency of bowel movements and diarrhea. Female patients often develop amenorrhea, decreased fertility, and an increased incidence of miscarriages. Children experience rapid growth with early bone maturation, whereas older patients may present with cardiovascular complications such as atrial fibrillation and congestive heart failure.

On physical examination, weight loss and facial flushing may be evident. The skin is warm and moist, and African American patients often note darkening of their skin. Tachycardia or atrial fibrillation is present, with cutaneous vasodilation leading to a widening of the pulse pressure and a rapid falloff in the transmitted pulse wave (collapsing pulse). A fine tremor, muscle wasting, and proximal muscle group weakness with hyperactive tendon reflexes often are present.

Approximately 50% of patients with Graves’ disease also develop clinically evident ophthalmopathy, and dermopathy occurs in 1% to 2% of patients. It is characterized by deposition of glycosaminoglycans, leading to thickened skin in the pretibial region and dorsum of the foot (Fig. 38-12). Eye symptoms include lid lag (von Graefe’s sign), spasm of the upper eyelid revealing the sclera above the corneoscleral limbus (Dalyrple’s sign), and a prominent stare, due to catecholamine excess. True infiltrative eye disease results in periorbital edema, conjunctival swelling and congestion (chemosis), proptosis, limitation of upward and lateral gaze (from involvement of the inferior and medial rectus muscles, respectively), keratitis, and even blindness due to optic nerve involvement. The etiology of Graves’ ophthalmopathy is not completely known; however,

RAIU = radioactive iodine uptake; TSH = thyroid-stimulating hormone.
orbital fibroblasts and muscles are thought to share a common antigen, the TSH-R. Ophthalmopathy is thought to result from inflammation caused by cytokines released from sensitized killer T lymphocytes and cytotoxic antibodies. Gynecomastia is common in young men. Rare bony involvement leads to subperiosteal bone formation and swelling in the metacarpals (thyroid acropachy). Onycholysis, or separation of fingernails from their beds, is a commonly observed finding. On physical examination, the thyroid usually is diffusely and symmetrically enlarged, as evidenced by an enlarged pyramidal lobe. There may be an overlying bruit or thrill over the thyroid gland and a loud venous hum in the supraclavicular space.

**Diagnostic Tests.** The diagnosis of hyperthyroidism is made by a suppressed TSH with or without an elevated free $T_4$ or $T_3$ level. If eye signs are present, other tests are generally not needed. However, in the absence of eye findings, an $^{123}$I uptake and scan should be performed. An elevated uptake, with a diffusely enlarged gland, confirms the diagnosis of Graves’ disease and helps to differentiate it from other causes of hyperthyroidism. Technetium scintigraphy (using pertechnetate, which is trapped by the thyroid, but not organified) can also be used to determine etiology. While technetium scans result in low range of normal uptake and high background activity, total-body radiation exposure is less than that of $^{123}$I scans. If free $T_4$ levels are normal, free $T_3$ levels should be determined, as they often are elevated in early Graves’ disease or toxic nodules ($T_4$ toxicosis). Anti-$T_g$ and anti-TPO antibodies are elevated in up to 75% of patients but are not specific. Elevated TSH-R or thyroid-stimulating antibodies (TSAb) are diagnostic of Graves’ disease and are increased in about 90% of patients. CT or MRI scans of the orbits are useful in evaluating Graves’ ophthalmopathy.

**Treatment.** Graves’ disease may be treated by any of three treatment modalities: antithyroid drugs, thyroid ablation with radioactive $^{131}$I, and thyroidectomy. The choice of treatment depends on several factors, as discussed in the following sections.

**Antithyroid Drugs** Antithyroid medications generally are administered in preparation for RAI ablation or surgery. The drugs commonly used are propylthiouracil (PTU, 100 to 300 mg three times daily) and methimazole (10 to 30 mg three times daily, then once daily). Methimazole has a longer half-life and can be dosed once daily. Both drugs reduce thyroid hormone production by inhibiting the organic binding of iodine and the coupling of iodothyrosines (mediated by TPO). In addition, PTU also inhibits the peripheral conversion of $T_4$ to $T_3$, making it useful for the treatment of thyroid storm. Both drugs can cross the placenta, inhibiting fetal thyroid function, and are excreted in breast milk, although PTU has a lower risk of transplacental transfer. Methimazole also has been associated with congenital aplasia; therefore, PTU is preferred in pregnant and breastfeeding women. Side effects of treatment include reversible granulocytopenia, skin rashes, fever, peripheral neuritis, polyarteritis, vasculitis, hepatitis, and, rarely, agranulocytosis and aplastic anemia. Patients should be monitored for these possible complications and should always be warned to stop PTU or methimazole immediately and seek medical advice should they develop a sore throat or fever. Treatment of agranulocytosis involves admission to the hospital, discontinuation of the drug, and broad-spectrum antibiotic therapy. Surgery should be postponed until the granulocyte count reaches 1000 cells/mm$^3$.

The dose of antithyroid medication is titrated as needed in accordance with TSH and $T_4$ levels. Most patients have improved symptoms in 2 weeks and become euthyroid in about 6 weeks. Some physicians use the block-replace regimen, by adding $T_4$ (0.05 to 0.10 mg) to prevent hypothyroidism and suppress TSH secretion, because some, but not all, studies suggest that this reduces recurrence rates. The length of therapy is debated. Treatment with antithyroid medications is associated
with a high relapse rate when these drugs are discontinued, with 40% to 80% of patients developing recurrent disease after a 1- to 2-year course. Patients with small glands are less likely to recur, so that treatment for curative intent is reserved for patients with (a) small, nontoxic goiters less than 40 g; (b) mildly elevated thyroid hormone levels; (c) negative or low titers of thyroid hormone receptor antibodies; and (d) rapid decrease in gland size with antithyroid medications. The catecholamine response of thyrotoxicosis can be alleviated by administering β-blocking agents. β-Blockade should be considered in all patients with symptomatic thyrotoxicosis and is recommended for elderly patients, those with coexistent cardiac disease, and patients with resting heart rates >90 bpm. These drugs have the added effect of decreasing the peripheral conversion of T4 to T3. Propranolol is the most commonly prescribed medication in doses of about 20 to 40 mg four times daily. Higher doses are sometimes required due to increased clearance of the medication. Caution should be exercised in patients with asthma. Calcium channel blockers are useful for rate control in patients in whom β-blockers are contraindicated.

Radioactive Iodine Therapy (131I) RAI forms the mainstay of Graves’ disease treatment in North America. The major advantages of this treatment are the avoidance of a surgical procedure and its concomitant risks, reduced overall treatment costs, and ease of treatment. Antithyroid drugs are given until the patient is euthyroid and then discontinued to maximize drug uptake. The 131I dose is calculated after a preliminary scan and usually consists of 8 to 12 mCi administered orally. After standard treatment with RAI, most patients become euthyroid within 2 months. However, only about 50% of patients treated with RAI are euthyroid 6 months after treatment, and the remaining are still hyperthyroid or already hypothyroid. After 1 year, about 2.5% of patients develop hypothyroidism each year. RAI also has been documented to lead to progression of Graves’ ophthalmopathy (33% after RAI compared to 16% after surgery), and ophthalmopathy is more common in smokers. Although there is no evidence of long-term problems with infertility, and overall cancer incidence rates are unchanged, there is a small increased risk of nodular goiter, thyroid cancer, and hyperparathyroidism (HPT) in patients who have been treated with RAI. Patients treated with RAI have an unexplained increase in their overall and cardiovascular mortality rates when compared to the general population.

RAI therapy is therefore most often used in older patients with small or moderate-sized goiters, those who have relapsed after medical or surgical therapy, and those in whom antithyroid drugs or surgery are contraindicated. Absolute contraindications to RAI include women who are pregnant (or planning pregnancy within 6 months of treatment) or breastfeeding. Relative contraindications include young patients (i.e., especially children and adolescents), those with thyroid nodules, and those with ophthalmopathy. Lack of access to a high-volume thyroid surgeon is also a consideration. The higher the initial dose of 131I, the earlier the onset and the higher the incidence of hypothyroidism.

Surgical Treatment In North America, surgery is recommended when RAI is contraindicated as in patients who (a) have confirmed cancer or suspicious thyroid nodules, (b) are young, (c) desire to conceive soon (<6 months) after treatment, (d) have had severe reactions to antithyroid medications, (e) have large goiters (>80 g) causing compressive symptoms, and (f) are reluctant to undergo RAI therapy. Relative indications for thyrotoxicosis usually is managed by radioiodine treatment.

Toxic Multinodular Goiter Toxic multinodular goiters usually occur in older individuals, who often have a prior history of a nontoxic multinodular goiter. Over several years, enough thyroid nodules become autonomous to cause hyperthyroidism. The presentation often is insidious in that hyperthyroidism may only become apparent when patients are placed on low doses of thyroid hormone suppression for the goiter. Some patients have T3 toxicity, whereas others may present only with atrial fibrillation or congestive heart failure. Hyperthyroidism also can be precipitated by iodide-containing drugs such as contrast media and the antiarrhythmic agent amiodarone (Jod-Basedow...
hyperthyroidism). Symptoms and signs of hyperthyroidism are similar to Graves’ disease, but extrathyroidal manifestations are absent.

**Diagnostic Studies.** Blood tests are similar to Graves’ disease with a suppressed TSH level and elevated free T<sub>3</sub> or T<sub>4</sub> levels. RAI uptake also is increased, showing multiple nodules with increased uptake and suppression of the remaining gland.

**Treatment.** Hyperthyroidism must be adequately controlled. Both RAI and surgical resection may be used for treatment. When surgery is performed, near-total or total thyroidectomy is recommended to avoid recurrence and the consequent increased complication rates with repeat surgery. Care must be taken in identifying the RLN, which may be found laterally on the thyroid (rather than posterior) or stretched anteriorly over a nodule. RAI therapy is reserved for elderly patients who represent very poor operative risks, provided there is no airway compression from the goiter and thyroid cancer is not a concern. However, because uptake is less than in Graves’ disease, larger doses of RAI often are needed to treat the hyperthyroidism. Furthermore, RAI-induced thyroiditis has the potential to cause swelling and acute airway compromise and leaves the goiter intact, with the possibility of recurrent hyperthyroidism.

**Toxic Adenoma** Hyperthyroidism from a single hyperfunctioning nodule typically occurs in younger patients who note recent growth of a long-standing nodule along with the symptoms of hyperthyroidism. Toxic adenomas are characterized by somatic mutations in the TSH-R gene, although G-protein–stimulating gene (gsp) mutations may occur also. Most hyperfunctioning or autonomous thyroid nodules have attained a size of at least 3 cm before hyperthyroidism occurs. Physical examination usually reveals a solitary thyroid nodule without palpable thyroid tissue on the contralateral side. RAI scanning shows a “hot” nodule with suppression of the rest of the thyroid gland. These nodules are rarely malignant. Smaller nodules may be managed with antithyroid medications and RAI. Larger nodules can require higher doses, which can lead to hypothyroidism. Surgery (lobectomy and isthmusectomy) is preferred to treat young patients and those with larger nodules. Percutaneous ethanol injection (PEI) has been reported to have reasonable success rates but has not been directly compared with surgery.

**Thyroid Storm** Thyroid storm is a condition of hyperthyroidism accompanied by fever, central nervous system agitation or depression, and cardiovascular and GI dysfunction, including hepatic failure. The condition may be precipitated by abrupt cessation of antithyroid medications, infection, thyroid or non-thyroid surgery, and trauma in patients with untreated thyrotoxicosis. Occasionally, thyroid storm may result from amiodarone administration or exposure to iodinated contrast agents or following RAI therapy. This condition was previously associated with high mortality rates but can be appropriately managed in an intensive care unit setting. β-Blockers are given to reduce peripheral T<sub>3</sub> to T<sub>4</sub> conversion and decrease the hyperthyroid symptoms. Oxygen supplementation and hemodynamic support should be instituted. Nonaspirin compounds can be used to treat pyrexia, and Lugol’s iodine or sodium ipodate (intravenously) should be administered to decrease iodine uptake and thyroid hormone secretion. PTU therapy blocks the formation of new thyroid hormone and reduces peripheral conversion of T<sub>4</sub> to T<sub>3</sub>. Corticosteroids often are helpful to prevent adrenal exhaustion and block hepatic thyroid hormone conversion.

**Hypothyroidism.** Deficiency in circulating levels of thyroid hormone leads to hypothyroidism and, in neonates, to cretinism, which is characterized by neurologic impairment and mental retardation. Hypothyroidism also may occur in Pendred’s syndrome (associated with deafness) and Turner’s syndrome. Conditions that cause hypothyroidism are listed in Table 38–2.

**Clinical Features** Failure of thyroid gland development or function in utero leads to cretinism and characteristic facies similar to those of children with Down syndrome and dwarfism. Failure to thrive and severe mental retardation often are present. Immediate testing and treatment with thyroid hormone at birth can lessen the neurologic and intellectual deficits. Hypothyroidism developing in childhood or adolescence results in delayed development and may also lead to abdominal distention, umbilical hernia, and rectal prolapse. In adults, symptoms in general are nonspecific, including tiredness, weight gain, cold intolerance, constipation, and menorrhagia. Patients with severe hypothyroidism or myxedema develop characteristic facial features due to the deposition of glycosaminoglycans in the subcutaneous tissues, leading to facial and peri orbital puffiness. The skin becomes rough and dry and often develops a yellowish hue from reduced conversion of carotene to vitamin A. Hair becomes dry and brittle, and severe hair loss may occur. There is also a characteristic loss of the outer two thirds of the eyebrows. An enlarged tongue may impair speech, which is already slowed, in keeping with the impairment of mental processes. Patients may also have nonspecific abdominal pain accompanied by distention and constipation. Libido and fertility are impaired in both sexes. Cardiovascular changes in hypothyroidism include bradycardia, cardiomegaly, pericardial effusion, reduced cardiac output, and pulmonary effusions. When hypothyroidism occurs as a result of pituitary failure, other features of hypopituitarism, such as pale, waxy skin; loss of body hair; and atrophic genitalia, may be present.
Laboratory Findings Hypothyroidism is characterized by low circulating levels of T₄ and T₃. Raised TSH levels are found in primary thyroid failure, whereas secondary hypothyroidism is characterized by low TSH levels that do not increase following TRH stimulation. Thyroid autoantibodies are highest in patients with autoimmune disease (Hashimoto’s thyroiditis, Graves’ disease) and may also be elevated in patients with nodular goiter and thyroid neoplasms. An electrocardiogram demonstrates decreased voltage with flattening or inversion of T waves.

Treatment T₄ is the treatment of choice and is administered in dosages varying from 50 to 200 μg per day, depending on the patient’s size and condition. Starting doses of 100 μg of T₄ daily are well tolerated; however, elderly patients and those with coexisting heart disease and profound hypothyroidism should be started on a considerably lower dose such as 25 to 50 μg daily because of associated hypercholesterolemia and atherosclerosis. The dose can be slowly increased over weeks to months to attain a euthyroid state. A baseline electrocardiogram should always be obtained in patients with severe hypothyroidism before treatment. T₄ dosage is titrated against clinical response and TSH levels, which should return to normal. The management of patients with subclinical hypothyroidism (normal T₄, slightly raised TSH) is controversial. Some evidence suggests that patients with subclinical hypothyroidism and increased antithyroid antibody levels should be treated because they will subsequently develop hypothyroidism. Patients who present with myxedema coma require initial emergency treatment with large doses of IV T₄ (300 to 400 μg), with careful monitoring in an intensive care unit setting.

Thyroiditis. Thyroiditis usually is classified into acute, subacute, and chronic forms, each associated with a distinct clinical presentation and histology.

Acute (Suppurative) Thyroiditis The thyroid gland is inherently resistant to infection due to its extensive blood and lymphatic supply, high iodide content, and fibrous capsule. However, infectious agents can seed it (a) via the hematogenous or lymphatic route, (b) via direct spread from persistent pyriform sinus fistulae or thyroglossal duct cysts, (c) as a result of penetrating trauma to the thyroid gland, or (d) due to immunosuppression. Streptococcus and anaerobes account for about 70% of cases; however, other species also have been cultured. Acute suppurative thyroiditis is more common in children and often is preceded by an upper respiratory tract infection or otitis media. It is characterized by severe neck pain radiating to the jaws or ear, fever, chills, odynophagia, and dysphonia. Complications such as systemic sepsis, tracheal or esophageal rupture, jugular vein thrombosis, laryngeal chondritis, and perichondritis or sympathetic trunk paralysis may also occur.

The diagnosis is established by leukocytosis on blood tests and FNAB for Gram’s stain, culture, and cytology. CT scans may help to delineate the extent of infection and identify abscesses. A persistent pyriform sinus fistula should always be suspected in children with recurrent acute thyroiditis. The sensitivity of identification of fistulae in the acute setting is lowest for barium esophagography (50%) and best for direct endoscopy (100%), with CT scans being intermediate (80%). Both barium esophagogram and CT scans have improved sensitivity once the acute inflammation has resolved (100% and 83%, respectively), with CT being better at defining the accurate anatomic pathway and its relationship to the thyroid gland. Treatment consists of parenteral antibiotics and drainage of abscesses. Thyroidectomy may be needed for persistent abscesses or failure of open drainage. Patients with pyriform sinus fistulae require complete resection of the sinus tract, including the area of the thyroid where the tract terminates, to prevent recurrence. Transnasal flexible fiberoptic laryngoscopy is being increasingly used to identify the internal opening of the pyriform sinus tract and may also allow electrocauterization of the tract, and success rates similar to open surgery have been reported.

Subacute Thyroiditis Subacute thyroiditis can occur in the painful or painless forms. Although the exact etiology is not known, painful thyroiditis is thought to be viral in origin or result from a postviral inflammatory response. Genetic predisposition may also play a role, as manifested by its strong association with the HLA-B35 haplotype. One model of pathogenesis suggests that viral or thyroid antigens, when presented by macrophages in the context of HLA-B35, stimulate cytotoxic T lymphocytes and damage thyroid follicular cells.

Painful thyroiditis most commonly occurs in 30- to 40-year-old women and is characterized by the sudden or gradual onset of neck pain, which may radiate toward the mandible or ear. History of a preceding upper respiratory tract infection often can be elicited. The gland is enlarged, exquisitely tender, and firm. The disorder classically progresses through four stages. An initial hyperthyroid phase, due to release of thyroid hormone, is followed by a second, euthyroid phase. The third phase, hypothyroidism, occurs in about 20% to 30% of patients and is followed by resolution and return to the euthyroid state in >90% of patients. A few patients develop recurrent disease.

In the early stages of the disease, TSH is decreased, and Tg, T₄, and T₃ levels are elevated due to the release of preformed thyroid hormone from destroyed follicles. The erythrocyte sedimentation rate is typically >100 mm/h. RA IU also is decreased (<2% at 24 hours), even in euthyroid patients, due to the release of thyroid hormones from destruction of the thyroid parenchyma. Painful thyroiditis is self-limited, and therefore, treatment is primarily symptomatic. Aspirin and other nonsteroidal anti-inflammatory drugs are used for pain relief, but steroids may be indicated in more severe cases. Short-term thyroid replacement may be needed and may shorten the duration of symptoms. Thyroidectomy is reserved for the rare patient who has a prolonged course not responsive to medical measures or for recurrent disease.

Painless thyroiditis is considered to be autoimmune in origin and may occur sporadically or in the postpartum period; the latter typically occurs at about 6 weeks after delivery in women with high TPO antibody titers in early pregnancy. This timing is thought to coincide with a decrease in the normal immune tolerance of pregnancy and consequent rebound elevation of antibody titers.

Painless thyroiditis also is more common in women and usually occurs between 30 and 60 years of age. Physical examination demonstrates a normal sized or minimally enlarged, slightly firm, nontender gland. Laboratory tests and RA IU are similar to those in painful thyroiditis, except for a normal erythrocyte sedimentation rate. The clinical course also parallels painful thyroiditis. Patients with symptoms may require β-blockers and thyroid hormone replacement. Thyroidectomy or RAI ablation is only indicated for the rare patient with recurrent, disabling episodes of thyroiditis.
Chronic Thyroiditis

Lymphocytic (Hashimoto’s) Thyroiditis. Lymphocytic thyroiditis was first described by Hashimoto in 1912 as struma lymphomatosa—a transformation of thyroid tissue to lymphoid tissue. It is the most common inflammatory disorder of the thyroid and the leading cause of hypothyroidism today.

Etiology, Pathogenesis, and Pathology Hashimoto’s thyroiditis is an autoimmune process that is thought to be initiated by the activation of CD4+ T (helper) lymphocytes with specificity for thyroid antigens. Once activated, T cells can recruit cytotoxic CD8+ T cells to the thyroid. Hypothyroidism results not only from the destruction of thyrocytes by cytotoxic T cells but also by autoantibodies, which lead to complement fixation and killing by natural killer cells or block the TSH-R. Antibodies are directed against three main antigens—Tg (60%), TPO (95%), and TSH-R (60%)—and, less commonly, the sodium/iodine symporter (25%). Apoptosis (programmed cell death) also has been implicated in the pathogenesis of Hashimoto’s thyroiditis. Chronic thyroiditis also has been associated with increased intake of iodine and administration of medications such as interferon-α, lithium, and amiodarone. Support for an inherited predisposition includes an increased incidence of thyroid autoantibodies in first-degree relatives of patients with Hashimoto’s thyroiditis compared to controls and the occurrence of the autoantibodies and hypothyroidism in patients with specific chromosomal abnormalities such as Turner’s syndrome and Down syndrome. Associations with HLA-B8, DR3, and DR5 haplotypes of the major histocompatibility complex also have been described. Alterations in CTLA4 have also been shown to increase the risk of developing Hashimoto’s thyroiditis. Other associated genes include various cytokine genes, GITR (glucocorticoid-induced tumor necrosis factor-receptor) and STAT3; however, these need further confirmatory studies.

On gross examination, the thyroid gland is usually mildly enlarged throughout and has a pale, gray-tan cut surface that is granular, nodular, and firm. On microscopic examination, the gland is diffusely infiltrated by small lymphocytes and plasma cells and occasionally shows well-developed germinal centers. Thyroid follicles are smaller than normal with reduced amounts of colloid and increased interstitial connective tissue. The follicles are lined by Hürthle or Askanazy cells, which are characterized by abundant eosinophilic, granular cytoplasm.

Clinical Presentation Hashimoto’s thyroiditis is also more common in women (male-to-female ratio is 1:10 to 20) between the ages of 30 and 50 years old. The most common presentation is that of a minimally or moderately enlarged firm granular gland discovered on routine physical examination or the awareness of a painless anterior neck mass, although 20% of patients present with hypothyroidism, and 5% present with hyperthyroidism (Hashitoxicosis). In classic goitrous Hashimoto’s thyroiditis, physical examination reveals a diffusely enlarged, firm gland, which also is lobulated. An enlarged pyramidal lobe often is palpable.

Diagnostic Studies When Hashimoto’s thyroiditis is suspected clinically, an elevated TSH and the presence of thyroid autoantibodies usually confirm the diagnosis. FNAB with ultrasound guidance is indicated in patients who present with a solitary suspicious nodule or a rapidly enlarging goiter. Thyroid lymphoma is a rare but well-recognized, ominous complication of chronic autoimmune thyroiditis and has a prevalence 80 times higher than expected frequency in this population than in a control population without thyroiditis. Studies of clonal similarity indicate that lymphoma may, in fact, evolve from Hashimoto’s thyroiditis.

Treatment Thyroid hormone replacement therapy is indicated in overtly hypothyroid patients, with a goal of maintaining normal TSH levels. The management of patients with subclinical hypothyroidism (normal T4 and elevated TSH) is controversial. A systematic review of cohort studies showed that in age- and sex-adjusted analyses, subclinical hypothyroidism is associated with a hazard ratio (HR) for coronary heart disease events of 1.89 (95% confidence interval [CI], 1.28 to 2.80; P < .001) and coronary heart disease mortality of 1.58 (95% CI, 1.10 to 2.27; P = .005) for a TSH level of 10 to 19.9 μIU/mL. The data for TSH levels of 5 to 10 μIU/mL was less convincing. An evaluation of the 12 randomized controlled trials in this area only showed a trend toward improvement of some lipid parameters, and none of the included trials evaluated overall mortality or cardiac morbidity. For this reason, levothyroxine is recommended for all patients with TSH levels >10 μIU/mL and patients with levels of 5 to 10 μIU/mL in the presence of a goiter or anti-TPO antibodies. Treatment is also advised especially for middle-aged patients with cardiovascular risk factors such as hyperlipidemia or hypertension and in pregnant patients. Surgery may occasionally be indicated for suspicion of malignancy or for goiters causing compressive symptoms or cosmetic deformity.

Riedel’s Thyroiditis Riedel’s thyroiditis is a rare variant of thyroiditis also known as Riedel’s struma or invasive fibrous thyroiditis that is characterized by the replacement of all or part of the thyroid parenchyma by fibrous tissue, which also invades into adjacent tissues. The etiology of this disorder is controversial, and it has been reported to occur in patients with other autoimmune diseases. This association, coupled with the presence of lymphoid infiltration and response to steroid therapy, suggests a primary autoimmune etiology. Riedel’s thyroiditis is also associated with other focal sclerosing syndromes including mediastinal, retroperitoneal, periportal, and retro-orbital fibrosis and sclerosing cholangitis, suggesting that it may, in fact, be a primary fibrotic disorder. It is now considered a manifestation of IgG4-related systemic disease characterized by elevated serum IgG4 levels and a lymphoplasmycatic infiltrate with an abundance of IgG4 bearing plasma cells. The disease occurs predominantly in women between the ages of 30 and 60 years old. It typically presents as a painless, hard anterior neck mass, which progresses over weeks to years to produce symptoms of compression, including dysphagia, dyspnea, choking, and hoarseness. Patients may present with symptoms of hypothyroidism and hypoparathyroidism as the gland is replaced by fibrous tissue. Physical examination reveals a hard, “woody” thyroid gland with fixation to surrounding tissues. The diagnosis needs to be confirmed by open thyroid biopsy because the firm and fibrous nature of the gland renders FNAB inadequate.

Surgery is the mainstay of the treatment. The chief goal of operation is to decompress the trachea by wedge excision of the thyroid isthmus and to make a tissue diagnosis. More extensive resections are not advised due to the infiltrative nature of the fibrotic process that obscures usual landmarks and structures. Hypothyroid patients are treated with thyroid hormone replacement. Some patients who remain symptomatic have been reported to experience dramatic improvement after treatment with corticosteroids and tamoxifen. Mycophenolate mofetil and more recently rituximab has also been used to attenuate the
inflammatory process and led to dramatic symptom improvements in some patients.15

**Goiter.** Any enlargement of the thyroid gland is referred to as a goiter. The causes of nontoxic goiters are listed in Table 38-3. Goiters may be diffuse, uninodular, or multinodular. Most nontoxic goiters are thought to result from TSH stimulation secondary to inadequate thyroid hormone synthesis and other paracrine growth factors.16 Elevated TSH levels induce diffuse thyroid hyperplasia, followed by focal hyperplasia, resulting in nodules that may or may not concentrate iodine, colloid nodules, or microfollicular nodules. The TSH-dependent nodules progress to become autonomous. Familial goiters resulting from inherited deficiencies in enzymes necessary for thyroid hormone synthesis may be complete or partial. The term endemic goiter refers to the occurrence of a goiter in a significant proportion of individuals in a particular geographic region. In the past, dietary iodine deficiency was the most common cause of endemic goiter. This condition has largely disappeared in North America due to routine use of iodized salt and iodination of fertilizers, animal feeds, and preservatives. However, in areas of iodine deficiency, such as Central Asia, South America, and Indonesia, up to 90% of the population have goiters. Other dietary goitrogens that may participate in endemic goiter formation include kelp, cassava, and cabbage. In many sporadic goiters, no obvious cause can be identified.

**Clinical Features** Most patients with nontoxic goiters are asymptomatic, although patients often complain of a pressure sensation in the neck. As the goiters become very large, compressive symptoms such as dyspnea and dysphagia ensue. Patients also describe having to clear their throats frequently (catarrh). Dysphonia from RLN injury is rare, except when malignancy is present. Obstruction of venous return at the thoracic inlet from a substernal goiter results in a positive Pemberton’s sign—facial flushing and dilatation of cervical veins upon raising the arms above the head (Fig. 38-13A). Sudden enlargement of nodules or cysts due to hemorrhage may cause acute pain. Physical examination may reveal a soft, diffusely enlarged gland (simple goiter) or nodules of various size and consistency in case of a multinodular goiter. Deviation or compression of the trachea may be apparent.

**Diagnostic Tests** Patients usually are euthyroid with normal TSH and low-normal or normal free T4 levels. If some nodules develop autonomy, patients have suppressed TSH levels or become hyperthyroid. RAI uptake often shows patchy uptake with areas of hot and cold nodules. FNAB is recommended in patients who have a dominant nodule or one that is painful or enlarging, as carcinomas have been reported in 5% to 10% of multinodular goiters. CT scans are helpful to evaluate the extent of retrosternal extension and airway compression (Fig. 38-13B).

**Treatment** Most euthyroid patients with small, diffuse goiters do not require treatment. Some physicians give patients with large goiters exogenous thyroid hormone to reduce the TSH stimulation of gland growth; this treatment may result in decrease and/or stabilization of goiter size and is most effective for small diffuse goiters. Endemic goiters are treated by iodine administration. Surgical resection is reserved for goiters that (a) continue to increase despite T4 suppression, (b) cause obstructive symptoms, (c) have substernal extension (considered a relative indication by some groups), (d) have malignancy suspected or proven by FNAB, and (e) are cosmetically unacceptable. Near-total or total thyroidectomy is the treatment of choice, and patients require lifelong T4 therapy.

**Solitary Thyroid Nodule** Solitary thyroid nodules are present in approximately 4% of individuals in the United States, whereas thyroid cancer has a much lower incidence of 40 new cases per 1 million. Therefore, it is of utmost importance to determine which patients with solitary thyroid nodule would benefit from surgery.

**History.** Details regarding the nodule, such as time of onset, change in size, and associated symptoms such as pain, dysphagia, dyspnea, or choking, should be elicited. Pain is an unusual symptom and, when present, should raise suspicion for intrathyroidal hemorrhage in a benign nodule, thyroiditis, or malignancy. Patients with MTC may complain of a dull, aching sensation. A history of hoarseness is worrisome, as it may be secondary to malignant involvement of the RLNs. Most importantly, patients should be questioned regarding risk factors for malignancy, such as exposure to ionizing radiation and family history of thyroid and other malignancies associated with thyroid cancer.

**External-Beam Radiation** Low-dose therapeutic radiation has been used to treat conditions such as tinea capitis (6.5 cGy), thymic enlargement (100 to 400 cGy), enlarged tonsils and adenoids (750 cGy), acne vulgaris (200 to 1500 cGy), and other conditions such as hemangioma and scrofula. Radiation (approximately 4000 cGy) is also an integral part of the management of patients with Hodgkin’s disease. It is now known that a history of exposure to low-dose ionizing radiation to the thyroid gland places the patient at increased risk for developing thyroid cancer. The risk increases linearly from 6.5 to 2000 cGy, beyond which the incidence declines as the radiation causes destruction of the thyroid tissue. The risk is maximum 20 to 30 years after exposure, but these patients require lifelong monitoring. During the nuclear fallout from Chernobyl in 1986, 131I release was accompanied by a marked increase in the incidence of both benign and malignant thyroid lesions noted within 4 years of exposure, particularly in children.17 Most thyroid carcinomas following radiation exposure are papillary, and some of these cancers with a solid type of histology and presence of RET/PTC translocations appear to be more aggressive. In general, there is a 40% chance that patients presenting with a thyroid nodule and a history of radiation have thyroid cancer. Of those patients who have thyroid cancer, the cancer is located in the dominant nodule in 60% of patients, but in the remaining 40% of patients, the cancer is in another nodule in the thyroid gland.

A family history of thyroid cancer is a risk factor for the development of both medullary and nonmedullary thyroid cancer. Familial MTCs occur in isolation or in association with other tumors as part of multiple endocrine neoplasia type 2 (MEN2) syndromes. Nonmedullary thyroid cancers can occur in association with other known familial cancer syndromes such as Cowden’s syndrome, Werner’s syndrome (adult progeroid syndrome), familial adenomatous polyposis, and DICER 1 (Table 38-4). Nonmedullary thyroid cancers can also occur independently of these syndromes as the predominant tumors in the families, and in fact nonsyndromic FNMTC accounts for 95% of cases. The definition of familial nonmedullary thyroid cancer (FNMTMC) is variable across the literature; however, in most studies, it is defined by the presence of two or more first-degree relatives with follicular cell–derived cancers.

FAP = familial adenomatous polyposis; FTC = follicular thyroid cancer; PTC = papillary thyroid cancer.

**Family History** A family history of thyroid cancer is a risk factor for the development of both medullary and nonmedullary thyroid cancer. Familial MTCs occur in isolation or in association with other tumors as part of multiple endocrine neoplasia type 2 (MEN2) syndromes. Nonmedullary thyroid cancers can occur in association with other known familial cancer syndromes such as Cowden’s syndrome, Werner’s syndrome (adult progeroid syndrome), familial adenomatous polyposis, and DICER 1 (Table 38-4). Nonmedullary thyroid cancers can also occur independently of these syndromes as the predominant tumors in the families, and in fact nonsyndromic FNMTC accounts for 95% of cases. The definition of familial nonmedullary thyroid cancer (FNMTMC) is variable across the literature; however, in most studies, it is defined by the presence of two or more first-degree relatives with follicular cell–derived cancers.

FNMTMC is now recognized as a distinct clinical entity associated with a high incidence of multifocal tumors and benign thyroid nodules. Some studies report that these patients have higher locoregional recurrence rates and consequently shorter disease-free survival. Several candidate chromosomal loci that predispose to these tumors have been identified, including MNG1 (14q32), thyroid carcinoma with ophthilia (TCO, on 19p13.2), PTPC/papillary renal neoplasia (PRN, on 1q21), NMTC1 (2q21), and FTEN (8p23.1-p22). Susceptibility genes include SRGAP1 (12q14), TITF-1/NKX2.1 (14q13), FOXE1 (9q22), and the telomere-telomerase complex.18

**Physical Examination.** The thyroid gland is best palpated from behind the patient and with the neck in mild extension. The cricoid cartilage is an important landmark, as the isthmus is situated just below it. Nodules that are hard, gritty, or fixed to surrounding structures such as the trachea or strap muscles are more likely to be malignant. The cervical chain of lymph nodes should be assessed as well as the nodes in the posterior triangle.

**Diagnostic Investigations.** An algorithm for the workup of a solitary thyroid nodule is shown in Fig. 38-14.

**Fine-Needle Aspiration Biopsy** FNAB has become the single most important test in the evaluation of thyroid masses and can be performed with or without ultrasound guidance. Ultrasound guidance is recommended for nodules that are difficult to palpate, for cystic or solid-cystic nodules that recur after the initial aspiration, and for multinodular goiters. A 23-gauge needle is inserted into the thyroid mass, and several passes are made while aspirating the syringe. After releasing the suction on the syringe, the needle is withdrawn and the cells are immediately placed on prelabeled dry glass slides; some are immersed in a 70% alcohol solution while others are air dried. A sample of the aspirate is also placed in a 90% alcohol solution for cytospin or cell pellet. The slides are stained by Papanicolaou’s or Wright’s stains and examined under the microscope. If a bloody aspirate is obtained, the patient should be repositioned in a more upright position and the biopsy repeated with a finer (25- to 30-gauge) needle.

After FNAB, the majority of nodules can be classified into several categories that determine further management. To address the issue of variability in the terminology of fine-needle aspiration (FNA), the National Cancer Institute (NCI) hosted the “NCI Thyroid Fine Needle Aspiration State of the Science Conference,” which then defined the Bethesda criteria for thyroid FNA.19 Accordingly, optimum cytology specimens should have at least six follicles each containing at least 10 to 15 cells from at least two aspirates.

The FNA is classified as “nondiagnostic or unsatisfactory” in 2% to 20% of cases and typically results from a virtually acellular specimen, cyst fluid, or the presence of blood or clotting artifact. The risk of malignancy in this setting ranges from 1% to 4%, and reaspiration under ultrasound guidance is recommended. A “benign” result is obtained in 60% to 70% of thyroid FNAs. The most common lesion in this setting is a follicular nodule (includes adenomatoid nodule, colloid nodule, and follicular adenoma). Other diagnoses include lymphocytic (Hashimoto’s) thyroiditis and granulomatous thyroiditis. False-negative results are reported in up to 3% of cases, and follow-up is recommended. A result of “atypia of unknown significance (AUS) or follicular lesion of unknown significance (FLUS)” is obtained in 3% to 6% of biopsies. The risk of malignancy in this scenario is difficult to determine; however, it is thought to be in the range of 5% to 15%. Clinical correlation and a repeat FNA are recommended for AUS lesions (which often results in...
a more definitive interpretation), although clinical observation or surgery may be appropriate because of worrisome clinical or ultrasound findings. The category of “follicular neoplasm” is intended to identify nodules that might be follicular carcinomas. The term suspicious for a follicular neoplasm is preferred by some laboratories for this category because up to 35% of cases turn out not to be neoplasms but hyperplastic proliferations of follicular cells, most commonly those of multinodular goiter. Lobectomy is the preferred treatment for this result, and approximately 15% to 35% of lesions placed in this category prove to be malignant. Hürthle cell neoplasms are also included in this category. Most papillary and other carcinomas can be diagnosed by FNA, but the features are subtle at times, such as in follicular variant of papillary carcinomas. If the diagnosis is uncertain, the lesions are classified as “suspicious for malignancy.” Lobectomy or near-total thyroidectomy is recommended because 60% to 75% turn out to be malignant. This category also includes lesions suspicious for medullary carcinoma and lymphoma, and ancillary testing such as immunohistochemical analysis and flow cytometry may be helpful. The risk of malignancy in lesions classified as “malignant” by FNA is 97% to 99%, and near-total/total thyroidectomy is recommended.

**Laboratory Studies** Most patients with thyroid nodules are euthyroid. Determining the blood TSH level is helpful. If a patient with a nodule is found to be hyperthyroid, the risk of malignancy is approximately 1%. Serum Tg levels cannot differentiate benign from malignant thyroid nodules unless the levels are extremely high, in which case metastatic thyroid cancer should be suspected. Tg levels are, however, useful in following patients who have undergone total thyroidectomy for thyroid cancer and also for serial evaluation of patients undergoing nonoperative management of thyroid nodules. Serum calcitonin levels should be obtained in patients with MTC or a family history of thyroid cancer; FNAB = fine-needle aspiration biopsy; AUS = atypia of unknown significance; FLUS = follicular lesion of unknown significance; FN = follicular neoplasm.

**Imaging** Ultrasound is helpful for detecting nonpalpable thyroid nodules, differentiating solid from cystic nodules, and identifying adjacent lymphadenopathy. Ultrasound evaluation can identify features of a nodule that increase the a priori risk of malignancy, such as fine stippled calcification and enlarged regional nodes; however, a tissue diagnosis is strongly recommended before thyroidectomy. Ultrasound also provides a noninvasive and inexpensive method of following the size of suspected benign nodules diagnosed by FNAB and for identifying enlarged lymph nodes. Ultrasound elastography is used to evaluate tissue stiffness noninvasively. This technique takes advantage of the fact that malignant nodules tend to be harder than benign nodules and thus deform less compared with the surrounding normal thyroid parenchyma. Larger studies are warranted before elastography and newer techniques such as contrast-enhanced ultrasound can be routinely included in the evaluation of thyroid nodules. CT and MRI are unnecessary in the routine evaluation of thyroid tumors except for large, fixed, or substernal lesions. Scanning the thyroid with 123I or 99mTc is rarely necessary, and thyroid scanning currently is recommended in the assessment of thyroid nodules only in patients...
who have follicular thyroid nodules on FNAB and a suppressed TSH. PET scanning does not play a major role in the primary evaluation of thyroid nodules.

**Management.** Malignant tumors are treated by thyroidectomy, as discussed earlier and later in this chapter in “Surgical Treatment under Malignant Thyroid Disease.” Simple thyroid cysts resolve with aspiration in about 75% of cases, although some require a second or third aspiration. If the cyst persists after three attempts at aspiration, unilateral thyroid lobectomy is recommended. Lobectomy also is recommended for cysts >4 cm in diameter or complex cysts with solid and cystic components, as the latter have a higher incidence of malignancy (15%). When FNAB is used in complex nodules, the solid portion should be sampled. If a colloid nodule is diagnosed by FNAB, patients should still be observed with serial ultrasound and Tg measurements. If the nodule enlarges, repeat FNAB often is indicated. Although controversial, levothyroxine in doses sufficient to maintain a serum TSH level between 0.1 and 1.0 μU/mL may also be administered. In areas with a high prevalence of iodine deficiency, this can decrease nodule size and potentially prevent the growth of new nodules. In iodine-sufficient populations, the data are less impressive. Randomized controlled trial analyses have shown that less than 25% of benign nodules shrink more than 50% with TSH suppression in iodine-replete populations.

Thyroidectomy should be performed if a nodule enlarges on TSH suppression, causes compressive symptoms, or for cosmetic reasons. An exception to this general rule is the patient who has had previous irradiation of the thyroid gland or has a family history of thyroid cancer. In these patients, total or near-total thyroidectomy is recommended because of the high incidence of thyroid cancer and decreased reliability of FNAB in this setting.

**Malignant Thyroid Disease**

In the United States, thyroid cancer accounts for <1% of all malignancies (2% of women and 0.5% of men) and is the most rapidly increasing cancer in women. Thyroid cancer is responsible for six deaths per million persons annually. Most patients present with a palpable swelling in the neck, which initiates assessment through a combination of history, physical examination, and FNAB.

**Molecular Genetics of Thyroid Tumorigenesis.** Several oncogenes and tumor suppressor genes are involved in thyroid tumorigenesis,22 as depicted in Table 38-5. The RET proto-oncogene (Fig. 38-15) plays a significant role in the pathogenesis of thyroid cancers. It is located on chromosome 10 and encodes a receptor tyrosine kinase, which binds several growth factors such as glial-derived neurotrophic factor and neurturin. The RET protein is expressed in tissues derived from the embryonic nervous and excretory systems. Therefore,

FTC = follicular thyroid cancer; GTP = guanosine triphosphate; MTC = medullary thyroid cancer; PTC = papillary thyroid cancer.
RET disruption can lead to developmental abnormalities in organs derived from these systems, such as the enteric nervous system (Hirschsprung’s disease) and kidney. Germline mutations in the RET proto-oncogene are known to predispose to MEN2A, MEN2B, and familial MTCs, and somatic mutations have been demonstrated in tumors derived from the neural crest, such as MTCs (30%) and pheochromocytomas. The tyrosine kinase domain of RET can fuse with other genes by rearrangement. These fusion products also function as oncogenes and have been implicated in the pathogenesis of PTCs. At least 15 RET/PTC rearrangements have been described and appear to be early events in tumorigenesis. Young age and radiation exposure seem to be independent risk factors for the development of RET/PTC rearrangements. Up to 70% of papillary cancers in children exposed to the radiation fallout from the 1986 Chernobyl disaster carry RET/PTC rearrangements, the most common being RET/PTC1 and RET/PTC3. These rearrangements confer constitutive activation of the receptor tyrosine kinases. RET/PTC3 is associated with a solid type of PTC that appears to present at a higher stage and to be more aggressive. It has now been established that RET/PTC3 signaling involves the mitogen-activated protein kinase (MAPK) pathway via other signaling molecules such as Ras, Raf, and MEK. In normal cells, physiological activation of Raf kinases occurs via direct interaction with guanosine triphosphate (GTP)-bound Ras, a membrane-bound small G protein. Activated Raf, a serine-threonine kinase, in turn phosphorylates MEK, another serine-threonine kinase. This leads to phosphorylation of ERK/MAPK, which phosphorylates regulatory molecules in the nucleus, thereby altering gene expression. Aberrant activation of the MAPK pathway leads to tumorigenesis. Aside from RET/PTC alterations, mutations in the Ras genes can also activate the MAPK pathway. Mutated RAS oncogenes have been identified in up to 20% to 40% of thyroid follicular adenomas and carcinomas, multinodular goiters, and papillary and anaplastic carcinomas. There are three Raf kinases, A-Raf, B-Raf (BRAF), and C-Raf. Mutations in BRAF also have been implicated in aberrant MAPK pathway activation and tumorigenesis. Of the various identified BRAF mutations, T1799A (V600E amino acid substitution) is the most common and occurs frequently in thyroid cancers. Interestingly, BRAF mutations occur in papillary and anaplastic tumors (average prevalence of 44% and 22%, respectively) but not in follicular thyroid cancers, suggesting a role in the pathogenesis of these malignancies. Studies also show that BRAF mutations are associated with more aggressive clinicopathologic features, including larger tumor size, invasion, and lymphadenopathy, and may have a role as prognostic markers.

The p53 gene is a tumor suppressor gene encoding a transcriptional regulator, which causes cell cycle arrest allowing repair of damaged DNA, thus helping to maintain genomic integrity. Mutations of p53 are rare in PTCs but common in undifferentiated thyroid cancers and thyroid cancer cell lines. Other cell cycle regulators and tumor suppressors such as p15 and p16 are mutated more commonly in thyroid cancer cell lines than in primary tumors. An oncogene resulting from the fusion of the DNA binding domain of the thyroid-transcription factor PAX8 gene to the peroxisome proliferator-activated receptor gamma 1 (PPARγ1) has been noted to play an important role
in the development of follicular neoplasms, including follicular cancers. Mutations in the telomerase reverse transcriptase catalytic subunit (TERT) promoter unit have also been recently been identified in well-differentiated thyroid cancers and appear to be related to poor prognosis. Thyroid cancer stem cells have also been identified; however, their role in thyroid carcinogenesis remains to be determined. Mutations in the kinases PIK3CA and AKT1 are rare in thyroid cancers and tend to occur as late events in tumorigenesis.

Specific Tumor Types

Papillary Carcinoma Papillary carcinoma accounts for 80% of all thyroid malignancies in iodine-sufficient areas and is the predominant thyroid cancer in children and individuals exposed to external radiation. Papillary carcinoma occurs more often in women, with a 2:1 female-to-male ratio, and the mean age at presentation is 30 to 40 years. Most patients are euthyroid and present with a slow-growing painless mass in the neck. Dysphagia, dyspnea, and dysphonnia usually are associated with locally advanced invasive disease. Lymph node metastases are common, especially in children and young adults, and may be the presenting complaint. “Lateral aberrant thyroid” almost always denotes a cervical lymph node that has been invaded by metastatic cancer. Suspicion of thyroid cancer often originates through physical examination of patients and a review of their history. Diagnosis is established by FNAB of the thyroid mass or lymph node. Once thyroid cancer is diagnosed on FNAB, a complete neck ultrasound is strongly recommended to evaluate the contralateral lobe and for lymph node metastases in the central and lateral neck compartments. Distant metastases are uncommon at initial presentation, but may ultimately develop in up to 20% of patients. The most common sites are lungs, pleura, liver, and brain.

Pathology. On gross examination, PTCs generally are hard and whitish and remain flat on sectioning with a blade, in contrast to normal tissue or benign nodular lesions that tend to bulge. Macroscopic calcification, necrosis, or cystic change may be apparent. Histologically, papillary carcinomas may exhibit papillary projections (Fig. 38-16A), a mixed pattern of papillary and follicular structures, or a pure follicular pattern (follicular variant). The diagnosis is established by characteristic nuclear cellular features. Cells are cuboidal with pale, abundant cytoplasm, crowded nuclei that may demonstrate “grooving,” and intranuclear cytoplasmic inclusions (leading to the designation of Orphan Annie nuclei [Fig. 38-16B]), which allow diagnosis by FNAB. Psammoma bodies, which are microscopic, calcified deposits representing clumps of sloughed cells, also may be present. Mixed papillary-follicular tumors and follicular variant of papillary thyroid carcinoma (FVPTC) are classified as papillary carcinomas because they behave biologically as papillary carcinomas. Two main subtypes of FVPTC are recognized: encapsulated and nonencapsulated (infiltrative). The former is challenging to diagnose. Since the tumors have no invasion, the diagnosis relies on the finding of characteristic nuclei, which can be subjective. In addition, several studies have shown that the encapsulated tumors have an indolent behavior and are genetically distinct from their infiltrative counterparts. As such, these tumors are now designated noninvasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP).

Multifocality is common in papillary carcinoma and may be present in up to 85% of cases on microscopic examination. Multifocality is associated with an increased risk of cervical nodal metastases, and these tumors may rarely invade adjacent structures such as the trachea, esophagus, and RLNs. Other variants of papillary carcinoma include tall cell, insular, columnar, diffuse sclerosing, clear cell, trabecular, and poorly differentiated types. These variants account for about 1% of all papillary carcinomas and are generally associated with a worse prognosis.

Minimal or occult/microcarcinoma refers to tumors of 1 cm or less in size with no evidence of local invasiveness through the thyroid capsule or angioinvasion, and that are not associated with lymph node metastases. They are nonpalpable and usually are incidental findings at operative, histologic, or autopsy examination. Studies have demonstrated occult PTC to be present in 2% to 36% of thyroid glands removed at autopsy. These tumors are also being identified more frequently due to the widespread use of ultrasound. These occult tumors are generally associated with a better prognosis than larger tumors, but they may be more aggressive than previously appreciated. About 25% of patients with these tumors have associated occult lymph node metastases.

Prognostic Indicators. In general, patients with PTC have an excellent prognosis with a >95% 10-year survival rate. Several prognostic indicators have been incorporated into various
staging systems, which enable patients to be stratified into low-risk and high-risk groups. Unfortunately, all of these classification systems rely on data that are not available preoperatively.

In 1987, Hay and colleagues at the Mayo Clinic proposed the AGES scoring system, which incorporates Age, histologic Grade, Extrathyroidal invasion, and metastases and tumor Size to predict the risk of dying from papillary cancer. Low-risk patients are young, with well-differentiated tumors, no metastases, and small primary lesions, whereas high-risk patients are older, with poorly differentiated tumors, local invasion, distant metastases, and large primary lesions. The MACIS scale is a postoperative system modified from the AGES scale. This scale incorporates distant Metastases, Age at presentation (<40 or >40 years old), Completeness of original surgical resection, extrathyroidal Invasion, and Size of original lesion (in centimeters) and classifies patients into four risk groups based on their scores. Cady proposed the AMES system to classify differentiated thyroid tumors into low- and high-risk groups using Age (men <40 years old, women <50 years old), Metastases, Extrathyroidal spread, and Size of tumors (< or >5 cm). A simplified system by DeGroot and associates uses four groups—class I (intradathroidal), class II (cervical nodal metastases), class III (extrathyroidal invasion), and class IV (distant metastases)—to determine prognosis. Another classification system is the TNM system (Tumor, Nodal status, Metastases; Table 38-6), which used by most medical centers in North America and has been recently updated. In this new version, minimal extrathyroidal extension is no longer considered T3a disease. Thyroglobulin doubling time (using levels obtained when TSH is <0.1 mIU/L) has also been demonstrated to be an independent prognostic marker for metastatic disease and recurrence.

Several molecular and genetic markers such as tumor DNA aneuploidy, decreased cyclic adenosine monophosphate response to TSH, increased epidermal growth factor binding, presence of N-ras and gsp mutations, overexpression of c-myc, and presence of p53 mutations also have been associated with a worse prognosis. The presence of BRAF V600E mutation, as previously mentioned, is associated with aggressive tumor characteristics, including extrathyroidal extension, older age at presentation, and lymph node and distant metastases. This mutation also appears to be an independent predictor of both tumor recurrence (even for early-stage disease) and tumor-related mortality. Some studies propose that BRAF mutation status on FNAB can be used to tailor initial management including more extensive initial surgical excision, high-dose postoperative RAI therapy, increased TSH suppression, and closer follow-up. The correlation of RET/PTC rearrangements and Ras mutations with prognosis is less clear. TERT promoter mutations have been associated with poor disease-specific and disease-free survival.

Surgical Treatment. Most authors agree that patients with high-risk tumors (judged by any of the classification systems discussed earlier in “Prognostic Indicators”) or bilateral tumors should undergo total or near-total thyroidectomy. The optimal surgical strategy in the majority of patients with low-risk (small, unilateral) cancers was controversial for many years, with the focus of the debate centering around outcome data and risks associated with extent of thyroidectomy in this group of patients. Proponents of total thyroidectomy indicate that it enables the use of RAI to effectively detect and treat residual thyroid tissue or metastatic disease and makes serum Tg level a more sensitive marker of recurrent or persistent disease. It is also known that a significant proportion (33% to 50%) of patients who develop a recurrence die from their disease, and even though the data are retrospective, long-term, follow-up studies suggest that recurrence rates are lowered and that survival is improved in patients undergoing near-total or total thyroidectomy. In addition, diminished survival is noted in patients with low-risk disease (mortality rates of 5% at 10 to 20 years), and it is not possible to accurately risk stratify patients preoperatively. In the last 10 years, a large study of >50,000 patients with papillary cancer demonstrated that, in multivariate analyses, total thyroidectomy led to a significantly improved recurrence and survival for tumors >1 cm. Furthermore, the authors also showed that patients with tumors 1 to 2 cm in diameter who were treated with lobectomy had a 24% higher risk of recurrence and a 49% higher risk of thyroid cancer mortality. Based on this information, the American Thyroid Association 2009 guidelines for the evidence-based management of thyroid cancers recommended a near-total or total thyroidectomy for primary cancers >1 cm unless there are contraindications to the surgery. However, additional studies since then have demonstrated no survival differences based on initial surgical procedure when adjusting for complexity/risk and comorbid diseases. This finding, coupled with a trend for increased use of ultrasound and Tg measurements to assess for recurrences and the declining use of RAI ablation, led to revised guidelines in 2015. Accordingly, either near-total(total thyroidectomy or lobectomy constitute appropriate initial treatment for tumors >1 cm and <4 cm without extrathyroidal extension or lymph node involvement (cN0). Of note, the guidelines do state that the treatment team may elect near-total/total thyroidectomy to facilitate RAI therapy, enhance follow-up based on disease features, or if the patient expresses a preference for complete thyroid excision.

There has also been in change in the management of papillary microcarcinomas (<1 cm) since at least two trials from Japan have shown that active surveillance (defined as observation without immediate surgery) can be a viable and safe first line of treatment for these very-low-risk tumors without extrathyroidal extension or lymph node metastases. Tumors that progress during monitoring are treated by surgery. If surgery is chosen as initial treatment for these patients, a thyroid lobectomy is considered sufficient.

When PTC is diagnosed by FNAB, the definitive operation can be done without confirming the diagnosis by frozen section during the operation. Patients with a nodule that is suspicious for papillary cancer should be treated by thyroid lobectomy, isthmectomy, and removal of any pyramidal lobe or adjacent lymph nodes. If intraoperative frozen-section examination of a lymph node or primary tumor confirms carcinoma, completion total or near-total thyroidectomy is performed. If a definitive diagnosis cannot be made or the surgeon is concerned about the viability of the parathyroid glands or the status of the RLN, the operation is terminated. When final histology confirms carcinoma, completion thyroidectomy is performed if deemed necessary based on risk-stratification. During thyroidectomy, enlarged or obviously involved central neck nodes should be removed (therapeutic central-compartment, level VI), along with nodes with known lateral neck metastases. Some investigators recommend routine bilateral central neck dissection due to the high incidence of microscopic metastases and data showing improved rates of recurrence and survival (compared to historic controls).

### DEFINITIONS

#### Primary tumor (T)
- **TX** = Primary tumor cannot be assessed
- **T0** = No evidence of primary tumor
- **T1** = Tumor ≤2 cm in greatest dimension limited to the thyroid
  - **T1a** = Tumor ≤1 cm in greatest dimension limited to the thyroid
  - **T1b** = Tumor >1 cm but ≤2 cm in greatest dimension limited to the thyroid
- **T2** = Tumor >2 cm but ≤4 cm in greatest dimension limited to the thyroid
- **T3** = Tumor >4 cm limited to the thyroid, or gross extrathyroidal extension invading only strap muscles
  - **T3a** = Tumor >4 cm limited to the thyroid
  - **T3b** = Gross extrathyroidal extension invading only strap muscles (sternohyoid, sternothyroid, thyrohyoid, or omohyoid muscles) from a tumor of any size
- **T4** = Includes gross extrathyroidal extension beyond the strap muscles
  - **T4a** = Gross extrathyroidal extension invading subcutaneous soft tissues, larynx, trachea, esophagus, or recurrent laryngeal nerve from a tumor of any size
  - **T4b** = Gross extrathyroidal extension invading prevertebral fascia or encasing the carotid artery or mediastinal vessels from a tumor of any size

#### Regional lymph nodes (N)
- **NX** = Regional lymph nodes cannot be assessed
- **N0** = No evidence of locoregional lymph node metastasis
  - **N0a** = One or more cytologically or histologically confirmed benign lymph nodes
  - **N0b** = No radiologic or clinical evidence of locoregional lymph node metastasis
- **N1** = Metastasis to regional nodes
  - **N1a** = Metastasis to level VI or VII (pretracheal, paratracheal, or prelaryngeal/Delphian, or upper mediastinal) lymph nodes. This can be unilateral or bilateral disease.
  - **N1b** = Metastasis to unilateral, bilateral, or contralateral lateral neck lymph nodes (levels I, II, III, IV, or V) or retropharyngeal lymph nodes

#### Distant Metastasis (M)
- **M0** = No distant metastasis
- **M1** = Distant metastasis

However, these risks need to be balanced with the increased risk of hypoparathyroidism with routine central neck dissection and the fact that some studies do not show any difference in recurrence rates or rates of low or undetectable Tg levels. The updated 2015 ATA guidelines for thyroid cancer management suggest that prophylactic (ipsilateral or bilateral) dissection may be performed in patients with advanced (T3 or T4) papillary thyroid carcinoma, or if the lateral neck nodes are involved with tumor (N1b), or if the information will help in treatment planning.40 The American Head and Neck Society urges the involvement of multidisciplinary teams in the decision-making process for prophylactic CND and indicates that it can be considered in patients with high risk of recurrence (to include older or young age, multifocal disease and extrathyroidal extension in addition to the aforementioned factors).42 Further prospective studies are needed before definitive recommendations can be made in this regard.

Biopsy-proven lymph node metastases detected clinically or by imaging in the lateral neck in patients with papillary carcinoma are managed with modified radical or functional neck dissection,40 as described later in this chapter in “Thyroid Surgery.” Dissection of the posterior triangle and suprathyroid dissection usually are not necessary unless there is extensive metastatic disease in levels 2, 3, and 4, but should be performed when appropriate. Prophylactic lateral neck node dissection is not necessary in patients with PTC because these cancers do not appear to metastasize systemically from lymph nodes, and micrometastases often can be ablated with RAI therapy.

**Follicular Carcinoma** Follicular carcinomas account for 10% of thyroid cancers and occur more commonly in iodine-deficient areas. The overall incidence of this tumor is declining in the United States, probably due to iodine supplementation and improved histologic classification. Women have a higher incidence of follicular cancer, with a female-to-male ratio of 3:1, and a mean age at presentation of 50 years old. Follicular cancers usually present as solitary thyroid nodules, occasionally with a history of rapid size increase, and long-standing goiter. Pain is uncommon, unless hemorrhage into the nodule has occurred. Unlike papillary cancers, cervical lymphadenopathy is uncommon at initial presentation (about 5%), although distant metastases may be present. In <1% of cases, follicular cancers may be hyperfunctioning, leading patients to present with signs and symptoms of thyrotoxicosis. FNAB is unable to distinguish benign follicular lesions from follicular carcinomas. Therefore, preoperative clinical diagnosis of cancer is difficult unless distant metastases are present. Large follicular tumors (>4 cm) in older men are more likely to be malignant.

Due to the limitations inherent in the FNAB diagnosis, a number of studies have focused on identifying molecular markers to distinguish benign from malignant follicular lesions. Many of these genetic changes can be identified using tissue obtained during FNAB. While no single marker has met the ideal characteristics of being simple to use, reproducible, and cost-effective, several combinations of markers appear to be useful in differentiating benign from malignant follicular lesions. A commonly used panel of seven genes used to “rule in” malignancy detects mutations in BRAF, Ras, RET/PTC, and PAX/PPARγ and has been associated with a sensitivity of 57% to 75%, specificity of 97% to 100%, PPV of 87% to 100%, and NPV of 79% to 86% in the case of nodules consistent with Follicular/Hürthle cell neoplasms or suspicious of the same.43 In contrast, the Afirma Gene Expression Classifier (GEC) uses a “rule out” strategy to identify benign nodules. This method uses material from additional FNA passes (in an RNA-preserving solution) to analyze a 167 gene panel, and the results obtained are reported as benign or suspicious.44 It is reported to have a lower PPV of 37% but a better NPV of 94% for Follicular/Hürthle cell neoplasms. Next generation sequencing techniques have been used to enhance malignancy detection.

![Graph showing cumulative death rates](image-url)
by including additional mutations and gene arrangements. The advanced version of this assay (ThyroSeq V2) had a sensitivity of 90%, specificity of 93%, PPV of 83%, and NPV of 96% in a study of Follicular/Hürthle cell neoplasm/suspicious of the same nodules, making it useful as both a “rule in” and “rule out” test. Of note, these assays have also been evaluated in “AUS/FLUS” and “suspicious for malignancy” nodules with varying results, i.e., the performance characteristics of these tests have been noted to change depending upon the prevalence of malignancy in the tested population (pretest probability). At this time, the ATA guidelines do not advise molecular testing in the work-up of “suspicious for malignancy” nodules. Molecular testing may be used to supplement cytology results for malignancy risk assessment in “AUS/FLUS” or “follicular/Hürthle cell neoplasm/suspicious of the same” nodules depending on feasibility and informed patient preference. Expression arrays also have been used to investigate the role of microRNAs, which are a new class of small, noncoding RNAs that have been implicated in carcinogenesis. The specific microRNAs miR-197 and miR-346 are upregulated in follicular thyroid cancers and have the potential to be used as diagnostic markers. Additional studies have also demonstrated the feasibility of studying a panel of microRNAs in a small number of FNA samples. ThyGenX/ThyraMIR uses a mutation panel supplemented with 10 miRNA markers, whereas Rosetta GX Reveal is exclusively based on miRNA markers; however, both require further validation.

Pathology. Follicular carcinomas usually are solitary lesions, and the majority are surrounded by a capsule. Histologically, follicles are present, but the lumen may be devoid of colloid. Architectural patterns depend on the degree of differentiation demonstrated by the tumor. Malignancy is defined by the presence of capsular and vascular invasion (Fig. 38-18). In general, minimally invasive tumors appear grossly encapsulated and have microscopic invasion through the tumor capsule without extension into the parenchyma and/or invasion into small- to medium-sized vessels (venous caliber) in or immediately outside the capsule, but not within the tumor. On the other hand, widely invasive tumors demonstrate evidence of large vessel invasion and/or broad areas of tumor invasion through the capsule. They may, in fact, be unencapsulated. It is important to note that there is a wide variation of opinion among clinicians and pathologists with respect to the above definitions. Tumor infiltration and invasion, as well as tumor thrombi within the middle thyroid or jugular veins, may be apparent at operation.

Surgical Treatment and Prognosis. Patients diagnosed by FNAB as having a follicular lesion should undergo thyroid lobectomy because at least 70% to 80% of these patients will have benign adenomas. Total thyroidectomy is recommended by some surgeons in older patients with follicular lesions >4 cm because of the higher risk of cancer in this setting (50%) and certainly should be performed in patients with atypia on FNA, a family history of thyroid cancer, or a history of radiation exposure. Intraoperative frozen-section examination usually is not helpful, but it should be performed when there is evidence of capsular or vascular invasion or when adjacent lymphadenopathy is present. Total thyroidectomy should be performed when thyroid cancer is diagnosed. There is debate among experts about whether patients with minimally invasive follicular cancers should undergo completion thyroidectomy because the prognosis is so good in these patients. A diagnosis of frankly invasive carcinoma or follicular carcinoma with angioinvasion, with or without capsular invasion, necessitates completion of total thyroidectomy primarily so that 131I can be used to detect and ablate metastatic disease. Propylactic nodal dissection is not needed because nodal involvement is infrequent, but in the unusual patient with nodal metastases, therapeutic neck dissection is recommended. Propylactic central neck dissection may be considered in patients with large tumors. The cumulative mortality from follicular thyroid cancer is approximately 15% at 10 years and 30% at 20 years. Poor long-term prognosis is predicted by age over 50 years old at presentation, tumor size >4 cm, higher tumor grade, marked vascular invasion, extrathyroidal invasion, and distant metastases at the time of diagnosis.

Hürthle Cell Carcinoma. Hürthle cell carcinomas account for approximately 3% of all thyroid malignancies and, under the World Health Organization classification, are considered to be a subtype of follicular thyroid cancer. Hürthle cell cancers also are characterized by vascular or capsular invasion and, therefore, cannot be diagnosed by FNAB. Tumors contain sheets of eosinophilic cells packed with mitochondria, which are derived from the oxyphilic cells of the thyroid gland. Hürthle cell tumors differ from follicular carcinomas in that they are more often multifocal and bilateral (about 30%), usually do not take up RAI (about 5%), are more likely to metastasize to local nodes (25%) and distant sites, and are associated with a higher mortality rate (about 20% at 10 years). Hence, they are considered to be a separate class of tumors by some groups.

Management is similar to that of follicular neoplasms, with lobectomy and isthmusectomy being sufficient surgical treatment for unilateral Hürthle cell adenomas. When Hürthle cell neoplasms are found to be invasive on definitive paraffin-section histology, then total thyroidectomy should be performed. These patients should also undergo routine central neck node removal, similar to patients with MTC, and modified radical neck dissection when lateral neck nodes are palpable or identified by ultrasonography. Although RAI scanning and ablation usually are ineffective, they probably should be considered to ablate any residual normal thyroid tissue and occasionally ablate tumors because there is no other good therapy.

Postoperative Management of Differentiated Thyroid Cancer

Radioiodine Therapy. The issue of whether RAI therapy offers any benefit to patients with differentiated thyroid cancer

Figure 38-18. Hematoxylin-eosin–stained section from follicular thyroid carcinoma showing capsular invasion.
remains controversial in the absence of prospective, random- ized controlled trials. Long-term cohort studies by Mazzaferri and associates and DeGroot and colleagues demonstrate that postoperative RAI therapy reduces recurrence (Fig. 38-19) and provides a small improvement in survival, even in low-risk patients. Screening with RAI is more sensitive than chest X-ray or CT scanning for detecting metastases; however, it is less sensitive than Tg measurements for detecting metastatic disease in most differentiated thyroid cancers except Hürthle cell tumors. Screening and treatment are facilitated by the removal of all normal thyroid tissue, which effectively competes for iodine uptake. Metastatic differentiated thyroid carcinoma can be detected and treated by \( ^{131}I \) in about 75% of patients. Multiple studies show that RAI effectively treats >70% of lung micrometastases that are detected by RAI scan in the presence of a normal chest X-ray, whereas the success rates drop to <10% with pulmonary macrometastases. Early detection therefore is very important to improve prognosis.

Several features place patients at increased risk for local recurrences or metastases. The 2015 ATA guidelines use various features to risk-stratify tumors. Low-risk papillary thyroid cancer includes those without local tumor invasion, all macroscopic tumor resected, absence of aggressive histology (e.g., tall cell, columnar cell carcinoma), no known distant metastases (clinical or on RAI scan if done), no vascular invasion, clinical N0 or ≤5 pathologic N1 micrometastases (<0.2 cm in largest dimension), intrathyroidal, encapsulated follicular variant of papillary thyroid cancer, intrathyroidal, well differentiated follicular thyroid cancer with capsular invasion and no or minimal (<4 foci) vascular invasion and intrathyroidal papillary microcarcinoma (unifocal or multifocal, including \( BRAF ^{V_{600}E} \) mutated). Intermediate-risk tumors include those showing microscopic invasion of tumor into the perithyroidal soft tissues or RAI-avid metastatic foci in the neck on the first posttreatment whole-body RAI scan. This group also includes tumors with aggressive histology (e.g., tall cell, columnar cell carcinoma), papillary thyroid cancer with vascular invasion, clinical N1 or >5 pathologic N1 with all involved lymph nodes <3 cm in largest dimension and multifocal papillary microcarcinoma with extra-thyroidal extension (ETE) and \( BRAF ^{V_{600}E} \) mutated (if known). High-risk tumors include those demonstrating macroscopic invasion of tumor into the perithyroidal soft tissues (gross ETE), incomplete tumor resection, and presence of distant metastases (or postoperative serum thyroglobulin suggestive of distant metastate) or pathologic N1 with any metastatic lymph node ≥3 cm in largest dimension. Follicular thyroid cancers with extensive vascular invasion (>4 foci of vascular invasion) also fall into this category. It is important to note that this risk assessment represents a continuum with recurrence rates from 1% to 2% for low-risk cancers to >50% for high-risk cancers.

The current ATA guidelines recommend RAI therapy after surgical treatment for all patients with high-risk disease, i.e., those with gross ETE and M1 disease. RAI therapy is not recommended for patients with papillary microcarcinomas, either uni- or multifocal. RAI remnant ablation is not routinely recommended after thyroidectomy for ATA low-risk DTC patients. However, it may be considered in patients with aggressive histology or vascular invasion. Consideration of RAI is recommended for patients with intermediate-risk disease and “generally favored” for patients with microscopic ETE due to the risk of recurrent disease, large (>2–3 cm) or clinically evident lymph nodes (central, mediastinal, and lateral neck) or presence of extranodal extension. Advancing age may also favor RAI use. However, RAI is not needed for patients with a few (<5) microscopic nodal metastases in the central compartment in the absence of other adverse features as there is insufficient evidence for its utility in this setting. It is generally favored for patients with lateral neck disease. There is currently no established role for molecular testing in determining RAI therapy.

Remnant ablation can be performed with either thyroid hormone withdrawal or recombinant TSH (rTSH) stimulation. This is based on randomized studies showing that both techniques are equally effective in preparing patients for ablation, with the latter being associated with an improved quality of life.49,50 In patients with ATA high-risk disease (including distant metastases), there is insufficient data to recommend thyro- gen-mediated ablation, and hormone withdrawal is preferred. Furthermore, if patients have comorbidities that can be exacerbated by severe hypothyroidism (cardiac or psychiatric conditions), consideration should be given to thyrogen-mediated RAI. If hormone withdrawal is used, \( T_3 \) therapy should be discontinued for approximately 6 weeks before scanning with \( ^{131}I \). Patients should receive \( T_3 \) during this time period to decrease the period of hypothyroidism. \( T_3 \) has a shorter half-life than \( T_4 \) (1 day vs. 1 week) and needs to be discontinued for 2 weeks to allow TSH levels to rise before treatment. Levels >30 mU/L are considered optimal, based on noncontrolled studies. A low-iodine diet also is recommended during this 2-week period. The usual protocol involved administering a screening dose of 1 to 3 mCi and measuring uptake 24 hours later. After a total thyro- idectomy, this value should be <1%. A “hot” spot in the neck after initial screening usually represents residual normal tissue in the thyroid bed. Some investigators recommend omitting the scanning dose altogether to minimize thyrocyte “stunning” and subsequent requirement for higher treatment doses. Others recommend scanning only if the size of the remnant cannot be determined by the operative report or ultrasound, or if the results would alter the decision to treat or the dose to be administered. Current guidelines recommend using either \( ^{123}I \) or low-activity \( ^{131}I \) (1- to 3-mCi dose) and delivering a therapeutic dose within 72 hours.

The recommended dose of RAI is 30 mCi if remnant abla- tion is performed after total thyroidectomy for ATA low-risk thyroid or intermediate-risk cancer with lower risk features (i.e., low-volume central neck nodal metastases with no other known gross residual disease or any other adverse features). If RAI is given for adjuvant treatment to treat suspected microscopic disease (in the absence of metastatic disease), doses ranging from 30 to 150 mCi are recommended, and there is no solid evidence to show that higher doses reduce the recurrence rates for T3 and N1 disease in this setting.

If patients have an elevated Tg level, but negative RAI scan on follow-up, some physicians recommend treating once with 100 mCi of \( ^{131}I \) and repeating the imaging 1 to 2 weeks later. Approximately one-third of these patients demonstrate uptake on posttreatment imaging, and Tg levels usually decrease in these patients, documenting therapeutic benefit. The maximum dose of radiiodine that can be administered at one time without performing dosimetry is approximately 200 mCi with a cumulative dose of 1000 to 1500 mCi. Up to 500 mCi can be given with proper pretreatment dosimetry. Recent studies also
Figure 38-19. Tumor recurrence at a median of 16.7 years after thyroid surgery. The numerator is the number of patients with recurrence, and the denominator is the number of patients in each time interval. The $P$ values are derived from log-rank statistical analysis of 40-year life-table data. Figure shows that all recurrences (A) and distant metastases (B) were reduced in patients who received radioactive iodine (RAI) in addition to thyroxine (T4) therapy. (Reproduced with permission from Mazzaferri E, Kloos R: Current approaches to primary therapy for papillary and follicular thyroid cancer, Clin Endocrinol Metab. 2001 Apr; 86(4):1447-1363.)
show an increase in the number of second cancers in patients treated with RAI. The early and delayed complications of RAI therapy are listed in Table 38-7.

**Thyroid Hormone** $T_4$ is necessary as replacement therapy in patients after total or near-total thyroidectomy, and also has the additional effect of suppressing TSH and reducing the growth stimulus for any possible residual thyroid cancer cells. TSH suppression reduces tumor recurrence rates. Current guidelines advise maintaining initial TSH levels <0.1 mU/mL in patients with high-risk thyroid cancer and in the range of 0.1 to 0.5 mU/mL in patients with intermediate-risk disease. For low-risk patients (with or without remnant ablation) with undetectable serum Tg levels, TSH levels can be maintained at the lower end of the reference range (0.5–2 mU/L). If these patients have low measureable Tg levels, it is recommended that TSH be maintained at or slightly below lower limit of normal (0.1 to 0.5 mU/L) while continuing surveillance for recurrence. In low-risk patients treated with lobectomy alone, it is advised to keep TSH in the mid to lower reference range (0.5–2 mU/L), and hormone therapy may be needed to maintain these levels. Further TSH suppression levels are determined by response to therapy. The risk of tumor recurrence must be balanced with the side effects associated with prolonged TSH suppression, including osteopenia and cardiac problems, particularly in older patients.

**Follow-Up of Patients With Differentiated Thyroid Cancer**

**Thyroglobulin Measurement** Tg and anti-Tg antibody levels should be measured initially at 6 to 12 month intervals and more frequently in patients with high-risk tumors. Further measurements are guided by response to therapy. Patients are considered to have an excellent response to treatment if suppressed Tg is <0.2 ng/mL and stimulated Tg is <1 ng/mL with negative imaging. In these patients, Tg levels can be followed every 12 to 24 months while on thyroid hormone as their risk of recurrence is low (1–4%). Patients with structurally or biochemically incomplete (negative imaging but suppressed Tg ≥1 ng/mL or stimulated Tg ≥10 ng/mL or rising anti-Tg levels) or indeterminate responses (nonspecific imaging findings, suppressed Tg detectable but <1 ng/mL, and stimulated Tg detectable but <10 ng/mL or stable or declining anti-Tg levels) require additional investigations. Tg measurements in FNAB aspirates have also been shown to be useful in the detection of nodal metastatic disease.

**Imaging** After the first posttreatment scan, low- and some intermediate-risk patients with negative TSH-stimulated Tg and cervical ultrasound do not require routine diagnostic whole-body radiiodine scans. However, diagnostic whole-body scans 6 to 12 months after remnant ablation may be of value in the follow-up of patients with high- or intermediate-risk patients with higher risk features. Other scenarios for follow-up scans include patients with abnormal uptake outside the thyroid bed on posttherapy scan, those with poorly informative postablotion scans (e.g., due to high thyroid bed uptake), and patients with Tg antibodies.

Cervical ultrasound be performed to evaluate the thyroid bed and central and lateral cervical nodal compartments at 6 and 12 months after thyroidectomy and then annually for at least 3 to 5 years, depending on the patient’s risk for recurrent disease and Tg status. Sonographically suspicious nodes ≥8 to 10 mm on the smallest diameter measurement should be biopsied for cytology as well as Tg measurement in the aspirate washout. Smaller nodes can be followed and biopsied if there is continued growth. FDG-PET and PET-CT scans have been shown to be useful to localize recurrent or persistent thyroid cancer in patients who have Tg-positive, RAI scan–negative disease. FDG-PET can also be useful for the initial staging of patients with poorly differentiated thyroid carcinomas or Hürthle cell tumors, particularly in patients with other evidence of disease on imaging or Tg levels. In addition, they may be used as a prognostic tool in patients with metastatic disease and to evaluate the response to treatment in patients with metastatic or locally advanced disease.

**Additional Treatment Modalities**

**Radiotherapy, Thermal Ablation, and Chemotherapy**

External-beam radiotherapy is occasionally required to control unresectable, locally invasive, or recurrent disease and to treat metastases in support bones to decrease the risk of fractures. It also is of value for the treatment and control of pain from bony metastases when there is minimal or no RAIU. Stereotactic brain radiotherapy and intensity-modulated radiation therapy have both been used successfully for metastatic lesions. Percutaneous thermal ablation by increasing (radiofrequency ablation) or decreasing temperature (cryoablation) in the lesion to induce irreversible cellular damage has shown promise for lung, bone, and liver lesions. Single-drug and multidrug chemotherapy has been used with little success in disseminated thyroid cancer, and there is no role for routine chemotherapy. Doxorubicin (Adriamycin) and paclitaxel (Taxol) were previously the most frequently used agents. The former acts as a radiation sensitizer and should be considered in patients undergoing external-beam radiation.

**Novel Therapies** These therapies are directed at the molecular pathways known to be involved in thyroid cancers. Sorafenib
and lenvatinib are U.S. Food and Drug Administration (FDA) and European Medical Agency (EMA)-approved for use in patients with advanced differentiated thyroid cancer that is non-responsive to RAI after evaluation in phase 3 placebo-controlled double blinded trials (the DECISION study and the SELECT study, respectively).55,56 Both drugs are multikinase inhibitors and target RET kinase and the vascular endothelial growth factor (VEGF)-receptor; however, lenvatinib also inhibits the fibroblast growth factor and the platelet-derived growth factor receptor. Sorafenib demonstrated progression-free survival (PFS) improvement by 5 months with about 12% partial response rates, whereas lenvatinib prolonged median PFS by 15.7 months compared with placebo with response rates of 65%, including some complete responses. Vandetanib is mainly a RET-kinase inhibitor, but it also affects the VEGF-receptor and epidermal growth factor receptor. It has been evaluated in a phase 2 trial and also demonstrated an improved PFS.57 However, none of the agents show improvements in overall survival. Moreover, they are associated with significant side effects (diarrhea, fatigue, hypertension, hepatotoxicity, bleeding, and thrombosis) that affect patient quality of life. As such, they are considered only in patients with metastatic, rapidly progressive, symptomatic disease that is unable to respond to other local treatment approaches and generally in the context of clinical trials. Oncogenic kinase inhibitors that selectively inhibit the mutant V600E BRAF kinase (dabrafenib) has also shown promise in treating a subset of patients with advanced differentiated thyroid cancer.58

**Medullary Carcinoma** MTC accounts for about 5% of thyroid malignancies and arises from the parafollicular or C cells of the thyroid, which, in turn, are derived from the ultimobranchial bodies. These cells are concentrated superolaterally in the thyroid lobes, and this is where MTC usually develops. C cells secrete calcitonin, a 32-amino-acid polypeptide that functions to lower serum calcium levels, although its effects in humans are minimal. Most MTCs occur sporadically. However, approximately 25% occur within the spectrum of several inherited syndromes such as familial MTC, MEN2A, and MEN2B. All these variants are known to result secondary to germline mutations in the RET proto-oncogene. The syndromes also are characterized by genotype-phenotype correlations, with specific mutations leading to particular clinical manifestations. The salient clinical and genetic features of these syndromes are outlined in Table 38-8. Some clinical features of MEN2B patients are shown in Fig. 38-20.

MEN2 = multiple endocrine neoplasia type 2; MTC = medullary thyroid cancer.

![Figure 38-20](image-url). Features of MEN2B: thickened lips (A) and mucosal neuromas (A and B).
Patients with MTC often present with a neck mass that may be associated with palpable cervical lymphadenopathy (15% to 20%). Pain or aching is more common in patients with these tumors, and local invasion may produce symptoms of dysphagia, dyspnea, or dysphonia. Distant blood-borne metastases to the liver, bone (frequently osteoblastic), and lung occur later in the disease. The female-to-male ratio is 1.5:1. Most patients present between 50 and 60 years old, although patients with familial disease present at a younger age. Medullary thyroid tumors secrete not only calcitonin and carcinoembryonic antigen (CEA), but also other peptides such as calcitonin gene–related peptide, histaminases, prostaglandins E₂, and F₂ alpha, and serotonin. Patients with extensive metastatic disease frequently develop diarrhea, which may result from increased intestinal motility and impaired intestinal water and electrolyte flux. About 2% to 4% of patients develop Cushing’s syndrome as a result of ectopic production of adrenocorticotropic hormone (ACTH).

Pathology. MTCs typically are unilateral (80%) in patients with sporadic disease and multicentric in familial cases, with bilateral tumors occurring in up to 90% of familial patients. Familial cases also are associated with C-cell hyperplasia, which is considered a premalignant lesion. Microscopically, tumors are composed of sheets of infiltrating neoplastic cells separated by collagen and amyloid. Marked heterogeneity is present; cells may be polygonal or spindle shaped. The presence of amyloid is a diagnostic finding, but immunohistochemistry for calcitonin is more commonly used as a diagnostic tumor marker. These tumors also stain positively for CEA and calcitonin gene–related peptide.

Diagnosis. The diagnosis of MTC is established by history, physical examination, raised serum calcitonin, or CEA levels, and FNAB cytology of the thyroid mass. Attention to family history is important because about 25% of patients with MTC have familial disease. Because it is not possible to distinguish sporadic from familial disease at initial presentation, all new patients with MTC should be screened for RET point mutations, pheochromocytoma, and HPT. Screening of patients with familial MTC for RET point mutations has largely replaced using provocative testing with pentagastrin or calcium–stimulated calcitonin levels to make the diagnosis. Calcitonin and CEA are used to identify patients with persistent or recurrent MTC. Calcitonin is a more sensitive tumor marker, but CEA is a better predictor of prognosis.

Treatment. The ATA published revised guidelines for the management of medullary cancers in 2015.⁵⁹ A neck ultrasound is recommended to evaluate the central and lateral neck compartments and the superior mediastinum. Serum calcitonin, CEA, calcium levels should also be measured, and RET proto-oncogene mutation testing should be performed. Pheochromocytomas need to be excluded. If patients are found to have a pheochromocytoma, this must be operated on first. Primary hyperparathyroidism, if present, is treated at the time of thyroidectomy. These tumors are generally (>50%) bilateral. Total thyroidectomy is the treatment of choice for patients with MTC because of the high incidence of multicentricity, the more aggressive course, and the fact that ¹³¹I therapy usually is not effective.

Central compartment nodes frequently are involved early in the disease process, so that a bilateral prophylactic central neck node dissection should be routinely performed. In patients with palpable or imaging-detected cervical nodes, symptoms and signs of distant disease or calcitonin levels >500 pg/mL, additional imaging to include a neck and chest CT and a triple-phase liver CT or contrast-enhanced MRI and an axial MRI/bone scan is recommended to assess for metastatic disease. In patients with no distant disease but nodal involvement, an ipsilateral or bilateral lateral neck dissection (levels IIa, III, IV, and V) is performed. Less aggressive neck surgery should be considered to preserve speech and swallowing while maintaining locoregional control in patients with limited metastatic disease. The role of prophylactic lateral neck dissection is controversial and may be considered based on calcitonin levels. Some groups favor this procedure if central neck lymph nodes are involved or if the primary tumor is ≥1.5 cm.

In the case of locally recurrent or widely metastatic disease, tumor debulking is advised not only to ameliorate symptoms of pain, flushing, and diarrhea, but also to decrease risk of death from recurrent central neck or mediastinal disease. External-beam radiotherapy is controversial but can be considered for patients with resected T4 disease and for patients with unresectable residual or recurrent tumor and symptomatic bony metastases. Liver metastases tend to be multiple and are typically not amenable to resection, percutaneous ethanol ablation, or radiofrequency ablation. However, chemoembolization may be helpful in this setting. There is no effective chemotherapy regimen.

Various targeted therapies directed against the RET kinase have been investigated for the treatment of MTC.⁵⁸ Many of these also inhibit VEGF receptor due to their close structural similarities. Sorafenib, sunitinib, lenvatinib, and cabozantinib are some such multikinase inhibitors, whereas axitinib and pazopanib act only on VEGFR. Vandetanib inhibits both targets and is also an EGF receptor inhibitor, and cabozantinib targets c-MET in addition to RET and VEGF receptor. Both drugs are currently approved by the FDA and EMA for the treatment of advanced and progressive MTC based on data that they prolong progression-free survival, in addition to reducing secretion of calcitonin and CEA.⁶⁰,⁶¹ They are recommended as first-line systemic therapy in symptomatic patients with advanced MTC. An anti-CEA monoclonal antibody (labetuzumab) also has shown antitumor response in a small group of patients. Patients with recurrent/metastatic disease should be enrolled in well-designed clinical trials.

In patients who have hypercalcemia and an increased PTH at the time of thyroidectomy, only obviously enlarged parathyroid glands should be removed. The other parathyroid glands should be preserved and marked in patients with normocalcemia, as only about 20% of patients with MEN2A develop HPT. When a normal parathyroid cannot be maintained on a vascular pedicle, it should be removed, biopsied to confirm that it is a parathyroid, and then autotransplanted to the forearm of the nondominant arm, particularly in patients with MEN2A. Reimplantation into the sternocleidomastoid muscle is also acceptable for patients with known MEN2B and familial MTC.

Prophylactic total thyroidectomy is indicated in RET mutation carriers once the mutation is confirmed. The ATA guidelines stratify mutation into various risk levels to offer recommendations regarding age at which a prophylactic...
thyroidectomy should be performed and to predict phenotypes, including pheochromocytomas. In general, in patients with less aggressive mutations (designated ATA moderate-risk), thyroideotomy may be delayed >5 years, especially if there is a normal annual serum calcitonin, neck ultrasound, less aggressive family history, or family preference. Children with MEN2A and mutations at codon 634 (designated high-risk) are advised to undergo thyroideotomy at <5 years of age, and those with MEN2B-related mutations (designated highest-risk) should undergo the procedure before age 1. Central neck dissection can be avoided in children who are RET-positive and calcitonin-negative with a normal ultrasound examination. When the calcitonin is increased or the ultrasound suggests a thyroid cancer, a prophylactic central neck dissection is indicated.

Postoperative Follow-Up and Prognosis. Patients are followed by annual measurements of calcitonin and CEA levels, in addition to history and physical examination. Other modalities used to localize recurrent disease include ultrasound, CT, MRI, and more recently, FDG-PET/CT scans. Prognosis is related to disease stage. The 10-year survival rate is approximately 80% but decreases to 45% in patients with lymph node involvement. Survival also is significantly influenced by disease type. It is best in patients with non-MEN familial MTC, followed by those with MEN2A, and then those with sporadic disease. Prognosis is the worst (survival of 35% at 10 years) in patients with MEN2B. Performing prophylactic surgery in RET oncogene mutation carriers not only improves survival rates but also renders most patients calcitonin free.

Anaplastic Carcinoma Anaplastic carcinoma accounts for approximately 1% of all thyroid malignancies in the United States. Women are more commonly affected, and the majority of tumors present in the seventh and eighth decade of life. The typical patient has a long-standing neck mass, which rapidly enlarges and may be painful. Associated symptoms such as dysphonia, dysphagia, and dyspnea are common. The tumor is large and may be fixed to surrounding structures or may be ulcerated with areas of necrosis (Fig. 38-21). Lymph nodes usually are palpable at presentation. Evidence of metastatic spread also may be present. Diagnosis is confirmed by FNAB revealing characteristic giant and multinucleated cells. Differential diagnoses on FNA can include lymphomas, medullary carcinomas, direct extension from a laryngeal carcinoma, or other metastatic disease. When spindle cell elements are present, primary and metastatic sarcomas need to be considered as well. Immunohistochemical markers can aid with excluding other carcinomas or melanoma. When spindle cell elements are present, a prophylactic central neck dissection is indicated.

Pathology. On gross inspection, anaplastic tumors are firm and whitish in appearance. Microscopically, sheets of cells with marked heterogeneity are seen. The three main histologic growth patterns are spindle cell, squamoid, and pleomorphic giant cell. Tumors may show a predominance of one pattern or a mixture of various patterns. Foci of more differentiated thyroid tumors, either follicular or papillary, may be seen, suggesting that anaplastic tumors arise from more well-differentiated tumors.

Treatment and Prognosis. This tumor is one of the most aggressive thyroid malignancies, with few patients surviving 6 months beyond diagnosis. All forms of treatment have been disappointing. The ATA has published guidelines for the management of patients with anaplastic cancer. Imaging ( ultrasound, CT, MRI, or PET-CT) should be obtained to assess resectability. All patients should have preoperative laryngoscopy to assess the status of the vocal cords. A total or near-total thyroideotomy with therapeutic lymph node dissection is recommended for patients with an intrathyroidal mass (although lobectomy may also be appropriate, particularly if there is concern for vocal cord paralysis). If extrathyroidal extension is present, an en bloc resection should be considered if all gross disease can be removed (R1). Tracheostomy should be avoided as long as possible unless there is impending airway loss. Adjuvant radiation which should be offered to patients with a good performance status and no metastatic disease who desire aggressive management. Cytotoxic chemotherapy (with some combination of a taxane, anthracycline, and platinum) is typically given concurrently and has been associated with prolonged survival, although these agents are also being used in a neoadjuvant fashion, particularly in patients with unresectable disease.

Lymphoma Lymphomas account for <1% of thyroid malignancies, and most are of the non-Hodgkin’s B-cell type. Although the disease can arise as part of a generalized lymphomatous condition, most thyroid lymphomas develop in patients with chronic lymphocytic thyroiditis. Chronic antigenic lymphocyte stimulation has been suggested to result in lymphocyte transformation. Patients usually present with symptoms similar to those of patients with anaplastic carcinoma, although the rapidly enlarging neck mass often is painless. Patients may present with acute respiratory distress. Ultrasound can be useful for early diagnosis, and lymphoma appears as a well-defined hypoechoic mass. The diagnosis usually is suggested by FNAB, but FNAB can be nondiagnostic, particularly in the setting of low-grade lymphomas. Therefore, needle core or open biopsy may be necessary for definitive diagnosis. Staging studies should be obtained expeditiously to assess the extent of extrathyroidal spread.
Treatment and Prognosis. Patients with thyroid lymphoma respond rapidly to chemotherapy (CHOP—cyclophosphamide, doxorubicin, vincristine, and prednisone), which also has been associated with improved survival. Combined treatment with radiotherapy and chemotherapy often is recommended. Thyroidectomy and nodal resection are used to alleviate symptoms of airway obstruction in patients who do not respond quickly to the above regimens or who have completed the regimen before diagnosis. Prognosis depends on the histologic grade of the tumor and whether the lymphoma is confined to the thyroid gland or is disseminated. The overall 5-year survival rate is about 50%; patients with extrathyroidal disease have markedly lower survival rates.

Metastatic Carcinoma The thyroid gland is a rare site of metastases from other cancers, including kidney, breast, lung, and melanoma. Clinical examination and a review of the patient’s history often suggest the source of the metastatic disease, and FNAB usually provides definitive diagnosis. Resection of the thyroid, usually lobectomy, may be helpful in many patients, depending on the status of their primary tumor.

Thyroid Surgery

Conduct of Thyroidectomy Patients with any recent or remote history of altered phonation or prior neck or upper chest surgery that places the recurrent laryngeal or vagus nerves at risk should undergo vocal cord assessment by direct or indirect laryngoscopy before thyroidectomy. Laryngeal examination is also advised in patients with known posterior extension of thyroid cancer and extensive central nodal metastases. The patient is positioned supine, with a sandbag between the scapulae. The head is placed on a donut cushion, and the neck is extended to provide maximal exposure. A Kocher transverse collar incision, typically 3 to 5 cm in length, is placed in or parallel to a natural skin crease 1 cm below the cricoid cartilage (Fig. 38-22A), although longer incisions may be needed. The subcutaneous tissues and platysma are incised sharply, and subplatysmal flaps are raised superiorly to the level of the thyroid cartilage and inferiorly to the suprasternal notch (Fig. 38-22B). The strap muscles are divided in the midline along the entire length of the mobilized flaps, and the thyroid gland is exposed. On the side to be approached first, the sternothyroid muscles are separated from the underlying sternothyroid muscle by blunt dissection until the internal jugular vein and ansa cervicalis nerve are identified. The strap muscles rarely need to be divided to gain exposure to the thyroid gland. If this maneuver is necessary, the muscles should be divided high to preserve their innervation by branches of the ansa cervicalis. If there is evidence of direct tumor invasion into the strap muscles, the portion of involved muscle should be resected en bloc with the thyroid gland. The sternothyroid muscle is then dissected off the underlying thyroid by a combination of sharp and blunt dissection, thus exposing the middle thyroid veins. The thyroid lobe is retracted medially and anteriorly, and the lateral tissues are swept posterolaterally using a peanut sponge. The middle thyroid veins are ligated and divided (Fig. 38-22C). Attention is then turned to the midline where Delphian nodes and the pyramidal lobe are identified. The fascia just cephalad and caudal to the isthmus is divided. The superior thyroid pole is identified by retracting the thyroid first inferiorly and medially, and then the upper pole of the thyroid is mobilized caudally and laterally. The dissection plane is kept as close to the thyroid as possible, and the superior pole vessels are individually identified, skeletonized, ligated, and divided low on the thyroid gland to avoid injury to the external branch of the superior laryngeal nerve (Fig. 38-22D). Once these vessels are divided, the tissues posterior and lateral to the superior pole can be swept from the gland in a posteromedial direction, to reduce the risk of damaging vessels supplying the upper parathyroid.

The RLNs should then be identified, and the ATA 2015 guidelines strongly recommend visual identification in all cases. The course of the right RLN is more oblique than the left RLN. The nerves can be most consistently identified at the level of the cricoid cartilage. The parathyroids usually can be identified within 1 cm of the crossing of the inferior thyroid artery and the RLN, although they also may be ectopic in location. The lower pole of the thyroid gland should be mobilized by gently sweeping all tissues dorsally. The inferior thyroid vessels are dissected, skeletonized, ligated, and divided as close to the surface of the thyroid gland as possible to minimize devascularization of the parathyroids (extracapsular dissection) or injury to the RLN. The RLN is most vulnerable to injury in the vicinity of the ligament of Berry. The nerve often passes through this structure along with small crossing arterial and venous branches (Fig. 38-22E). Any bleeding in this area should be controlled with gentle pressure before carefully identifying the vessel and ligating it. Use of the electrocautery should be avoided in proximity to the RLN. Once the ligament is divided, the thyroid can be separated from the underlying trachea by sharp dissection. The pyramidal lobe, if present, must be dissected in a cephalad direction to above the level of the notch in the thyroid cartilage or higher in continuity with the thyroid gland. If a lobectomy is to be performed, the isthmus is divided flush with the trachea on the contralateral side and suture ligated. The procedure is repeated on the opposite side for a total thyroidectomy.

Parathyroid glands located anteriorly on the surface of the thyroid that cannot be dissected from the thyroid with a good blood supply or that have been inadvertently removed during the thyroidectomy should be resected, confirmed as parathyroid tissue by frozen section, divided into 1-mm fragments, and reimplemented into individual pockets in the sternocleidomastoid muscle. The sites should be marked with silk sutures and a clip. Various novel techniques using indocyanine fluorescence angiography and near-infrared autofluorescence have shown utility in the identification and viability assessment of parathyroid glands; however, they are not routinely used at the present time. If a subtotal thyroidectomy is to be performed, once the superior pole vessels are divided and the thyroid lobe mobilized anteriorly, the thyroid lobe is cross-clamped with a Mayo clamp, leaving approximately 4 g of the posterior portion of the thyroid. The thyroid remnant is suture ligated, taking care to avoid injury to the RLN. Routine drain placement rarely is necessary. After adequate hemostasis is obtained, the strap muscles are reaproximated in the midline. The platysma is approximated in a similar fashion. The skin can be closed with subcuticular sutures or clips.

Nerve Monitoring Intraoperative RLN and external laryngeal nerve monitoring techniques are being increasingly used during thyroid and parathyroid surgery. Both continuous monitoring using endotracheal tube electrodes and intermittent monitoring by periodic stimulation and laryngeal palpation are used. Many published studies have established the feasibility of nerve monitoring; however, none were able to show that the technique equivocally reduces nerve injury (particularly by experienced

Adopted. The current ATA guidelines recommend that intraoperative neural stimulation may be used to facilitate nerve identification of the RLN and confirm its function, especially prior to proceeding with contralateral thyroidectomy.

**Minimally Invasive Approaches** Several approaches to minimally invasive thyroidectomy have been described. Mini-incision procedures use a small, 3-cm incision with no flap creation and minimal dissection to deliver the thyroid into the wound and then perform the pretracheal and paratracheal dissection. Video assistance can be used to improve the visualization.
via the small incision. Totally endoscopic approaches also have been described, via the supraventricular, anterior chest, axillary, and breast approach. The axillary, anterior chest, and breast approaches eliminate the skin incision in the neck but are more invasive. The endoscopic approaches can also be performed with the assistance of robotic techniques. More recently, there have been studies of transoral robotic-assisted thyroidectomy in which the thyroid is approached through the oral cavity. These methods are feasible, but clear benefits over the “traditional” open approach via small neck incisions have not been established.

Typically, endoscopic thyroidectomies are performed under general anesthesia. For the axillary approach, a 30-mm skin incision is made in the axilla, and 12-mm and 5-mm trocars are inserted through this incision (Fig. 38-22F). An additional 5-mm trocar is inserted adjacent to the incision. For the anterior chest approach, a 12-mm skin incision is made in the skin of the anterior chest approximately 3 to 5 cm below the border of the ipsilateral clavicle. Two additional 5-mm trocars are inserted by endoscopic guidance below the ipsilateral clavicle, and carbon dioxide (CO₂) is then insufflated up to a pressure of 4 mmHg to facilitate creation of a working space. The anterior border of the sternocleidomastoid muscle is then separated from the sternohyoid muscle to expose the sternothyroid muscle. The thyroid gland is exposed by splitting the sternothyroid muscle. The lower pole is retracted upward and dissected from the adipose tissue to identify the RLN. As the RLN is exposed, Berry’s ligament is exposed and incised with a 5-mm clip or laparoscopic coagulating shears. The upper pole of the thyroid gland is separated from the cricothyroid muscle, and the external branch of the superior laryngeal nerve can be identified during this maneuver. The upper pole of the thyroid gland then is dissected free.

**Surgical Removal of Intrathoracic Goiter** A goiter is considered mediastinal if at least 50% of the thyroid tissue is located intrathoracically. Mediastinal goiters can be primary or secondary. Primary mediastinal goiters constitute approximately 1% of all mediastinal goiters and arise from accessory (ectopic) thyroid tissue located in the chest. These goiters are supplied by intrathoracic blood vessels and do not have any connection to thyroid tissue in the neck. The vast majority of mediastinal goiters are, however, secondary mediastinal goiters that arise from downward extension of cervical thyroid tissue along the fascial planes of the neck and derive their blood supply from the superior and inferior thyroid arteries. Virtually all intrathoracic goiters can be removed via a cervical incision. Patients who have (a) invasive thyroid cancers, (b) had previous thyroid operations and may have developed parasitic mediastinal vessels, or (c) primary mediastinal goiters with no thyroid tissue in the neck may require a median sternotomy for removal. The chest, however, should be prepared in most cases in the event it is necessary to perform a median sternotomy to control mediastinal bleeding or completely remove an unsuspected invasive cancer. The goiter is approached via a neck incision. The superior pole vessels and the middle thyroid veins are identified and ligated first. Early division of the isthmus helps with subsequent mobilization of the substernal goiter from beneath the sternum. Placement of large 1-0 or 2-0 sutures deep into the goiter, when necessary, helps deliver it. For patients in whom thyroid cancer is suspected or demonstrated in an intrathoracic gland, attempts should be made to avoid rupture of the thyroid capsule. When sternotomy is indicated, the sternum usually should be divided to the level of the third intercostal space and then laterally on one side at the space between the third and fourth ribs (Fig. 38-23).

**Central and Lateral Neck Dissection for Nodal Metastases** Central compartment (medial to the carotid sheath) lymph nodes frequently are involved in patients with papillary, medullary, and Hürthle cell carcinomas and should be removed at the time of thyroidectomy, preserving the RLNs and parathyroid glands. Central neck dissection is particularly important in patients with medullary and Hürthle cell carcinoma because of the high frequency of microscopic tumor spread and because these tumors cannot be ablated with ¹³¹I. An ipsilateral modified radical neck dissection is indicated in the presence of palpable cervical lymph nodes or prophylactically in some patients with medullary carcinoma.

A modified radical (functional) neck dissection can be performed via the cervical incision used for thyroidectomy, which can be extended laterally (Fig. 38-24A) to the anterior margin of the trapezius muscle. The procedure involves removal of all fibro-fatty tissue along the internal jugular vein (levels II, III, and IV) and the posterior triangle (level V). In contrast to a radical neck dissection, the internal jugular vein, the spinal accessory nerve, the cervical sensory nerves, and the sternocleidomastoid muscle are preserved unless they are adherent to or invaded by tumor. The procedure begins by opening the plane between the strap muscles medially and the sternocleidomastoid muscle laterally. The anterior belly of the omohyoid muscle is retracted laterally, and the dissection is carried posteriorly until the carotid sheath is reached. The internal jugular vein is retracted medially with a vein retractor and the fibro-fatty tissue and lymph nodes are dissected away from it by a combination of sharp and blunt dissection. The lateral dissection is carried along the posterior border of the sternocleidomastoid muscle, removing the tissue from the posterior triangle. The deep dissection plane is the anterior scalenus muscle, the phrenic nerve, the brachial plexus, and the medial scalenus muscle. The phrenic nerve is preserved on the scalenus anterior muscle, as are the cervical sensory nerves in most patients (Fig. 38-24B). Dissection along the spinal accessory nerve superiorly is most important because this is a frequent site of metastatic disease.
Complications of Thyroid Surgery  Nerves, parathyroids, and surrounding structures are all at risk of injury during thyroidectomy. Injury to the RLN may occur by severance, ligation, or traction, but should occur in <1% of patients undergoing thyroidectomy by experienced surgeons. The RLN is most vulnerable to injury during the last 2 to 3 cm of its course, but also can be damaged if the surgeon is not alert to the possibility of nerve branches and the presence of a nonrecurrent nerve, particularly on the right side. If the injury is recognized intraoperatively, most surgeons advocate primary reapproximation of the perineurium using nonabsorbable sutures. Approximately 20% of patients are at risk of injury to the external branches of the

Figure 38-24. Conduct of neck dissection. A. Incisions for modified radical neck dissection. B. Anatomic relations of structures identified during a modified radical neck dissection. a. = artery; m. = muscle; n. = nerve.
superior laryngeal nerve, especially if superior pole vessels are ligated en masse. The cervical sympathetic trunk is at risk of injury in invasive thyroid cancers and retroesophageal goiters and may result in Horner’s syndrome. Transient hypocalcemia (from surgical injury or inadvertent removal of parathyroid tissue) has been reported in up to 50% of cases, but permanent hypoparathyroidism occurs <2% of the time. Postoperative hypocalcemia is more likely in patients who undergo concomitant thyroidectomy and central and lateral neck dissection and in patients with Graves’ disease. Postoperative hematomas or bleeding may also complicate thyroidectomies and rarely necessitate emergency reoperation to evacuate the hematoma. Bilateral vocal cord dysfunction with airway compromises requires immediate reintubation and tracheostomy. Seromas may need aspiration to relieve patient discomfort. Wound cellulitis and infection and injury to surrounding structures, such as the carotid artery, jugular vein, and esophagus, are infrequent.

**PARATHYROID**

**Historical Background**

In 1849, the curator of the London Zoological Gardens, Sir Richard Owen, provided the first accurate description of the normal parathyroid gland after autopsy examination of an Indian rhinoceros. However, human parathyroids were not grossly and microscopically described until 1879 by Ivar Sandström, a medical student in Uppsala, Sweden. He suggested that these glands be named the *glandulae parathyroideae*, although their function was not known.

The association of HPT and the bone disease osteitis fibrosa cystica (described by von Recklinghausen) was recognized in 1903. Calcium measurement became possible in 1909, and the association between serum calcium levels and the parathyroid glands was established. The first successful parathyroidectomy was performed in 1925 by Felix Mandl on a 38-year-old man who had severe bone pain secondary to advanced osteitis fibrosa cystica. The patient’s condition dramatically improved after the operation, and he lived for another 7 years before dying of recurrent HPT or renal failure. In 1926, the first parathyroid operation was performed at Massachusetts General Hospital. Edward Churchill, assisted by an intern named Oliver Cope, operated on the famous sea captain Charles Martell for severe primary HPT (PHPT). It was not until his seventh operation, which included total thyroidectomy, that an ectopic adenoma was found subterminally. Unfortunately, Captain Martell died 6 weeks later, likely due to laryngeal spasm and complications of renal stones and ureteral obstruction. The first successful parathyroidectomy for HPT in the United States was performed on a 56-year-old woman in 1928 by Isaac Y. Olch at the Barnes Hospital in St. Louis, Missouri. At operation, a parathyroid adenoma was found attached to the left lower lobe of the thyroid gland. Postoperatively, the patient developed tetany, requiring lifelong supplemental calcium.

**Embryology**

In humans, the superior parathyroid glands are derived from the fourth branchial pouch, which also gives rise to the thyroid gland. The third branchial pouches give rise to the inferior parathyroid glands and the thymus (Fig. 38-25). The parathyroids remain closely associated with their respective branchial pouch derivatives. The position of normal superior parathyroid glands is more consistent, with 80% of these glands being found near the posterior aspect of the upper and middle thyroid lobes, at the level of the cricoid cartilage. Approximately 1% of normal upper glands may be found in the parasiophageal or retroesophageal space. Enlarged superior glands may descend in the tracheoesophageal groove and come to lie caudal to the inferior glands. Truly ectopic superior parathyroid glands are rare, but they may be found in the middle or posterior mediastinum or in the aortopulmonary window. As the embryo matures, the thymus and inferior parathyroids migrate together caudally in the neck. The most common location for inferior glands is within a distance of 1 cm from a point centered where the inferior thyroid artery and RLN cross. Approximately 15% of inferior glands...
are found in the thymus. The position of the inferior glands, however, tends to be more variable due to their longer migratory path. Undescended inferior glands may be found near the skull base, angle of the mandible, or superior to the upper parathyroid glands along with an undescended thymus. The frequency of intrathyroidal glands is about 2%.

Anatomy and Histology
Most patients have four parathyroid glands. The superior glands usually are dorsal to the RLN at the level of the cricoid cartilage, whereas the inferior parathyroid glands are located ventral to the nerve. Normal parathyroid glands are gray and semitransparent in newborns but appear golden yellow to light brown in adults. Parathyroid color depends on cellularity, fat content, and vascularity. Moreover, they often are embedded in and sometimes difficult to discern from surrounding fat. Normal parathyroid glands are located in loose tissue or fat and are ovoid. They measure up to 7 mm in size and weigh approximately 40 to 50 mg each. Parathyroid glands usually derive their blood supply from branches of the inferior thyroid artery, although branches from the superior thyroid artery supply at least 20% of upper glands. Branches from the thyroidea ima, and vessels to the trachea, esophagus, larynx, and mediastinum may also be found. The parathyroid glands drain ipsilaterally by the superior, middle, and inferior thyroid veins.

Akerström and colleagues, in an autopsy series of 503 cadavers, found four parathyroid glands in 84% of cases. Supernumerary glands were present in 13% of patients, most commonly in the thymus. Only 3% of patients had less than four glands. Similar results were obtained in other dissection studies of 428 human subjects by Gilmour who reported a 6.7% incidence of supernumerary glands.

Histologically, parathyroid glands are composed of chief cells and oxyphil cells arranged in trabeculae, within a stroma composed primarily of adipose cells (Fig. 38-26). The parathyroid glands of infants and children are composed mainly of chief cells, which produce parathyroid hormone (PTH). Acidophilic, mitochondria-rich oxyphil cells are derived from chief cells, can be seen around puberty, and increase in numbers in adulthood. A third group of cells, known as water-clear cells, are also derived from chief cells, are present in small numbers, and are rich in glycogen. Although most oxyphil and water-clear cells retain the ability to secrete PTH, their functional significance is not known.

Parathyroid Physiology and Calcium Homeostasis
Calcium is the most abundant cation in human beings and has several crucial functions. Extracellular calcium levels are 10,000-fold higher than intracellular levels, and both are tightly controlled. Extracellular calcium is important for excitation-contraction coupling in muscle tissues, synaptic transmission in the nervous system, coagulation, and secretion of other hormones. Intracellular calcium is an important second messenger regulating cell division, motility, membrane trafficking, and secretion. Calcium is absorbed from the small intestine in its inorganic form. Calcium fluxes in the steady state are depicted in Fig. 38-27.

Extracellular calcium (900 mg) accounts for only 1% of the body’s calcium stores, the majority of which is sequestered in the skeletal system. Approximately 50% of the serum calcium is in the ionized form, which is the active component. The remainder is bound to albumin (40%) and organic anions such as phosphate and citrate (10%). The total serum calcium levels range from 8.5 to 10.5 mg/dL (2.1 to 2.6 mmol/L), and ionized calcium levels range from 4.4 to 5.2 mg/dL (1.1 to 1.3 mmol/L). Both concentrations are tightly regulated. The total serum calcium level must always be considered in its relationship to plasma protein levels, especially serum albumin. For each gram per deciliter of alteration of serum albumin above or below 4.0 mg/dL, there is a 0.8 mg/dL increase or decrease in protein-bound calcium and, thus, in total serum calcium levels. Total and, particularly, ionized calcium levels are influenced by various hormone systems.

Parathyroid Hormone. The parathyroid cells rely on a G-protein–coupled membrane receptor, designated the calcium-sensing receptor (CASR), to regulate PTH secretion by sensing extracellular calcium levels (Fig. 38-28). PTH secretion also is stimulated by low levels of 1,25-dihydroxy vitamin D, calcitriol (1-hydroxycholecalciferol), and hypomagnesemia. The PTH gene is located on chromosome 11. PTH is synthesized in the parathyroid gland as a precursor hormone proPTH, which is cleaved first to proPTH and then to the final 84-amino-acid PTH. Secreted PTH has a half-life of 2 to 4 minutes. In the liver, PTH is metabolized into the active N-terminal component and the relatively inactive C-terminal fragment. The C-terminal component is excreted by the kidneys and accumulates in chronic renal failure.

PTH functions to regulate calcium levels via its actions on three target organs, the bone, kidney, and gut. PTH increases the resorption of bone by stimulating osteoclasts and promotes the release of calcium and phosphate into the circulation. At the kidney, calcium is primarily absorbed in concert with sodium in the proximal convoluted tubule, but fine adjustments occur more distally. PTH acts to limit calcium excretion at the distal convoluted tubule via an active transport mechanism. PTH also inhibits phosphate reabsorption (at the proximal convoluted tubule) and bicarbonate reabsorption. It also inhibits the Na+/H+ antiporter, which results in a mild metabolic acidosis in hyperparathyroid states. PTH and hypophosphatemia also enhance 1-hydroxylation of 25-hydroxyvitamin D, which is responsible for its indirect effect of increasing intestinal calcium absorption.

Calcitonin. Calcitonin is produced by thyroid C cells and functions as an antihypercalcemic hormone by inhibiting osteoclast-mediated bone resorption. Calcitonin production is stimulated

Figure 38-26. Normal parathyroid histology showing chief cells interspersed with adipose cells.
Vitamin D. Vitamin D refers to vitamin D$_2$ and vitamin D$_3$, both of which are produced by photolysis of naturally occurring sterol precursors. Vitamin D$_3$ is available commercially in pharmaceutical preparations, whereas vitamin D$_2$ is the most important physiologic compound and is produced from 7-dehydrocholesterol, which is found in the skin. Vitamin D is metabolized in the liver to its primary circulating form, 25-hydroxyvitamin D. Further hydroxylation in the kidney results in 1,25-dihydroxy vitamin D, which is the most metabolically active form of vitamin D. Vitamin D stimulates the absorption of calcium and phosphate from the gut and the resorption of calcium from the bone.

Hyperparathyroidism

Hyperfunction of the parathyroid glands may be classified as primary, secondary, or tertiary. PHPT arises from increased PTH production from abnormal parathyroid glands and results from a disturbance of normal feedback control exerted by serum calcium. Elevated PTH levels may also occur as a compensatory response to hypocalcemic states resulting from chronic renal failure or GI malabsorption of calcium. This secondary HPT can be reversed by correction of the underlying problem (e.g., kidney transplantation for chronic renal failure). However, chronically stimulated glands may occasionally become autonomous, resulting in persistence or recurrence of hypercalcemia after successful renal transplantation, resulting in tertiary HPT.

Primary Hyperparathyroidism. PHPT is a common disorder, affecting 100,000 individuals annually in the United States. PHPT occurs in 0.1% to 0.3% of the general population and is more common in women (1:500) than in men (1:2000). Increased PTH production leads to hypercalcemia via increased GI absorption of calcium, increased production of vitamin D$_3$, and reduced renal calcium clearance. PHPT is characterized by increased parathyroid cell proliferation and PTH secretion that is independent of calcium levels.

Etiology. The exact cause of PHPT is unknown, although exposure to low-dose therapeutic ionizing radiation and familial predisposition account for some cases. Various diets and intermittent exposure to sunshine may also be related. Other causes include renal leak of calcium and declining renal function with age as well as alteration in the sensitivity of parathyroid glands to suppression by calcium. The latency period for development of PHPT after radiation exposure is longer than that for the development of thyroid tumors, with most cases occurring 30 to 40 years after exposure. Patients who have been exposed to radiation have similar clinical presentations and calcium levels when compared to patients without a history of radiation exposure. However, the former tends to have higher PTH levels and a higher incidence of concomitant thyroid neoplasms. Lithium therapy has been known to shift the set point for PTH secretion in parathyroid cells, thereby resulting in elevated PTH levels and mild hypercalcemia. Lithium stimulates the growth of abnormal parathyroid glands in vivo and also in susceptible patients in vivo. PHPT results from the enlargement of a single gland or parathyroid adenoma in approximately 80% of cases, multiple adenomas or hyperplasia in 15% to 20% of patients, and parathyroid carcinoma in 1% of patients. Existence of two enlarged glands or double adenomas is supported by biochemical (calcium and PTH), intraoperative PTH (IOPHT), molecular, and histologic data. This entity is less common in younger patients but accounts for up to 10% of older patients with PHPT. It should be emphasized that when more than one abnormal parathyroid gland is identified preoperatively or intraoperatively, the patient has hyperplasia (all glands abnormal) until proven otherwise.

Genetics. Most cases of PHPT are sporadic. However, PHPT also occurs within the spectrum of a number of inherited
disorders such as MEN1, MEN2A, isolated familial HPT, and familial HPT with jaw-tumor syndrome. All of these syndromes are inherited in an autosomal dominant fashion. PHPT is the earliest and most common manifestation of MEN1 and develops in 80% to 100% of patients by age 40 years old. These patients also are prone to pancreatic neuroendocrine tumors and pituitary adenomas and, less commonly, to adrenocortical tumors, lipomas, skin angiomas, and carcinoid tumors of the bronchus, thymus, or stomach. About 50% of patients develop gastrinomas, which often are multiple and metastatic at diagnosis. Insulinomas develop in 10% to 15% of cases, whereas many patients have nonfunctional pancreatic endocrine tumors. Prolactinomas occur in 10% to 50% of MEN1 patients and constitute the most common pituitary lesion. MEN1 has been shown to result from germline mutations in the \textit{MEN1} gene, a tumor suppressor gene located on chromosome 11q12-13 that encodes menin, a protein that is postulated to interact with the transcription factors JunD and nuclear factor-κB in the nucleus, in addition to replication protein A and other proteins.\textsuperscript{70} Most \textit{MEN1} mutations result in a nonfunctional protein and are scattered throughout the translated nine exons of the gene. This makes presymptomatic screening for mutation carriers difficult. \textit{MEN1} mutations also have been found in kindreds initially suspected to represent isolated familial HPT. HPT develops in about 20% of patients with MEN2A and generally is less severe. MEN2A is caused by germline mutations of the \textit{RET} proto-oncogene located on chromosome 10. In contrast to MEN1, genotype-phenotype correlations have been noted in this syndrome in that individuals with mutations at codon 634 are more likely to develop HPT. Patients with the familial HPT with jaw-tumor syndrome have an increased predisposition to parathyroid carcinoma. This syndrome maps to a tumor suppressor locus \textit{HRPT2} (CDC73 or parafibromin) on chromosome 1. Patients belonging to isolated HPT kindreds also appear to demonstrate linkage to \textit{HRPT2}. More recently, a subset of patients with MEN-1 phenotype in the absence of \textit{MENIN} mutations were found to harbor inactivating mutation

Figure 38-28. Regulation of calcium homeostasis. The calcium-sensing receptor (CASR) is expressed on the surface of the parathyroid cell and senses fluctuations in the concentration of extracellular calcium. Activation of the receptor is thought to increase intracellular calcium levels, which, in turn, inhibit parathyroid hormone (PTH) secretion via posttranslational mechanisms. Increased PTH secretion leads to an increase in serum calcium levels by increasing bone resorption and enhancing renal calcium reabsorption. PTH also stimulates renal 1-α-hydroxylase activity, leading to an increase in 1,25-dihydroxy vitamin D, which also exerts a negative feedback on PTH secretion. PKC = protein kinase C; PLC = phospholipase C. (Reproduced with permission from Carling T: Molecular pathology of parathyroid tumors, Trends Endocrinol Metab. 2001 Mar;12(2):53-58.)
in the tumor suppressor gene \textit{CDKN1B} on chromosome 12p13 and given the diagnosis of MEN4.\textsuperscript{71-72} \textit{CDKN1B} encodes p27kip1, which is involved in cyclin D1 signaling. Approximately 25% to 40% of sporadic parathyroid adenomas and some hyperplastic parathyroid glands have loss of heterozygosity (LOH) at 11q13, the site of the \textit{MEN1} gene. The parathyroid adenoma 1 oncogene (\textit{PRAD1} or \textit{CCND1}), which encodes cyclin D1, a cell cycle control protein, is overexpressed in about 18% of parathyroid adenomas. This was demonstrated to result from a rearrangement on chromosome 11 that places the \textit{PRAD1} gene under the control of the PTH promoter. Sporadic parathyroid tumors also appear to carry alterations in cyclin dependent kinase inhibitor encoding genes, in particular somatic inactivating mutations of \textit{CDKN1B}. Other chromosomal regions deleted in parathyroid adenomas and possibly reflecting loss of tumor suppressor genes include 1p, 6q, and 15q, whereas amplified regions suggesting oncogenes have been identified at 16p and 19p. \textit{RET} mutations are rare in sporadic parathyroid tumors. Sporadic parathyroid cancers are characterized by uniform loss of the tumor suppressor gene \textit{RB}, which is involved in cell cycle regulation, and 60% have \textit{HRPT2} (CDC73) mutations. These alterations are rare in benign parathyroid tumors and may have implications for diagnosis. The \textit{p53} tumor suppressor gene is also inactivated in a subset (30%) of parathyroid carcinomas.\textsuperscript{73}

\textbf{Clinical Manifestations} Patients with PHPT formerly presented with the “classic” pentad of symptoms (i.e., kidney stones, painful bones, abdominal groans, psychic moans, and fatigue overtones). With the advent and widespread use of automated blood analyzers in the early 1970s, there has been an alteration in the “typical” patient with PHPT. They are more likely to be minimally symptomatic or asymptomatic. Currently, most patients present with weakness, fatigue, polydipsia, polyuria, nocturia, bone and joint pain, constipation, decreased appetite, nausea, heartburn, pruritus, depression, and memory loss. Patients with PHPT also tend to score lower than healthy controls when assessed by general multidimensional health assessment tools such as the Medical Outcomes Study Short-Form Health Survey (SF-36) and other specific questionnaires. Furthermore, these symptoms and signs improve in most, but certainly not all, patients after parathyroidectomy. Truly “asymptomatic” PHPT appears to be rare, occurring in <5% of patients, as determined by prospectively administered questionnaires. Complications of PHPT are described in the following section.

\textbf{Renal Disease.} Approximately 80% of patients with PHPT have some degree of renal dysfunction or symptoms. Kidney stones were previously reported in up to 80% of patients but now occur in about 20% to 25%. The calculi are typically composed of calcium phosphate or oxalate. In contrast, PHPT is found to be the underlying disorder in only 3% of patients presenting with nephrolithiasis. \textit{Nephrocalcinosis}, which refers to renal parenchymal calcification, is found in <5% of patients and is more likely to lead to renal dysfunction. Chronic hypercalcemia also can impair concentrating ability, thereby resulting in polyuria, polydipsia, and nocturia. The incidence of hypertension is variable but has been reported to occur in up to 50% of patients with PHPT. Hypertension appears to be more common in older patients and correlates with the magnitude of renal dysfunction and, in contrast to other symptoms, is least likely to improve after parathyroidectomy.

\textbf{Bone Disease.} Bone disease, including osteopenia, osteoporosis, and osteitis fibrosa cystica, is found in about 15% of patients with PHPT. Increased bone turnover, as found in patients with osteitis fibrosa cystica, can be determined by documenting an elevated blood alkaline phosphatase level. Advanced PHPT with osteitis fibrosa cystica now occurs in <5% of patients. It has pathognomonic radiologic findings, which are best seen on X-rays of the hands and are characterized by subperiosteal resorption (most apparent on the radial aspect of the middle phalanx of the second and third fingers), bone cysts, and tufting of the distal phalanges (Fig. 38-29). The skull also may be affected and appears mottled with a loss of definition of the inner and outer cortices. Brown or osteoclastic tumors and bone cysts also may be present. Severe bone disease, resulting in bone pain and tenderness and/or pathologic fractures, is rarely observed nowadays. However, reductions of bone mineral density (BMD) with osteopenia and osteoporosis are more common. Patients with normal serum alkaline phosphatase levels almost never have clinically apparent osteitis fibrosa cystica. HPT typically results in a loss of bone mass at sites of cortical bone such as the radius and relative preservation of cancellous bone such as that located at the vertebral bodies. Patients with PHPT, however, also may

have osteoporosis of the lumbar spine that improves dramatically following parathyroidectomy. Fractures also occur more frequently in patients with PHPT, and the incidence of fractures also decreases after parathyroidectomy. Bone disease correlates with serum PTH and vitamin D levels.

Gastrointestinal Complications. PHPT has been associated with peptic ulcer disease. In experimental animals, hypergastrinemia has been shown to result from PTH infusion into blood vessels supplying the stomach, independent of its effects on serum calcium. An increased incidence of pancreatitis also has been reported in patients with PHPT, although this appears to occur only in patients with profound hypercalcemia (Ca\(^{2+}\) >12.5 mg/dL). Patients with PHPT also have an increased incidence of choledocholithiasis, presumably due to an increase in biliary calcium, which leads to the formation of calcium bilirubinate stones.

Neuropsychiatric Complications. Severe hypercalcemia may lead to various neuropsychiatric manifestations such as florid psychosis, obtundation, or coma. Other findings such as depression, anxiety, and fatigue are more commonly observed in patients with only mild hypercalcemia. The etiology of these symptoms is not known. Studies demonstrate that levels of certain neurotransmitters (monoamine metabolites 5-hydroxyindoleacetic acid and homovanillic acid) are reduced in the cerebrospinal fluid of patients with PHPT when compared to controls. Electroencephalogram abnormalities also occur in patients with primary and secondary HPT and normalize following parathyroidectomy.

Other Features. PHPT also can lead to fatigue and muscle weakness, which is prominent in the proximal muscle groups. Although the exact etiology of this finding is not known, muscle biopsy studies show that weakness results from a neuromyopathy, rather than a primary myopathic abnormality. Patients with HPT also have an increased incidence of chondrocalcinosis, gout, and pseudogout, with deposition of uric acid and calcium pyrophosphate crystals in the joints. Calcification at ectopic sites such as blood vessels, cardiac valves, and skin also has been reported, as has hypertrophy of the left ventricle independent of the presence of hypertension. There is also evidence for subtle cardiovascular manifestations in mild disease, such as changes in endothelial function, increased vascular stiffness, and perhaps subtle diastolic dysfunction. Several large studies from Europe also suggest that PHPT is associated with increased death rates from cardiovascular disease and cancer even in patients with mild HPT, although this finding was not substantiated in North American studies.

Physical Findings Parathyroid tumors are seldom palpable, except in patients with profound hypercalcemia or parathyroid cancer. A palpable neck mass in a patient with PHPT is more likely to be thyroid in origin or a parathyroid cancer. Patients also may demonstrate evidence of band keratopathy, a deposition of calcium in Bowman’s membrane just inside the iris of the eye. This nonspecific condition generally is caused by chronic eye diseases such as uveitis, glaucoma, and trauma but also may occur in the presence of conditions associated with high calcium or phosphate levels. Fibro-osseous jaw tumors, and/or the presence of familial disease in patients with PHPT and jaw tumors, if present, should alert the physician to the possibility of parathyroid carcinoma.

Differential Diagnosis Hypercalcemia may be caused by a multitude of conditions, as listed in Table 38-9. PHPT and malignancy account for >90% of all cases of hypercalcemia. PHPT is more common in the outpatient setting, whereas malignancy is the leading cause of hypercalcemia in hospitalized patients. PHPT can virtually always be distinguished from other diseases causing hypercalcemia by a combination of history, physical examination, and appropriate laboratory investigations.

Hypercalcemia associated with malignancy includes three distinct syndromes. Although bone metastases may cause hypercalcemia, patients with solid tumors of the lung, breast, kidney, head and neck, and ovary often have humoral hypercalcemia of malignancy, without any associated bony metastases. In addition, hypercalcemia also may be associated with hematologic malignancies such as multiple myeloma. Humoral hypercalcemia of malignancy is known to be mediated primarily by PTH-related peptide (PTHrP), which also plays a role in the hypercalcemia associated with bone metastases and multiple myeloma.

Thiazide diuretics cause hypercalcemia by decreasing renal clearance of calcium. This corrects in normal patients within days to weeks after discontinuing the diuretic, but patients with PHPT continue to be hypercalcemic. Thiazide diuretics can, therefore, exacerbate underlying PHPT and can be used to unmask PHPT in patients with borderline hypercalcemia. Familial hypocalciuric hypercalcemia 1 (FHH1) is a rare autosomal dominant condition with nearly 100% penetrance and results from inherited heterozygous mutations in the CASR gene located on chromosome 3. Homozygous germline mutations at this locus result in neonatal severe primary hyperparathyroidism and calcemia, a condition that can rapidly prove fatal. Patients with FHH1 generally have lifelong hypercalcemia, which is not corrected by parathyroidectomy. A milder form of the disease known as familial hypocalciuric hypercalcemia results from germline inactivating mutations in the intracytoplasmic tail domain of the CaSR gene. These patients have an appropriate hypercalciuric response to elevated calcium and PTH in addition to hypermagnesemia and hyperphosphaturia. Some cases benefit from parathyroidectomy. Recently two new types of FHH (2 and 3) have been described. These are associated with germline inactivating mutations of GNA11(19p13.3) and AP2S1(19q12.2) genes. Both mutations cause hypocalciuric hypercalcemia through aberrant inactivation of CaSR signaling. Although clinical presentation in FHH2 is similar to FHH1, those with FHH3 tend to have higher PTH levels and osteomalacia.

PTHrP = parathyroid hormone-related protein; VIP = vasoactive intestinal peptide.
Hypercalcemia also is found in approximately 10% of patients with sarcoidosis secondary to increased 25-hydroxy vitamin D 1-hydroxylase activity in lymphoid tissue and pulmonary macrophages, which is not subject to inhibitory feedback control by serum calcium. Thyroid hormone also has bone-resorption properties, thus causing hypercalcemia in thyrotoxic states, especially in immobilized patients. Hemoconcentration appears to be an important factor in the hypercalcemia associated with adrenal insufficiency and pheochromocytoma, although the latter patients may have associated parathyroid tumors (MEN2A), and some pheochromocytomas are known to secrete PTHrP. Other endocrine lesions such as vasoactive intestinal peptide–secreting tumors may be associated with hypercalcemia due to increased secretion of PTHrP. Milk-alkali syndrome requires the ingestion of large quantities of calcium with an absorbable alkali such as that used in the treatment of peptic ulcer disease with antacids. Ingestions of large quantities of vitamins D and A are infrequent causes of hypercalcemia, as is immobilization.

**Diagnostic Investigations**

**Biochemical Studies.** The presence of an elevated serum calcium and intact PTH or two-site PTH levels, without hypocalciuria, establishes the diagnosis of PHPT with virtual certainty. These sensitive PTH assays use immunoradiometric or immunoluminescent techniques and can reliably distinguish PHPT from other causes of hypercalcemia. Furthermore, they do not cross-react with PTHrP (Fig. 38-30). In patients with metastatic cancer and hypercalcemia, intact PTH levels help to determine whether the patient also has concurrent PHPT. Although extremely rare, a patient with hypercalcemia may have a tumor that secretes PTH. FNAB of such a tumor for PTH levels or selective venous catheterization of the veins draining such tumors can help clarify the diagnosis.

Patients with PHPT also typically have decreased serum phosphate (~50%) and elevated 24-hour urinary calcium concentrations (~60%). A mild hyperchloremic metabolic acidosis also is present (80%), thereby leading to an elevated chloride-to-phosphate ratio (~33). Urinary calcium levels need not be measured routinely, except in patients who have not had previously documented normocalcemia or have a family history of hypercalcemia to rule out FHH. In patients with FHH, 24-hour urinary calcium excretion is characteristically low (<100 mg/d). Furthermore, the serum calcium-to-creatinine clearance ratio (24-hour urine calcium/plasma total calcium/24-hour urine creatinine/plasma creatinine) usually is <0.01 in patients with FHH, whereas it is typically >0.02 in patients with PHPT, although there are exceptions to this. Other biochemical features of PHPT are listed in Table 38-10. Elevated levels of alkaline phosphatase may be found in approximately 10% of patients with PHPT and are indicative of high-turnover bone disease. These patients are prone to developing postoperative hypocalcemia due to bone hunger. Serum and urine protein electrophoresis may be necessary to exclude multiple myeloma.

BFHH = benign familial hypocalciuric hypercalcemia; PTH = parathyroid hormone.

---

Figure 38-30. Intact parathyroid hormone (PTH) measurement allows differentiation between the various causes of hypercalcemia. (Reproduced with permission from Endres DB, Villanueva R, Sharp CF, et al. Measurement of parathyroid hormone. Endocrinol Metab Clin North Am. 1989 Sep;18(3):611-629.)
Occasionally, patients present with normocalcemic PHPT due to vitamin D deficiency, a low serum albumin, excessive hydration, a high-phosphate diet, or a low normal blood calcium set point. These patients have increased total PTH levels with or without increased blood ionized calcium levels and must be distinguished from patients with renal leak hypercalcemia who also have increased PTH levels due to excessive calcium loss in the urine. This can be accomplished by administering thiazide diuretics. In patients with idiopathic hypercalcemia, the urinary calcium level falls, and the secondary increase in the blood PTH level also decreases to normal, whereas patients with normocalcemic HPT continue to have elevated urine calcium and blood PTH levels and may, in fact, become hypercalcemic.

**Radiologic Tests.** In patients with profound hypercalcemia or PHPT associated with vitamin D deficiency, hand and skull X-rays may demonstrate osteitis fibrosa cystica, but this is rare in current clinical practice. BMD studies using dual-energy absorptiometry are being increasingly used to assess the effects of PHPT on bone. PHPT primarily leads to one loss at cortical sites such as the distal radius while bone density is preserved at sites such as the lumbar spine. Current evaluation of patients with PHPT includes vertebral imaging by X-ray or vertebral fracture assessment (VFA) or CT scan in addition to BMD studies. Measurement of trabecular bone score (TBS) is optional. In addition, renal imaging by ultrasound, X-ray, or CT scan is also recommended. Parathyroid localization studies are not used to confirm the diagnosis of PHPT, but rather to aid in identifying the location of the offending gland(s), as discussed later in “Preoperative Localization Tests.”

**Treatment**

**Indications for Parathyroidectomy and Role of Medical Management.** Most authorities agree that patients who have developed complications and have “classic” symptoms of PHPT should undergo parathyroidectomy. However, the treatment of patients with asymptomatic PHPT has been the subject of controversy, due, in part, to the fact that there is little agreement on what constitutes an asymptomatic patient.

At the National Institutes of Health consensus conference in 1990, “asymptomatic” PHPT was defined as “the absence of common symptoms and signs of PHPT, including no bone, renal, gastrointestinal, or neuromuscular disorders.” To determine the best course of action for these patients, it is important to consider the natural history of untreated PHPT and the outcomes of treatment options, both medical and surgical.

With respect to the natural history, the panel advocated nonoperative management of these patients with mild PHPT based on observational studies, which suggested relative stability of biochemical parameters over time. However, the consensus panel considered certain patients to be candidates for surgery based on testing or other information indicating end-organ effects or a higher likelihood of disease progression, and this led to the establishment of initial guidelines for parathyroidectomy. Subsequently, another observational study on the natural history of treated versus untreated HPT was published by Silverberg and colleagues. Their cohort of 52 patients with asymptomatic HPT followed without surgery, levels of serum and urinary calcium, PTH, alkaline phosphatase, and vitamin D metabolites remained relatively stable over a 10-year period in most patients. Average bone mass also remained relatively stable. However, the study also reported development of a new indication for surgery in 14 (27%) of 52 of their asymptomatic patients and, because approximately 50% of their patients were initially treated surgically, overall, about 75% of patients were underwent parathyroidectomy. Age <50 years was predictive of progression, and patients undergoing parathyroidectomy showed not only normalization of calcium and PTH levels but also improved BMD at the spine and hip. Based on these and other studies, the guidelines were reassessed at a second workshop on asymptomatic PHPT held at the National Institutes of Health in 2002.

Since that time, additional studies have provided further insights into the natural history of treated and untreated HPT. Three of these were randomized, controlled, prospective studies ranging in duration from 1 to 3.5 years. One was an observational study (a continuation of the Columbia University PHPT Project) but was notable for its long duration of follow-up of 15 years. These studies confirmed the relative stability of various biochemical indices, thus validating the need for guidelines. However, the long-term study suggested that the stability was not indefinite as calcium levels tended to rise in years 13 to 15. In addition, the study also demonstrated that bone density measurements remained stable for 8 to 10 years, but cortical bone density worsened after year 10. More concerning was the fact that 60% of patients lost >10% of their BMD over the 15-year observation period. Furthermore, whether patients met the 2002 guidelines for surgery did not appear to predict the risk of progressive disease, with 40% of patients undergoing follow-up eventually needing surgery. Although there are no randomized trials, registry data also suggest that fracture risk is increased for PHPT up to 10 years prior to diagnosis and treatment.

Medical options for treating PHPT and its complications include antiresorptive treatments such as bisphosphonates, hormone replacement therapy (HRT), and selective estrogen receptor modulators such as raloxifene. Bisphosphonates and HRT are reasonable options in patients for whom skeletal protection is needed, as evidence from randomized, placebo-controlled trials indicates that these medications are very effective at decreasing bone turnover and increasing BMD in PHPT, with the effects being comparable to patients undergoing parathyroidectomy. Caution needs to be exercised due to the nonskeletal effects of HRT, and hence, bisphosphonates are preferred. There are no clinical studies regarding the effects of raloxifene on BMD in HPT, and none of these agents affects calcium or PTH levels. More recently, calcimimetics (modifiers of the sensitivity of the CASR) have been used in randomized, multicenter controlled trials and have been shown to decrease both serum calcium and PTH levels in both symptomatic and asymptomatic PHPT patients. Unfortunately, bone density failed to improve in medically treated patients. Although this therapy shows promise, long-term outcome data are lacking, and their routine use is not advocated at this time, except in patients who are very poor operative risks or refuse surgery.

Successful parathyroidectomy results in resolution of osteitis fibrosa cystica and decreased formation of renal stones in symptomatic (classic) patients. In addition, it results in improved BMD (6% to 8% in the first year and up to 12% to 15% at 15 years) and fracture risk (by 50% at hip and upper arm and 30% overall) after adjustment for age, sex, and previous fractures over a 20-year observation period. There are also data to show that it improves a number of the nonspecific manifestations of PHPT such as fatigue, polydipsia, polyuria and nocturia.
bone and joint pain, constipation, nausea, and depression in many patients. This also has been demonstrated using symptom questionnaires and various standardized general quality-of-life assessments such as the SF-36 and a specific parathyroidectomy assessment of symptoms scale. The increased death rate in patients with PHPT appears to be reversible by successful parathyroidectomy, at least in some studies. Lastly, parathyroidectomy can be accomplished with >95% success rates with minimal morbidity, even in elderly patients and is the only curative treatment option for PHPT. Previous investigations have also documented that parathyroidectomy is more cost-effective than medical management or follow-up.

Given these findings, it is recommended that parathyroidectomy should be offered to virtually all patients except those in whom the operative risks are prohibitive. This is also acknowledged by the panel of the latest workshop, which stated that “even though patients may not meet the guidelines for surgical intervention, it is always a reasonable option in those who do not have medical contraindications.” This was first stated in the 2008 guidelines and reiterated in the most recent revision in 2014, which advised parathyroidectomy for patients with smaller elevations in serum calcium levels (>1 mg/dL above the upper limit of normal) and if BMD measured at any of three sites (radius, spine, or hip) is greater than 2.5 standard deviations below those of gender- and race-matched, not age-matched, controls (i.e., peak bone density or T score [rather than Z score] <2.5). In addition, patients <50 years of age were advised to undergo parathyroidectomy. Parathyroidectomy is also indicated for creatinine clearance <60 cc/minute and urine calcium >400 mg/day in the presence of increased stone risk by biochemical stone risk analysis. The significant changes from the previous guidelines pertain to the fact that (a) patients with nephrolithiasis or nephrocalcinosis by X-ray, ultrasound, or CT scan and (b) those with vertebral fracture by X-ray, CT, MRI, or VFA are also candidates for parathyroidectomy. The current guidelines are summarized in Table 38-11.

It is important to point out that the neurocognitive and neuropsychological aspects of PHPT remain a topic of controversy with respect to the guidelines for parathyroidectomy. Although there were more studies since the previous iteration of the guidelines, there were concerns that while some lacked adequate controls and were plagued by problems related to the instruments used to quantify these nonspecific symptoms, others showed variability in improvement of neurocognitive symptoms following parathyroidectomy. Similarly, uncertainty is also present concerning the cardiovascular consequences of mild HPT. Therefore, the workshop panel emphasizes that these criteria alone should not be used as guidelines for surgical intervention.

Since there are no definitive criteria to indicate which patients with mild PHPT will develop progressive disease, more clinical studies are required. Patients who do not undergo surgery should undergo routine follow-up as outlined in the recent workshop summary statement, consisting of annual calcium and serum creatinine measurements, and measurements of BMD at three sites every 1 to 2 years.

GFR = glomerular filtration rate; HPT = hyperparathyroidism; NIH = National Institutes of Health; SD = standard deviation; VFA = vertebral fracture assessment

Preoperative Localization Tests. Localization studies may be classified into noninvasive or invasive modalities. These studies have variable performance characteristics, which, in turn, vary with operator and institutional experience, as outlined in Table 38-12. Localization studies have permitted surgeons to perform more limited operations, some of them under local anesthesia. These “minimally invasive” procedures include unilateral and focused neck exploration, radio-guided parathyroidectomy, and several endoscopic or video-assisted approaches. The use of localization studies has been shown in some studies to be associated with lower morbidity rates (hypoparathyroidism and RLN injury) and decreased operative times, reduced duration of hospital stay, and improved cosmetic outcomes, while maintaining success rates similar to those obtained with traditional bilateral neck explorations. Some studies also show that use of localization studies may be more cost-effective. Overall, it has become routine to localize hyperfunctioning parathyroid glands before parathyroidectomy. It is important to point out that imaging is not a diagnostic approach, and the decision for exploration should be made before any imaging is performed. $^{99m}$Tc-labeled sestamibi (Fig. 38-31A) is the most widely used and accurate modality with a sensitivity >80% for detection of parathyroid adenomas. Sestamibi (Cardiolite) initially was introduced for cardiac imaging and is concentrated in mitochondria-rich tissue. It was subsequently noted to be useful for parathyroid localization due to the delayed washout of the radiouclide from hypercellular parathyroid tissue compared to thyroid tissue. Sestamibi scans generally are complemented by neck ultrasound (Fig. 38-31B), which can identify adenomas with >75% sensitivity in experienced centers and is most useful in identifying intrathyroidal parathyroids. Single-photon emission CT, particularly when used with CT, has been shown to be superior to other nuclear medicine-based imaging. Specifically, single-photon emission CT can indicate whether an adenoma is located in the anterior or posterior mediastinum (aortopulmonary window), thus enabling the surgeon to modify the operative approach accordingly. CT and MRI scans are less sensitive than sestamibi scans, but they are helpful in localizing large paraesophageal and mediastinal glands. More recently, four-dimensional CT (4D-CT) has shown utility in parathyroid localization. This technique incorporates the perfusion of contrast in hyperfunctioning parathyroid tissue over time, thus providing functional information in addition to the anatomic information provided by conventional three-dimensional CT imaging. In one study, 4D-CT showed improved sensitivity of 88% compared to...
that of sestamibi (65%) and ultrasound (57%) for lateralization of the enlarged gland and also showed superiority when localization to the correct quadrant was examined. A combination of 4D-CT and ultrasound has been reported to have a positive predictive value of 92% for single-gland disease and 75% for multiple-gland disease.

IOPTH was initially introduced in 1993 and is used to determine the adequacy of parathyroid resection (Fig. 38-32). IOPTH measurements, like localization studies, are less reliable in multiglandular disease. Bilateral internal jugular vein sampling has also been used to lateralize tumors intraoperatively but is less accurate.

**Operative Approaches** Unilateral parathyroid exploration was first carried out using intraoperative staining of a biopsy from the normal parathyroid gland with Sudan black dye to rule out a double adenoma. Initially, the choice of side to be explored was random, but the introduction of preoperative localization studies has enabled a more directed approach. In contrast, the focused approach identifies only the enlarged parathyroid gland, and no attempts are made to locate other parathyroid glands. Unilateral neck explorations have several advantages over bilateral neck exploration, including reduced operative times and complications, such as injury to the RLN and hypoparathyroidism. However,

| **Table 38-12** Commonly used parathyroid localization studies |
|-----------------|-----------------|-----------------|
| **STUDY**       | **ADVANTAGES**   | **DISADVANTAGES** |
| Preoperative, noninvasive | | |
| Sestamibi-technetium-99m scan | Allows planar and SPECT imaging | False-positive tests due to thyroid neoplasms, lymphadenopathy |
| Ultrasound | Identification of juxta- and intrathyroidal tumors | False-positive results due to thyroid nodules, cysts, lymph nodes, esophageal lesions |
| CT scan | Localization of ectopic (mediastinal) glands | Not useful for juxta- or intrathyroidal glands, False-positive results from lymph nodes, Relatively high cost, Radiation exposure, Requires IV contrast, Interference from shoulders and metallic clips |
| MRI scan | Localization of ectopic tumors | Expensive |
| | No radiation exposure | False-positive results from lymph nodes and thyroid nodules |
| | No IV contrast | Cannot be used in claustrophobic patients |
| Four-dimensional CT scan | Structural and functional information | Similar to CT scan |
| Preoperative, invasive | | |
| FNAB | Can distinguish parathyroid tumor from lymphadenopathy using PTH assay | Experienced cytologist needed |
| Angiogram | Provides a road map for selective venous sampling | Expensive |
| | Treatment of mediastinal tumors by embolization | Experienced radiologist needed |
| Venous sampling | Useful to lateralize tumor in equivocal cases or negative localization studies | Expensive, experienced radiologist needed |
| Intraoperative | | |
| PTH assay | Immediate confirmation of tumor removal | Expensive |
| | | Increased operative time, decreased accuracy in multiple-gland disease |

CT = computed tomography; FNAB = fine-needle aspiration biopsy; IV = intravenous; MRI = magnetic resonance imaging; PTH = parathyroid hormone; SPECT = single-photon emission computed tomography.
most existing studies comparing the two approaches are retrospective and do not analyze the results on an intent-to-treat basis. Another argument against a unilateral exploration is the risk of missing another adenoma on the opposite side of the neck. The incidence of double adenomas has been reported to range from 0% to 10%, with an increased incidence in elderly patients. The risk of missing a second adenoma is higher in populations with a higher incidence of multiple adenomas, such as those with familial HPT, MEN syndromes, and the elderly. Another difficulty inherent with unilateral exploration is the inability to discern whether the combination of an abnormal gland and a normal gland on the initial side constitutes a single adenoma or asymmetric hyperplasia. A recently published update on the 5-year results of a randomized trial comparing unilateral versus bilateral neck exploration did not note any difference in the rates of recurrent or persistent disease in the two groups of patients. These issues will only be resolved by a large, prospective, multicenter study or improved molecular analytic techniques.
Radio-guided parathyroidectomy takes advantage of the ability of parathyroid tumors to retain 99mTc-sestamibi. Before surgery, 1 to 2 mCi of the isotope is injected, and a hand-held gamma probe is used to guide the identification of the enlarged gland, taking care to ensure the equilibration of radioactivity counts in all quadrants. Reported advantages include easier localization, particularly in reoperative cases, and the ability to perform the procedure under local anesthesia or sedation using smaller incisions. Many studies demonstrated the feasibility of this technique; however, it is rarely used now, largely because it offers little advantage over preoperative sestamibi scans and is associated with increased operative times. Like preoperative scanning, it also has reduced accuracy in the presence of multiglandular disease.

Endoscopic approaches include both video-assisted and total endoscopic techniques. Total endoscopic parathyroidectomy was first described by Gagner in 1996, and several other investigators have since reported on this technique. Although port placements are variable, as is the case with endoscopic thyroidectomy, they all involve creation of a working space in the neck using CO₂ insufflation, with the reported advantages being superior cosmesis and excellent visualization. Although feasible, these techniques also have been associated with increased operating times, more personnel, and greater expense, and have, in general, not been useful for patients with multiglandular disease, a large thyroid mass, or previous neck surgery and irradiation. Their greatest use has been in patients with tumors at ectopic sites such as the mediastinum where thoracoscopic parathyroidectomy is an excellent alternative to sternotomy. A bloodless field is important to allow identification of parathyroid glands. The middle thyroid veins are ligated and divided, thus enabling medial and anterior retraction of the thyroid lobe, with the aid of a peanut sponge or placement of 2-0 silk sutures into the thyroid. The space between the carotid sheath and thyroid is then opened by gentle sharp and blunt dissection, from the cricoid cartilage superiorly to the thy- mus inferiorly and the RLN is identified. Approximately 85% of the parathyroid glands are found within 1 cm of the junction of the inferior thyroid artery and RLNs. The upper parathyroid glands usually are superior to this junction and dorsal (posterior) to the nerve, whereas the lower glands are located inferior to the junction and ventral (anterior) to the recurrent nerve. Because parathyroid glands are partly surrounded by fat, any fat lobule at typical parathyroid locations should be explored because the normal or abnormal parathyroid gland may be concealed in the fatty tissue. The thin fascia overlying a “suspicious” fat lobule should be incised using a sharp curved hemostat and scalpel. This maneuver often causes the parathyroid gland to “pop” out. Alternatively, gentle, blunt peanut sponge dissection between the carotid sheath and the thyroid gland often reveals a “float” sign, suggesting the site of the abnormal parathyroid gland. Normal parathyroids are light beige and only slightly darker or brown compared to adjacent fat.

Parathyroid tissue needs to be distinguished from normal or brown fat tissue, thyroid nodules, lymph nodes, and ectopic thymus. Lymph nodes generally are light beige to whitish gray in color, glassy, and multiple in number, whereas thyroid nodules generally are more vascular, firm, dark or reddish brown in color, and have a more variegated appearance. Intraoperatively,
a suspicious nodule may be aspirated using a fine needle attached to a syringe containing 1 cc of saline. Very high PTH levels in the aspirate have been shown to be diagnostic in the intraoperative identification of parathyroid glands. Several characteristics such as size (>7 mm), weight, and color are used to distinguish normal from hypercellular parathyroid glands. Hypercellular glands generally are darker, more firm, and more vascular than normocellular glands. No single method is 100% reliable, and therefore, the parathyroid surgeon must rely on experience and, at times, advice from a pathologist to help distinguish normal from hypercellular glands. Although several molecular studies have shown use in distinguishing parathyroid adenomas from hyperplasia, this determination also must be made by the surgeon intraoperatively by documenting the presence of a normal parathyroid gland.

**Location of Parathyroid Glands.** The majority of lower parathyroid glands are found in proximity to the lower thyroid pole (Fig. 38-33A). If not found at this location, the thyrothymic ligament and thymus should be mobilized. The upper end of the cervical thymus is gently grasped with a right-angle clamp, and the distal portion is bluntly dissected from perithymic fat with a peanut sponge. One can then “walk down” the thymus with successive right-angle clamps (Fig. 38-33B). Applying light tension along with a “twisting” motion helps to free the upper thymus. The carotid sheath also should be opened from the bifurcation to the base of the neck if the parathyroid tumor cannot be found. If these maneuvers are unsuccessful, an intrathyroidal gland should be sought by using intraoperative ultrasound, incising the thyroid capsule on its posterolateral surface, or by performing an ipsilateral thyroid lobectomy and “bread-loafing” the thyroid lobe. Preoperative or intraoperative ultrasonography can be useful for identifying intrathyroidal parathyroid glands. Rarely, the third branchial pouch may maldescend and be found high in the neck (undescended parathyroid), anterior to the carotid bulb, along with the missing parathyroid gland. Upper parathyroid glands are more consistent in position and usually are found near the junction of the upper and middle thirds of the gland, at the level of the cricoid cartilage (Fig. 38-33C). Ectopic upper glands may be found in carotid sheath, tracheoesophageal groove, retroesophageal, or in the posterior mediastinum. The locations of ectopic upper and lower parathyroid glands are shown in Fig. 38-34. Every attempt must be made to identify all four glands. Treatment depends on the number of abnormal glands.

1. A single adenoma is presumed to be the cause of a patient’s PHPT if only one parathyroid tumor is identified and the other parathyroid glands are normal, a situation present in about 80% of patients with PHPT. Adenomas typically have an atrophic rim of normal parathyroid tissue, but this characteristic may be absent. The adenoma is dissected free of surrounding tissue, taking care to stay immediately adjacent to the tumor, without fracturing it. The vascular pedicle is clamped, divided, and ligated. Care should be taken to not rupture the parathyroid gland to decrease the risk of parathyromatosis. If there is any question about the presumed normal glands, one of them should be biopsied and examined by frozen section.

2. If two abnormal and two normal glands are identified, the patient has double adenomas. Triple adenomas are present if three glands are abnormal and one is normal. Multiple adenomas are more common in older patients with an incidence of up to 10% in patients >60 years old. The abnormal glands should be excised, provided the remaining glands are confirmed as such, thus excluding asymmetric hyperplasia after biopsy and frozen section.

3. If all parathyroid glands are enlarged or hypercellular, patients have parathyroid hyperplasia that has been shown to occur in about 15% of patients in various series. These glands are often lobulated, usually lack the rim of normal
parathyroid gland seen in adenomas, and may be variable in size. It often is difficult to distinguish multiple adenomas from hyperplasia with variable gland size. Hyperplasia may be of the chief cell (more common), mixed, or clear cell type. Patients with hyperplasia may be treated by subtotal parathyroidectomy or by total parathyroidectomy and autotransplantation, with the choice of procedure being determined by rates of recurrence, postoperative hypocalcemia, and failure rates of autotransplanted tissue. Initial studies demonstrated equivalent cure rates and postoperative hypocalcemia for the two techniques, with the latter having the added advantage of avoiding recurrence in the neck. However, autotransplanted tissue may fail to function in about 5% of cases.

All four parathyroid glands are identified and carefully mobilized. For patients with hyperplasia, a titanium clip is placed across the most normal gland, leaving a 50-mg remnant and taking care to avoid disturbing the vascular pedicle and that the gland is resected with a sharp scalpel. If possible, it is preferable to subtotally resect an inferior gland, which is more easily accessible in case of recurrence due to its anterior location with respect to the RLN. The resected parathyroid tissue is confirmed by frozen section or PTH assay. If the remnant appears to be viable, the remaining glands are resected. If there is any question as to the viability of the initially subtotally resected gland, another gland is chosen for subtotal resection, and the initial remnant is removed. Whenever multiple parathyroids are resected, it is preferable to cryopreserve tissue, so that it may be autotransplanted should the patient become hypoparathyroid. Parathyroid tissue usually is transplanted into the nondominant forearm. A horizontal skin incision is made overlying the brachioradialis muscle a few centimeters below the antecubital fossa. Pockets are made in the belly of the muscle, and one to two pieces of parathyroid tissue measuring 1 mm each are placed into each pocket. A total of 12 to 14 pieces are transplanted. Autotransplanted tissue also has been reported to function when transplanted into fat.

**Indications for Sternotomy**

A sternotomy is usually not recommended at the initial operation, unless the calcium level is >13 mg/dL. Rather, it is preferred to biopsy the normal glands and subsequently close the patient’s neck and obtain localizing studies, if they were not obtained previously. Intraoperative PTH assay during the operation from large veins may be helpful. Using highly selective venous catheterization postoperatively also may be needed when noninvasive localization studies are negative, equivocal, or conflicting. Lower parathyroid glands tend to migrate into the anterior mediastinum in the thymus or perithymic fat and usually can be approached via a cervical incision. A sternotomy is needed to deliver these tumors in approximately 5% of cases. Generally, the gland can be approached by a partial sternotomy to the third intercostal space. The midline sternotomy can be extended to the left or right side as required. Upper glands tend to migrate to the posterior mediastinum in the tracheoesophageal groove. Mediastinal glands also may be found in the aortopulmonary window or pericardium, or attached to the ascending aorta, aortic arch, or its branches.

**Special Situations**

**Normocalcemic Hyperparathyroidism.** This disorder is becoming increasingly recognized in clinical practice (prevalence from 0.5% to 16%) and is defined by the presence of an elevated PTH level with repeatedly normal calcium (including ionized calcium) levels. In addition, other secondary causes of elevated PTH should be ruled out, namely, vitamin D deficiency, osteomalacia, hypercalcemia (renal leak), and renal insufficiency. Data regarding the natural history of this disorder are limited. In a series of 37 patients, Lowe and colleagues showed that 19% of patients became frankly hypercalcemic within 3 years. In addition, 57% developed osteoporosis, 11% developed fragility fractures, and 14% developed nephrolithiasis. Although the study had some limitations, it led the authors to suggest that normocalcemic HPT may represent a variant of “symptomatic” PHPT and may not be an early form of “asymptomatic” disease. Limited studies show that
Parathyroidectomy is more likely to be unsuccessful in these patients. In the absence of strong data, no guidelines are available for this entity. As such, most clinicians follow a conservative course unless patients progress to the classic hypercalcemic form or develop nephro lithiasis, reduced bone mineral density, or fragility fractures.

**Parathyroid Carcinoma.** Parathyroid cancer accounts for approximately 1% of PHPT cases. It may be suspected preoperatively by the presence of severe symptoms, serum calcium levels >14 mg/dL, significantly elevated PTH levels (five times normal), and a palpable parathyroid gland. Local invasion is quite common; approximately 15% of patients have lymph node metastases, and 33% have distant metastases at presentation. Intraoperatively, parathyroid cancer is suspected by the presence of a large, gray-white to gray-brown parathyroid tumor that is adherent to or invasive into surrounding tissues like muscle, thyroid, RLN, trachea, or esophagus. Enlarged lymph nodes also may be present. Frozen sections are generally unreliable. Accurate diagnosis necessitates histologic examination. The major diagnostic criteria include vascular or capsular invasion, trabecular or fibrous stroma, and frequent mitoses. It is, however, important to emphasize that these classic findings are not as frequently noted as previously reported, and some may be found in benign adenomas as well.

Treatment of parathyroid cancer consists of neck exploration, with en bloc excision of the tumor and the ipsilateral thyroid lobe, in addition to the removal of contiguous lymph nodes (tracheoesophageal, paratracheal, and upper mediastinal). The recurrent nerve is not sacrificed unless it is directly involved with tumor. Adherent soft tissue structures (strap muscles or other soft tissues) should also be resected. Modified radical neck dissection is recommended in the presence of lateral lymph node metastases. Prophylactic neck dissection is not advised. If the diagnosis is made postoperatively, a decision must be made regarding the adequacy of initial surgery based on a review of operative notes, pathology reports, localization studies, and calcium and PTH levels. If any question exists, histologic review by another experienced pathologist can be helpful. Additional procedures can include ipsilateral thyroid lobectomy with resection of contiguous structures and lymph nodes if the features are typical or the patient remains hypercalcemic. Patients with equivocal pathologic findings and normocalcemia may be monitored closely. Reoperation is indicated for locally recurrent or metastatic disease to control hypercalcemia. Adjuvant radiation therapy should be considered in patients at high risk of local recurrence such as those with close or positive margins, invasion of surrounding structures, or tumor rupture. Radiation may also be used as primary therapy in unresectable disease or for palliation of bone metastases. Chemotherapy is not very effective. Bisphosphonates have shown some effectiveness in treating hypercalcemia associated with parathyroid carcinoma. Cinacalcet hydrochloride, a calcimimetic, can reduce PTH levels by directly binding to the CASR cells on the parathyroid gland and has been shown to be useful in controlling hypercalcemia in patients with refractory parathyroid carcinoma. Other promising approaches include antiparathyroid hormone immunotherapy, octreotide, and the telomerase inhibitor azidothymidine, but additional investigations are needed in this area.

**Familial Hyperparathyroidism.** PHPT may occur as a component of various inherited syndromes such as MEN1 and MEN2A. Inherited PHPT also can occur as isolated familial HPT (non-MEN) or familial HPT with jaw tumors. The diagnosis of familial HPT is known or suspected in approximately 85% of patients preoperatively. Furthermore, patients with hereditary HPT generally have a higher incidence of multiglandular disease, supernumerary glands, and recurrent or persistent disease. Therefore, these patients warrant a more aggressive approach and are not candidates for various focused surgical approaches. Although not absolutely necessary, preoperative sestamibi scan and ultrasound can be obtained in patients with inherited HPT to identify potential ectopic glands. A standard bilateral neck exploration is performed, along with a bilateral cervical thymectomy, regardless of the results of localization studies. Both subtotal parathyroidectomy and total parathyroidectomy with autotransplantation are appropriate, and parathyroid tissue also should be cryopreserved. If an adenoma is found in patients with familial HPT, the adenoma and the ipsilateral normal parathyroid glands are resected. The normal-appearing glands on the contralateral side are biopsied and marked, so that only one side of the neck will need to be explored in the event of recurrence. Patients with MEN2A require total thyroidectomy and central neck dissection for prevention/treatment of MTC, a procedure that places the parathyroids at risk. Moreover, HPT is less aggressive in these patients. Hence, only abnormal parathyroid glands need to be resected at neck exploration. The other normal parathyroid glands should be marked with a clip.

**Neonatal Hyperparathyroidism.** Infants with neonatal HPT present with severe hypercalcemia, lethargy, hypotonia, and mental retardation. This disorder is associated with homozygous mutations in the CASR gene. As indicated earlier, urgent total parathyroidectomy (with autotransplantation and cryopreservation) and thymectomy are indicated. Subtotal resection is associated with high recurrence rates.

**Parathyromatosis.** Parathyromatosis is a rare condition characterized by the finding of multiple nodules of hyperfunctioning parathyroid tissue throughout the neck and mediastinum, usually following a previous parathyroidectomy. The true etiology of parathyromatosis is not known. It is postulated to arise either from overgrowth of congenital parathyroid rests (ontogenous parathyromatosis) or seeding at surgery from rupture of parathyroid tumors or subtotal resection of hyperplastic glands. Parathyromatosis represents a rare cause of persistent or recurrent HPT and can be identified intraoperatively. Aggressive local resection of these deposits can result in normocalcemia but is rarely curative. Some studies suggest that these patients have low-grade carcinoma because of invasion into muscle and other structures distant from the resected parathyroid tumor.

**Postoperative Care and Follow-Up.** Patients who have undergone parathyroidectomy are advised to undergo calcium level checks 2 weeks postoperatively, at 6 months, and then annually. Recurrences are rare (<1%), except in patients with familial HPT. Recurrence rates of 15% at 2 years and 67% at 8 years have been reported for MEN1 patients.

**Persistent and Recurrent Hyperparathyroidism.** Persistence is defined as hypercalcemia that fails to resolve after parathyroidectomy and is more common than recurrence, which refers to HPT occurring after an intervening period of at least 6 months of biochemically documented normocalcemia. Recurrent disease is far less common than persistent HPT; however, both occur more frequently in the setting of familial HPT and MEN1, in particular. The most common causes for both these states include ectopic parathyroids, unrecognized
hyperplasia, or supernumerary glands. More rare causes include parathyroid carcinoma, missed adenoma in a normal position, incomplete resection of an abnormal gland, parathyromatosis, or an inexperienced surgeon. The most common sites of ectopic parathyroid glands in patients with persistent or recurrent HPT are paraesophageal (28%), mediastinal (26%), intrathyroidal (11%), carotid sheath (9%), and high cervical or undescended (2%) (Fig. 38-35).

Once the diagnosis of persistent or recurrent HPT is suspected, it should be confirmed by the necessary biochemical tests. Other causes of an elevated serum PTH such as renal insufficiency, renal calcium leak, and GI tract abnormalities should be considered. A detailed family history should be performed to screen for familial disease, as this will influence the operative approach. In particular, a 24-hour urine collection should be performed to rule out FHH. In redo-parathyroid surgery, the glands are more likely to be in ectopic locations, and postoperative scarring tends to make the procedure more technically demanding. Cure rates are generally lower (80–90% compared with 95–99% for initial operation), and risk of injury to RLNs and permanent hypocalcemia are higher. Therefore, an evaluation of severity of HPT and the patient’s anesthetic risk (using the American Society of Anesthesiology classification of physical status or the Goldman cardiac index) is important. There are no published guidelines directly applicable to this group of patients. In general, patients with significant and ongoing problems such as recurrent kidney stones, a markedly elevated calcium level, or ongoing bone loss will need reexploration. Patients in whom the diagnosis remains in question or those with equivocal or minimal symptoms may be considered for conservative management. Preoperative localization studies are routinely performed. Noninvasive studies such as a sestamibi scan and ultrasound are obtained, supplemented by 4D-CT scans. If these studies are negative, discordant, or equivocal, obtaining an ultrasound-guided aspirate of a suspicious cervical lesion or a highly selective venous catheterization for PTH levels (by an experienced angiographer) is recommended. Previous operative notes and pathology reports should be carefully reviewed and reconciled with the information obtained from localization studies before any neck reexploration. An algorithm for the treatment of patients with recurrent and persistent HPT is shown in Fig. 38-36.

Generally, these patients are approached with a focused exploration. The lateral approach is frequently used and can be achieved via the previous incision. The plane between the sternocleidomastoid and strap muscle is opened and allows for early identification of the RLN. Parathyroid tissue is cryopreserved routinely. Use of adjuncts, such as measuring intraoperative PTH levels, is critical to ensure adequate resection and avoid potentially harmful additional explorations. In case of difficult reexplorations, additional techniques such as bilateral internal jugular vein sampling for PTH, thyroid lobectomy on the side of the missing gland, cervical thymectomy, and ligation of the ipsilateral inferior thyroid artery (after lobectomy, to cause infarction of the missing gland) may be needed. Blind mediastinal exploration is not recommended. In patients who are denied, refuse, or fail exploration, medical options such as cinacalcet may be considered.

Figure 38-35. Anatomic location of ectopic parathyroid glands. Numbers represent number of glands found in each location, with a total of 54. Figure 38-36. Management of recurrent and persistent hyperparathyroidism (HPT). FHH = familial hypocalciuric hypercalcemia; PTH = parathyroid hormone.

Hypercalcemic Crisis. Patients with PHPT may occasionally present acutely with nausea, vomiting, fatigue, muscle weakness, confusion, and a decreased level of consciousness—a complex referred to as hypercalcemic crisis. These symptoms result from severe hypercalcemia from uncontrolled PTH secretion, worsened by polyuria, dehydration, and reduced kidney function and may occur with other conditions causing hypercalcemia. Calcium levels are markedly elevated and may be as high as 16 to 20 mg/dL. Parathyroid tumors tend to be large or multiple and may be palpable. Patients with parathyroid cancer or familial HPT are more likely to present with hypercalcemic crisis.

Treatment consists of therapies to lower serum calcium levels followed by surgery to correct HPT. The mainstay of therapy involves rehydration with a 0.9% saline solution to keep urine output >100 cc/h. Once urine output is established, diuretics and furosemide (which increases renal calcium clearance) are begun. If these methods are unsuccessful, other drugs may be used to lower serum calcium levels as outlined in Table 38-13. Occasionally, in life-threatening cases, hemodialysis may be of benefit.

Secondary Hyperparathyroidism. Secondary HPT commonly occurs in patients with chronic renal failure but also may occur in those with hypocalcemia secondary to inadequate calcium or vitamin D intake or malabsorption. The pathophysiology of HPT in chronic renal failure is complex and appears to be related to hyperphosphatemia (and resultant hypocalcemia), deficiency of 1,25-dihydroxy vitamin D due to loss of renal tissue, low calcium intake, decreased calcium absorption, and abnormal parathyroid cell response to extracellular calcium or vitamin D in vitro and in vivo. Patients generally are hypocalcemic or normocalcemic. Aluminum hydroxide, which often was used as a phosphate binder, has been shown to contribute to the osteomalacia observed in this disease. These patients generally are treated medically with a low-phosphate diet, phosphate binders, adequate intake of calcium and 1, 25-dihydroxy vitamin D, and a high-calcium, low-aluminum dialysis bath. Calcimimetics have been shown to control parathyroid hyperplasia and osteitis fibrosa cystica associated with secondary HPT in animal studies and to decrease plasma PTH and total and ionized calcium levels in humans.

As the indications for parathyroidectomy were not well established, surgical treatment was traditionally recommended for patients with bone pain, pruritus, and (a) a calcium-phosphate product ≥70, (b) calcium >11 mg/dL with markedly elevated PTH, (c) calciphylaxis, (d) progressive renal osteodystrophy, and (e) soft tissue calcification and tumoral calcinosis, despite maximal medical therapy. Following the introduction of calcimimetics, there appears to have been a reduction in parathyroidectomy rates. Parathyroidectomy has been reported to maintain biochemical targets for up to 5 years and improve bone density, fracture risk, calcinosis, hemoglobin levels, and even long-term survival. Studies also report that in a large series of patients on hemodialysis, calcimimetics increased the likelihood of achieving goal PTH (≤300 pg/mL), calcium, phosphate, and Ca × PO₄ product, in addition to reducing the risk of fractures and cardiovascular complications.

In the absence of randomized trials comparing medical therapy with parathyroidectomy, current recommendations from the National Kidney Foundation’s Kidney Disease Quality Outcomes Initiative (KDOQI) advise parathyroidectomy for patients on maximal medical therapy with (a) severe HPT (defined as PTH >800 pg/mL), (b) hypercalcemia, (c) osteoporosis or pathologic bone fracture, (d) Symptoms and signs such as pruritus, bone pain, severe vascular calcifications, myopathy, and (e) calciphylaxis. Calciphylaxis is a rare, limb- and life-threatening complication of secondary HPT characterized by painful (sometimes throbbing), violaceous, and mottled lesions usually on the extremities, which often become necrotic and progress to non-healing ulcers, gangrene, sepsis, and death. Skin biopsy can be helpful to make the diagnosis. These are critically ill, high-risk patients, but successful parathyroidectomy sometimes relieves symptoms. Not all patients with calciphylaxis will have high PTH levels, and parathyroidectomy should not be undertaken in the absence of documented hyperparathyroidism. Assessment of parathyroid mass is thought to be an important factor for predicting the response to medical management. Therefore, some groups recommend parathyroidectomy if the glands are >1 cm (or >500 mm³) on ultrasound. These glands are more likely to have developed nodular hyperplasia and hence might be refractory to medical management.

Patients should undergo routine dialysis the day before surgery to correct electrolyte abnormalities. Localization studies are not necessary but can identify ectopic parathyroid glands. A bilateral neck exploration is indicated. The parathyroid glands in secondary HPT are characterized by asymmetric enlargement and nodular hyperplasia. These patients may be treated by subtotal resection, leaving about 50 mg of the most normal parathyroid gland or total parathyroidectomy and autotransplantation.
of parathyroid tissue into the brachioradialis muscle of the non-
dominant forearm, with parathyroid cryopreservation. Upper
thymectomy usually is performed because 15% to 20% of
patients have one or more parathyroid glands situated in the thy-
mus or perithymic fat. Some groups recommend total parathy-
roidectomy without autotransplantation because it is associated
with a lower rate of recurrence.95 While it may be preferable in
patients with calciphylaxis, this procedure is contraindicated in
some patients with chronic renal failure.

Tertiary Hyperparathyroidism. Generally, renal transplan-
tation is an excellent method of treating secondary HPT, but
some patients develop autonomous parathyroid gland function
and tertiary HPT. Tertiary HPT can cause problems similar to
PHPT, such as pathologic fractures, bone pain and worsened
bone disease, renal stones, peptic ulcer disease, pancreatitis,
and mental status changes. The transplanted kidney is also at
risk from tubulointerstitial calcification and volume depletion.
Similar to patients with secondary HPT, many patients with ter-
tiary HPT are being treated with cinacalcet. Although the drug
is effective and well-tolerated in these patients, the long-term
effects on kidney allograft function are not known, and many
of these patients have persistence of their hypercalcemic symp-
toms. On the other hand, parathyroidectomy has been shown to
lead to a more immediate and dramatic reduction in hypercal-
cemic symptoms. As such, operative intervention is indicated if
autonomous PTH secretion persists for >1 year after a successful
transplant in patients with hypophosphatemia, low BMD/severe
osteopenia, symptoms, and signs such as fatigue, pruritis, bone
pain, peptic ulcer disease or nephrocalcinosis, provided they
are deemed operative candidates.96 All parathyroid glands
should be identified. The traditional surgical management of
these patients consisted of subtotal or total parathyroid-
ectomy with autotransplantation and an upper thymectomy.
Some authors suggest that these patients derive similar benefit
from excision of only obviously enlarged glands, while avoid-
ing the higher risks of hypocalcemia associated with the for-
mer approach. Others recommend that all parathyroid glands
be identified and subtotal parathyroidectomy be performed as
long-term follow-up studies show that limited excisions in these
patients are associated with an up to fivefold increased risk of
recurrent or persistent disease. Further studies are needed to
define the best operative approach for these patients.

Complications of Parathyroid Surgery. Parathyroidectomy
can be accomplished successfully in >95% of patients with
minimal mortality and morbidity, provided the procedure is
performed by a surgeon experienced in parathyroid surgery.

BSA = body surface area; IM = intramuscular; IV = intravenous; SC = subcutaneous.
Specific complications include transient and permanent vocal cord palsy and hypoparathyroidism. The latter is more likely to occur in patients who undergo four-gland exploration with biopsies, subtotal resection with an inadequate remnant, or total parathyroidectomy with a failure of autotransplanted tissue. Furthermore, hypocalcemia is more likely to occur in patients with high-turnover bone disease as evidenced by elevated preoperative alkaline phosphatase levels. Vocal cord paralysis and hypoparathyroidism are considered permanent if they persist for >6 months. Fortunately, these complications are rare, occurring in approximately 1% of patients undergoing surgery by experienced parathyroid surgeons.

Patients with symptomatic hypocalcemia or those with calcium levels <8 mg/dL are treated with oral calcium supplementation (up to 1-2 g every 4 hours). 1,25-Dihydroxy vitamin D (calcitriol [Rocaltril] 0.25–0.5 μg twice a day) may also be required, particularly in patients with severe hypercalcemia and elevated serum alkaline phosphatase levels, preoperatively and with osteitis fibrosa cystica. Intravenous calcium supplementation rarely is needed, except in cases of severe, symptomatic hypocalcemia.

**Hypoparathyroidism**

Hypocalcemia can be the result of a multitude of conditions, which are listed in Table 38-14. The parathyroid glands may be congenitally absent in DiGeorge syndrome, which also is characterized by lack of thymic development and, therefore, a thymus-dependent lymphoid system. By far, the most common cause of hypoparathyroidism is thyroid surgery, particularly total thyroidectomy with a concomitant central neck dissection. Patients often develop transient hypocalcemia due to ischemia of the parathyroid glands; permanent hypoparathyroidism is rare. Hypoparathyroidism also may occur after parathyroid surgery, which is more likely if patients undergo a subtotal resection or total parathyroidectomy with parathyroid autotransplantation.

Acute hypocalcemia results in decreased ionized calcium and increased neuromuscular excitability. Patients initially develop circumoral and fingertip numbness and tingling. Mental symptoms include anxiety, confusion, and depression. Physical examination reveals positive Chvostek’s sign (contraction of facial muscles elicited by tapping on the facial nerve anterior to the ear) and Trousseau’s sign (carpopedal spasm that is elicited by occluding blood flow to the forearm with a blood pressure cuff for 2–3 minutes). Tetany, which is characterized by tonic-clonic seizures, carpopedal spasm, and laryngeal stridor, may prove fatal and should be avoided. Most patients with postoperative hypocalcemia can be treated with oral calcium and vitamin D supplements; IV calcium infusion is rarely required except in patients with preoperative osteitis fibrosa cystica.

**ADRENAL**

**Historical Background**

Eustachius provided the first accurate anatomic account of the adrenals in 1563. The anatomic division of the adrenals into the cortex and medulla was described much later, by Cuvier in 1805. Subsequently, Thomas Addison in 1855 described the features of adrenal insufficiency, which still bear his name. DeCrecchio provided the first description of congenital adrenal hyperplasia (CAH) occurring in a female pseudohermaphrodite in 1865. Pheochromocytomas were first identified by Frankel in 1885, but were not named as such until 1912 by Pick, who noted the characteristic chromaffin reaction of the tumor cells. Adrenaline was identified as an agent from the adrenal medulla that elevated blood pressure in dogs and was subsequently named epinephrine in 1897. The first successful adrenalectomies for pheochromocytoma were performed by Roux in Switzerland and Charles Mayo in the United States.

In 1932, Harvey Cushing described 11 patients who had moon facies, truncal obesity, hypertension, and other features of the syndrome that now bears his name. Although several individuals prepared adrenocortical extracts to treat adrenalec-tomized animals, cortisol was first synthesized by Kendall. Aldosterone was identified in 1952, and the syndrome resulting from excessive secretion of this mineralocorticoid was first described in 1955 by Conn.

**Embryology**

The adrenal or suprarenal glands are two endocrine organs in one; an outer cortex and an inner medulla, each with distinct embryologic, anatomic, histologic, and secretory features. The cortex originates around the fifth week of gestation from the mesodermal tissue near the gonads on the adrenogenital ridge (Fig. 38-37). Therefore, ectopic adrenocortical tissue may be found in the ovaries, spermatic cord, and testes. The cortex differentiates further into a thin, definitive cortex and a thicker, inner fetal cortex. The latter is functional and produces fetal adrenal steroids by the eighth week of gestation, but undergoes involution after birth, resulting in a decrease in adrenal weight during the first three postpartum months. The definitive cortex persists after birth to form the adult cortex over the first 3 years of life. In contrast, the adrenal medulla is ectodermal in origin and arises from the neural crest. At around the same time as cortical development, neural crest cells migrate to the para-aortic and paravertebral areas and toward the medial aspect of the developing cortex to form the medulla. Most extra-adrenal neural tissue regresses but may persist at several sites. The largest of these is located to the left of the aortic bifurcation near the inferior mesenteric artery origin and is designated as the organ of Zuckerkandl. Adrenal medullary tissue also may be found in neck, urinary bladder, and para-aortic regions. Several

Anatomy

The adrenal glands are paired, retroperitoneal organs located superior and medial to the kidneys at the level of the eleventh ribs. The normal adrenal gland measures 5 × 3 × 1 cm and weighs 4 to 5 g. The right gland is pyramidal shaped and lies in close proximity to the right hemidiaphragm, liver, and inferior vena cava (IVC). The left adrenal is closely associated with the aorta, spleen, and tail of the pancreas. Each gland is supplied by three groups of vessels—the superior adrenal arteries derived from the inferior phrenic artery, the middle adrenal arteries derived from the aorta, and the inferior adrenal arteries derived from the renal artery. Other vessels originating from the intercostal and gonadal vessels may also supply the adrenals. These arteries branch into about 50 arterioles to form a rich plexus beneath the glandular capsule and require careful dissection, ligation, and division during adrenalectomy. In contrast to the arterial supply, each adrenal usually is drained by a single, major adrenal vein. The right adrenal vein is usually short and drains into the IVC, whereas the left adrenal vein is longer and empties into the left renal vein after joining the inferior phrenic vein. Accessory veins occur in 5% to 10% of patients—on the right, these vessels may drain into the right hepatic vein or the right renal vein; on the left, accessory veins may drain directly into the left renal vein. The anatomic relationships of the adrenals and surrounding structures are depicted in Fig. 38-38.

The adrenal cortex appears yellow due to its high lipid content and accounts for about 80% to 90% of the gland’s volume. Histologically, the cortex is divided into three zones—the zona glomerulosa, zona fasciculata, and zona reticularis. The outer area of the zona glomerulosa consists of small cells and is the site of production of the mineralocorticoid hormone, aldosterone. The zona fasciculata is made up of larger cells, which often appear foamy due to multiple lipid inclusions, whereas the zona reticularis cells are smaller. These latter zones are the site of production of glucocorticoids and adrenal androgens. The adrenal medulla constitutes up to 10% to 20% of the gland’s volume and is reddish-brown in color. It produces the catecholamine hormones epinephrine and norepinephrine. The cells of the adrenal medulla are arranged in cords and are polyhedral in shape. They are often referred to as chromaffin cells because they stain specifically with chromium salts.

Adrenal Physiology

Cholesterol, derived from the plasma or synthesized in the adrenal, is the common precursor of all steroid hormones derived from the adrenal cortex. Cholesterol initially is cleaved within mitochondria to 5-6-pregnanolone, which in turn is transported to the smooth endoplasmic reticulum where it forms the substrate for various biosynthetic pathways leading to steroidogenesis (Fig. 38-39).

Mineralocorticoids. The major adrenal mineralocorticoid hormones are aldosterone, 11-deoxycorticosterone (DOC), and cortisol. Cortisol has minimal effects on the kidney due to hormone degradation. Aldosterone secretion is regulated primarily by the renin-angiotensin system. Decreased renal blood flow, decreased plasma sodium, and increased sympathetic tone all stimulate the release of renin from juxtaglomerular cells. Renin, in turn, leads to the production of angiotensin I from its precursor angiotensinogen. Angiotensin I is cleaved by pulmonary angiotensin-converting enzyme (ACE) to angiotensin II; the latter is not only a potent vasoconstrictor, but it also leads to increased aldosterone synthesis and release. Hyperkalemia is another potent stimulator of aldosterone synthesis, whereas ACTH, pituitary pro-opiomelanocortin, and antidiuretic hormone are weak stimulators.

Aldosterone is secreted at a rate of 50 to 250 μg/d (depending on sodium intake) and circulates in plasma chiefly as a complex with albumin. Small amounts of the hormone bind to corticosteroid-binding globulin, and approximately 30% to 50% of secreted aldosterone circulates in a free form. The hormone has a half-life of only 15 to 20 minutes and is rapidly cleared via the liver and kidney. A small quantity of free aldosterone also is excreted in the urine. Mineralocorticoids cross the cell membrane and bind to cytosolic receptors. The receptor-ligand complex subsequently is transported into the nucleus where it induces the transcription and translation of specific genes. Aldosterone functions mainly to increase sodium reabsorption and potassium and hydrogen ion excretion at the level of the renal distal convoluted tubule. Less commonly, aldosterone increases sodium absorption in salivary glands and GI mucosal surfaces.
**Glucocorticoids.** The secretion of cortisol, the major adrenal glucocorticoid, is regulated by ACTH secreted by the anterior pituitary, which, in turn, is under the control of corticotrophin-releasing hormone (CRH) secreted by the hypothalamus. ACTH is a 39-amino-acid protein, which is derived by cleavage from a larger precursor, pro-opiomelanocortin. ACTH is further cleaved into \( \alpha \)-melanocyte-stimulating hormone and corticotrophin-like intermediate peptide. ACTH not only stimulates the secretion of glucocorticoids, mineralocorticoids, and adrenal androgens, but is also trophic for the adrenal glands. ACTH secretion may be
stimulated by pain, stress, hypoxia, hypothermia, trauma, and hypoglycemia. ACTH secretion fluctuates, peaking in the morning and reaching nadir levels in the late afternoon. Thus, there is a diurnal variation in the secretion of cortisol, with peak cortisol excretion also occurring in the early morning and declining during the day to its lowest levels in the evening (Fig. 38-40). Cortisol controls the secretion of both CRH and ACTH via a negative feedback loop. A similar mechanism leads to the inhibition of CRH secretion by ACTH.

Cortisol is transported in plasma bound primarily to corticosteroid-binding globulin (75%) and albumin (15%). Approximately 10% of circulating cortisol is free and is the biologically active component. The plasma half-life of cortisol is 60 to 90 minutes and is determined by the extent of binding and rate of inactivation. Cortisol is converted to di- and tetrahydrocortisol and cortisone metabolites in the liver and the kidney. The majority (95%) of cortisol and cortisone metabolites are conjugated with glucuronic acid in the liver, thus facilitating their renal excretion. A small amount of unmetabolized cortisol is excreted unchanged in the urine.

Glucocorticoid hormones enter the cell and bind cytosolic steroid receptors. The activated receptor-ligand complex is then transported to the nucleus where it stimulates the transcription of specific target genes via a “zinc finger” DNA binding element. Cortisol also binds the mineralocorticoid receptor with an affinity similar to aldosterone. However, the specificity of mineralocorticoid action is maintained by the production of 11β-hydroxysteroid dehydrogenase, an enzyme that inactivates cortisol to cortisone in the kidney. Glucocorticoids have important functions in intermediary metabolism but also affect connective tissue, bone, immune, cardiovascular, renal, and central nervous systems, as outlined in Table 38-15.

**Sex Steroids.** Adrenal androgens are produced in the zona fasciculata and reticularis from 17-hydroxypregnenolone in response to ACTH stimulation. They include dehydroepiandrosterone (DHEA) and its sulfated counterpart (DHEAS), androstenedione, and small amounts of testosterone and estrogen. Adrenal androgens are weakly bound to plasma albumin. They exert their major effects by peripheral conversion to the more potent testosterone and dihydrotestosterone but also have weak intrinsic androgen activity. Androgen metabolites are conjugated as glucuronides or sulfates and excreted in the urine. During fetal development, adrenal androgens promote the formation of male genitalia. In normal adult males, the contribution of adrenal androgens is minimal; however, they are responsible for the development of secondary sexual characteristics at puberty. Adrenal androgen excess leads to precocious puberty in boys and virilization, acne, and hirsutism in girls and women.

**Catecholamines.** Catecholamine hormones (epinephrine, norepinephrine, and dopamine) are produced not only in the central and sympathetic nervous system but also the adrenal medulla. The substrate, tyrosine, is converted to catecholamines via a series of steps shown in Fig. 38-41A. Phenylethanolamine N-methyltransferase, which converts norepinephrine to epinephrine, is only present in the adrenal medulla and the organ of Zuckerkandl. Therefore, the primary catecholamine produced may be used to distinguish adrenal medullary tumors from those situated at extra-adrenal sites. Catecholamines are stored in granules in combination with other neuropeptides, ATP, calcium, magnesium, and water-soluble proteins called chromogranins. Hormonal secretion is stimulated by various stress stimuli and mediated by the release of acetylcholine at the preganglionic nerve terminals. In the circulation, these proteins are bound to albumin and other proteins. Catecholamines are cleared by several mechanisms including reuptake by sympathetic nerve endings, peripheral inactivation by catechol O-methyltransferase and monoamine oxidase, and direct excretion by the kidneys. Metabolism of catecholamines takes place...

primarily in the liver and kidneys and leads to the formation of metabolites such as metanephrines, normetanephrines, and VMA, which may undergo further glucuronidation or sulfation before being excreted in the urine (Fig. 38-41B).

Adrenergic receptors are transmembrane-spanning molecules that are coupled to G proteins. They may be subdivided into α and β subtypes, which are localized in different tissues, have varying affinity to various catecholamines, and mediate distinct biologic effects (Table 38-16). The receptor affinities for α receptors are—epinephrine > norepinephrine >> isoproterenol; β₁ receptors—iso- proterenol > epinephrine = norepinephrine; and β₂ receptors—iso- proterenol > epinephrine >> norepinephrine.

Disorders of the Adrenal Cortex

Hyperaldosteronism. Hyperaldosteronism may be secondary to stimulation of the renin-angiotensin system from renal artery stenosis and to low-flow states such as congestive heart failure and cirrhosis. Hyperaldosteronism resulting from these conditions is reversible by treatment of the underlying cause. Primary hyperaldosteronism results from autonomous aldosterone secretion, which, in turn, leads to suppression of renin secretion. Primary aldosteronism usually occurs in individuals between the ages of 30 to 50 years old and accounts for 1% of hypertension cases. It is associated with hypokalemia; however, more patients with Conn’s syndrome are being diagnosed with normal potassium levels. Most cases result from a solitary functioning adrenal adenoma (~70%) and idiopathic bilateral hyperplasia (30%). Adrenocortical carcinoma and glucocorticoid-suppressible hyperaldosteronism are rare, each accounting for <1% of cases. Glucocorticoid-suppressible hyperaldosteronism is an autosomal dominant form of hypertension in which aldosterone secretion is abnormally regulated by ACTH. This condition is caused by recombinations between linked genes encoding closely related isozymes, 11b-hydroxylase (CYP11B1), and aldosterone synthase (CYP11B2) generating a dysregulated chimeric gene with aldosterone synthase activity. This entity is now designated familial hyperaldosteronism type I (FH-I).

Initially, FH-III referred to patients with massive adrenal hyperplasia refractory to glucocorticoid administration. However, the term is now more commonly used to describe patients with primary hyperaldosteronism due to germline KCNJ5 mutations. This gene encodes an inward rectifier potassium channel, and the mutations affected amino acids in or close to the channel’s selectivity filter. Somatic gain of function mutations are found in up to 40% of aldosterone-producing adenomas (APA). Familial hyperaldosteronism type II refers to families in which two first-degree relatives have been diagnosed with primary hyperaldosteronism (adrena or hyperplasia) and in whom types I and III have been excluded. Other genes mutated in (APA) include CACNA1D (encodes the plasma membrane calcium ATPase), ATP2B3 (encodes the plasma membrane Ca²⁺ ATPase), CACNA1H (encodes the α₁ subunit of the T-type voltage calcium channel), and CTNNB1 (β-catenin).

Symptoms and Signs Patients typically present with hypertension, which is long-standing, moderate to severe, and may be difficult to control despite multiple-drug therapy. Other symptoms include muscle weakness, polydipsia, polyuria, nocturia, headaches, and fatigue. Weakness and fatigue are related to the presence of hypokalemia.

Diagnostic Studies

Laboratory Studies. Hypokalemia is a common finding, and hyperaldosteronism must be suspected in any hypertensive patient who presents with coexisting spontaneous hypokalemia (K <3.2 mmol/L) or hypokalemia (<3 mmol/L) while on diuretic therapy, despite potassium replacements. However, it is important to note that up to 40% of patients with a confirmed aldosteronoma were normokalemic preoperatively. Once the diagnosis is suspected, further tests are necessary to confirm the diagnosis. Before testing, patients must receive adequate sodium and potassium. Antihypertensive medications should be held, if possible, and spironolactone, β-blockers, ACE inhibitors, and angiotensin II receptor blockers should be avoided. Patients with primary hyperaldosteronism have an elevated plasma aldosterone concentration level with a suppressed plasma renin activity; a plasma aldosterone concentration-to-plasma renin activity ratio of 1:25 to 30 is strongly suggestive of the diagnosis. False-positive results can occur, particularly in patients with chronic renal failure. Patients with primary hyperaldosteronism also fail to suppress aldosterone levels with sodium loading. This test can be performed by performing a 24-hour urine collection for cortisol, sodium, and aldosterone after 5 days of a high-sodium diet or alternatively giving the...
**Figure 38-41.** A. Synthesis of catecholamines. B. Metabolism of catecholamine hormones.
In this procedure, the adrenal veins are cannulated, and blood samples for aldosterone and cortisol are obtained from both adrenal veins and the vena cava after ACTH administration. Measurement of cortisol levels is necessary to confirm proper placement of the catheters in the adrenal veins. A greater than fourfold difference in the aldosterone-to-cortisol ratios between the adrenal veins indicates the presence of a unilateral tumor. Some investigators use this study routinely, but it is invasive, requires an experienced interventional radiologist, and can lead to adrenal vein rupture in approximately 1% of cases. Therefore, most groups advocate use of this modality selectively in ambiguous cases, when the tumor cannot be localized and in patients with bilateral adrenal enlargement to determine whether there is unilateral or bilateral increased secretion of aldosterone. Additional indications for forgoing AVS include patients who are suspected of having adrenocortical carcinoma, those with comorbid conditions precluding surgery and those with proven familial hyperaldosteronism type I or III. Scintigraphy with \(^{131}\text{I}-6\beta\)-iodomethyl noriodocholesterol (NP-59) also may be used for the same purpose. Like cholesterol, this compound is taken up by the adrenal cortex, but unlike cholesterol, it remains in the gland without undergoing further metabolism. Adrenal adenomas appear as “hot” nodules with suppressed contralateral uptake, whereas hyperplastic glands show bilaterally increased uptake. This test, however, is not widely available. Newer isotopes such as \(^{11}\text{C}\)-metomidate in conjunction with PET-CT have also shown promise in the localization of aldosteronomas.
**Treatment** Preoperatively, control of hypertension and adequate potassium supplementation (to keep K >3.5 mmol/L) are important. Patients generally are treated with spironolactone (an aldosterone antagonist), amiloride (a potassium-sparing diuretic that blocks sodium channels in the distal nephron), nifedipine (a calcium channel blocker), or captopril (an ACE inhibitor). Unilateral tumors producing aldosterone are best managed by adrenalectomy, either by a laparoscopic approach (preferred) or via a posterior open approach. If a carcinoma is suspected because of the large size of the adrenal lesion or mixed hormone secretion, an anterior transabdominal approach is preferred to permit adequate determination of local invasion and distal metastases. Only 20% to 30% of patients with hyperaldosteronism secondary to bilateral adrenal hyperplasia benefit from surgery, and as described, selective venous catheterization is useful to predict which patients will respond. For the other patients, medical therapy with spironolactone, amiloride, or triamterene is the mainstay of management. Glucocorticoid-suppressible hyperaldosteronism is treated by administering exogenous dexamethasone at doses of 0.5 to 1 mg daily. Treatment with spironolactone may help decrease glucocorticoid requirements in this condition and avoid symptoms of Cushing’s syndrome. Postoperatively, some patients experience transient hypoaldosteronism requiring mineralocorticoids for up to 3 months. Recent studies suggest that postresection hyperkalemia may be more common and last longer than previously appreciated; therefore, it should be screened for in patients who are older and who have had a longer duration of hypertension, impaired kidney function, and higher preoperative aldosterone levels, making them a high-risk group. Rarely, acute Addison’s disease may occur 2 to 3 days after adrenalectomy. Adrenalectomy is >90% successful in improving hypokalemia and about 70% successful in correcting hypertension. Patients who respond to spironolactone therapy and those with a shorter duration of hypertension with minimal renal damage are more likely to achieve improvement in hypertension, whereas male patients, those >50 years old, and those with multiple adrenal nodules, are least likely to benefit from adrenalectomy.

**Cushing’s Syndrome.** Cushing described patients with a peculiar fat deposition, amenorrhea, impotence (men), hirsutism, purple striae, hypertension, diabetes, and other features that constitute the syndrome (Fig. 38-43). He also recognized that several of these patients had basophilic tumors of the pituitary gland and concluded that these tumors produced hormones that caused adrenocortical hyperplasia, thus resulting in the manifestations of the syndrome. Today, the term Cushing’s syndrome refers to a complex of symptoms and signs resulting from hypersecretion of cortisol regardless of etiology. In contrast, Cushing’s disease refers to a pituitary tumor, usually an adenoma, which leads to bilateral adrenal hyperplasia and hypercortisolism. Cushing’s syndrome (endogenous) is a rare disease, affecting 10 in 1 million individuals. It is more common in adults but may occur in children. Women are more commonly affected (male-to-female ratio is 1:8). Although most individuals have sporadic disease, Cushing’s syndrome may be found in MEN1 families and can result from ACTH-secreting pituitary tumors, primary adrenal neoplasms, or an ectopic ACTH-secreting carcinoid tumor (more common in men) or bronchial adenoma (more common in women).

Cushing’s syndrome may be classified as ACTH-dependent or ACTH-independent (Table 38-17). The most common cause of hypercortisolism is exogenous administration of steroids. However, approximately 70% of cases of endogenous Cushing’s syndrome are caused by an ACTH-producing pituitary tumor. Primary adrenal sources (adenoma, hyperplasia, and

ACTH = adrenocorticotropic hormone; CRH = corticotrophin-releasing hormone.
cancer) account for about 20% of cases, and ectopic ACTH-secreting tumors account for <10% of cases. CRH also may be secreted ectopically in bronchial carcinoid tumors, pheochromocytomas, and other tumors. These patients are difficult to distinguish from those with ectopic ACTH production, but can be diagnosed by determining CRH levels. Patients with major hypertension, psychosis, pregnancy, chronic renal failure, or stress also may have elevated cortisol levels and symptoms of hypercortisolism. However, these manifestations resolve with treatment of the underlying disorder, and these patients are deemed to have pseudo-Cushing’s syndrome.

Primary adrenal hyperplasia may be micronodular, macronodular, or massively macronodular. Adrenal hyperplasia resulting from ACTH stimulation usually is macronodular (3-cm nodules). Primary pigmented nodular adrenocortical disease is a rare cause of ACTH-independent Cushing’s syndrome, which is characterized by the presence of small (<5 mm), black adrenal nodules. Primary pigmented nodular adrenocortical disease may be associated with Carney complex (atrial myxomas, schwannomas, and pigmented nevi) and is thought to be immune related.

**Symptoms and Signs** The classical features of Cushing’s syndrome are listed in Table 38-18. Early diagnosis of this disease requires a thorough knowledge of these manifestations, coupled with a high clinical suspicion. In some patients, symptoms are less pronounced and may be more difficult to recognize, particularly given their diversity and the absence of a single defining symptom or sign. Progressive truncal obesity is the most common symptom, occurring in up to 95% of patients. This pattern results from the lipogenic action of excessive corticosteroids centrally and catabolic effects peripherally, along with peripheral muscle wasting. Fat deposition also occurs in unusual sites, such as the supraclavicular space and posterior neck region, leading to the so-called buffalo hump. Purple striae are often visible on the protuberant abdomen. Rounding of the face leads to moon facies, and thinning of subcutaneous tissues leads to plethora. There is an increase in fine hair growth on the face, upper back, and arms, although true virilization is more commonly seen with adrenocortical cancers. Endocrine abnormalities include glucose intolerance, amenorrhea, and decreased libido or impotence. In children, Cushing’s syndrome is characterized by obesity and stunted growth. Patients with Cushing’s disease also may present with headaches, visual field defects, and panhypopituitarism. Hyperpigmentation of the skin, if present, suggests an ectopic ACTH-producing tumor with high levels of circulating ACTH.

**Diagnostic Tests** The aims of diagnostic tests in the evaluation of patients suspected of having Cushing’s syndrome are twofold: to confirm the presence of Cushing’s syndrome and to determine its etiology (Fig. 38-44).

**Laboratory Studies.** Cushing’s syndrome is characterized by elevated glucocorticoid levels that are not suppressible by exogenous hormone administration and loss of diurnal variation. This phenomenon is used to screen patients using the overnight low-dose dexamethasone suppression test. In this test, 1 mg of a synthetic glucocorticoid (dexamethasone) is given at 11 p.m. and plasma cortisol levels are measured at 8 a.m. the following morning. Physiologically normal adults suppress cortisol levels to <3 μg/dL, whereas most patients with Cushing’s syndrome do not. False-negative results may be obtained in patients with mild disease; therefore, some authors consider the test positive only if cortisol levels are suppressed to <1.8 μg/dL. False-positive results can occur in up to 3% of patients with chronic renal failure, depression, or those taking medications such as phenytoin, which enhance dexamethasone metabolism. In patients with a negative test but a high clinical suspicion, the classic low-dose dexamethasone (0.5 mg every 6 hours for eight doses, or 2 mg over 48 hours) suppression test or urinary cortisol measurement should be performed. Measurement of elevated 24-hour urinary cortisol levels is a very sensitive (95–100%) and specific (98%) modality of diagnosing Cushing’s syndrome and is particularly useful for identifying patients with pseudo-Cushing’s syndrome. A urinary cortisol-free excretion of less than 100 μg/dL (in most laboratories) rules out hypercortisolism. Recently, salivary cortisol measurements using commercially available kits also have demonstrated superior sensitivity in diagnosing Cushing’s syndrome and are being increasingly used. Overall, 24-hour urinary tests for free cortisol and the overnight dexamethasone suppression test at the 5 μg/dL cutoff have the highest specificity for the diagnosis of Cushing’s syndrome. Once a diagnosis of hypercortisolism is established, further testing is aimed at determining whether it is ACTH-dependent or ACTH-independent Cushing’s syndrome. This is best accomplished by measurement of plasma ACTH levels (normal 10–100 pg/mL). Elevated ACTH levels are found in patients with adrenal hyperplasia due to Cushing’s disease (15–500 pg/mL) and those with CRH-secreting tumors, but the highest levels are found in patients with ectopic sources of ACTH (>1000 pg/mL). In contrast, ACTH levels are characteristically suppressed (<5 pg/mL) in patients with primary cortisol-secreting adrenal tumors. The high-dose dexamethasone suppression test is used to distinguish between the causes of ACTH-dependent Cushing’s syndrome (pituitary vs. ectopic). The standard test (2 mg dexamethasone every 6 hours for 2 days) or the overnight test (8 mg) may be used, with 24-hour urine collections for cortisol and 17-hydroxy steroids performed over the second day. Failure to suppress urinary cortisol by 50% confirms the diagnosis of an ectopic ACTH-producing tumor. Patients suspected of having ectopic tumors should also undergo testing for MTC and pheochromocytoma. Bilateral petrosal vein sampling also is helpful for determining whether the patient has Cushing’s disease or ectopic Cushing’s syndrome.

The CRH test also is helpful in determining the etiology of Cushing’s syndrome. Ovine CRH (1 μg/kg) is administered intravenously, followed by serial measurements of ACTH and cortisol at 15-minute intervals for 1 hour. Patients with a primary adrenal hypercortisolism exhibit a blunted response (ACTH peak <10 pg/mL), whereas those with ACTH-dependent Cushing’s syndrome demonstrate a higher elevation of ACTH (>30 pg/mL). CRH stimulation also can enhance the usefulness of petrosal vein sampling. Patients with pituitary tumors also have a higher peak ACTH than those with ectopic ACTH-producing tumors.

**Radiologic Studies.** CT and MRI scans of the abdomen can identify adrenal tumors with 95% sensitivity. They also are helpful in distinguishing adrenal adenomas from carcinomas, as discussed in the subsequent section “Adrenocortical Cancer.” MRI scans have the added advantage of allowing assessment of vascular anatomy. Adrenal adenomas appear darker than the liver on T2-weighted imaging. Radioscintigraphic imaging of the adrenals using NP-59 also can be used to distinguish adenoma from hyperplasia. Reports suggest that “cold” adrenal nodules are more likely to be cancerous, although this distinction is not absolute. NP-59 scanning is most useful in identifying patients with an adrenal source of hypercortisolism and primary pigmented micronodular hyperplasia.

Thin-section head CT scans are 22% sensitive, and contrast-enhanced brain MRI scans are 33% to 67% sensitive at identifying pituitary tumors. Inferior petrosal sinus sampling for ACTH before and after CRH injection has been helpful in this regard and has a sensitivity approaching 100%. In this study, catheters are placed in both internal jugular veins and a peripheral vein. A ratio of petrosal to peripheral vein ACTH level of >2 in the basal state and >3 after CRH stimulation is diagnostic.

---

**Figure 38-44.** Diagnosis of Cushing’s syndrome. ACTH = adrenocorticotropic hormone; CT = computed tomography; DST = dexamethasone suppression test.
of a pituitary tumor. In patients suspected of having ectopic ACTH production, CT or MRI scans of the chest and anterior mediastinum are performed first, followed by imaging of the neck, abdomen, and pelvis if the initial studies are negative.

**Treatment** Laparoscopic adrenalectomy is the treatment of choice for patients with adrenal adenomas. Open adrenalectomy is reserved for large tumors (≥6 cm) or those suspected to be adrenocortical cancers. Bilateral adrenalectomy is curative for primary adrenal hyperplasia.

The treatment of choice in Cushing’s disease is transsphenoidal excision of the pituitary adenoma, which is successful in 80% of patients. Pituitary irradiation has been used for patients with persistent or recurrent disease after surgery. However, it is associated with a high rate of panhypopituitarism, and some patients develop visual deficits. This has led to increased use of stereotactic radiosurgery, which uses CT guidance to deliver high doses of radiotherapy to the tumor (photon or gamma knife) and also bilateral laparoscopic adrenalectomy. Patients who fail to respond to either treatment are candidates for pharmacologic therapy with adrenal inhibitors (medical adrenalectomy) such as ketoconazole, metyrapone, or aminoglutethimide.

Patients with ectopic ACTH production are best managed by treating the primary tumor, including recurrences, if possible. Medical or bilateral laparoscopic adrenalectomy has been used to palliate patients with unresectable disease and those whose ectopic ACTH-secreting tumor cannot be localized.

Patients undergoing surgery for a primary adrenal adenoma secreting glucocorticoids require preoperative and postoperative steroids due to suppression of the contralateral adrenal gland. These patients are also at increased predisposition for infectious and thromboembolic complications, the latter due to a hypercoagulable state resulting from an increase in clotting factors including factor VIII and von Willebrand’s factor complex, and by impaired fibrinolysis. Duration of steroid therapy is determined by the ACTH stimulation test. Exogenous steroids may be needed for up to 2 years but are needed indefinitely in patients who have undergone bilateral adrenalectomy. This latter group of patients also may require mineralocorticoid replacement therapy. Typical replacement doses include hydrocortisone (10–20 mg every morning and 5–10 mg every evening) and fludrocortisone (0.05–0.1 mg/d every morning).

**Adrenocortical Cancer.** Adrenal carcinomas are rare neoplasms with a worldwide incidence of two per 1 million. These tumors have a bimodal age distribution, with an increased incidence in children and adults in the fourth and fifth decades of life. The majority are sporadic, but adrenocortical carcinomas also occur in association with germline mutations of p53 (Li-Fraumeni syndrome) and MEN1 (multiple endocrine neoplasia type 1) genes. Loci on 11p (Beckwith-Wiedemann syndrome), 2p (Carney complex), and 9q also have been implicated. Somatic p53 mutations are present in up to 33% of tumors, and LOH at the p53 locus has been reported in >85% of adrenocortical carcinomas. In addition, insulin-like growth factor II is overexpressed in 90% of tumors, and approximately 30% harbor somatic activating mutations in the β-catenin gene. Recently identified genes mutated in adrenal cancers include ZNRF3 (an E3 ubiquitin ligase) and others involved in chromatin modeling and several microRNAs. Patterns of mutations may also help better define prognosis in adrenocortical cancers.104

**Symptoms and Signs** Approximately 50% of adrenocortical cancers are nonfunctioning. The remaining secrete cortisol (30%), androgens (20%), estrogens (10%), aldosterone (2%), or multiple hormones (35%). Patients with functioning tumors often present with the rapid onset of Cushing’s syndrome accompanied by virilizing features. Nonfunctioning tumors more commonly present with an enlarging abdominal mass and abdominal or back pain. Rarely, weight loss, anorexia, and nausea may be present.

**Diagnostic Tests** Diagnostic evaluation of these patients begins with measurement of serum electrolyte levels to rule out hypokalemia, urinary catecholamines to rule out pheochromocytomas, an overnight 1-mg dexamethasone suppression test, and a 24-hour urine collection for cortisol, and 17-ketosteroids to rule out Cushing’s syndrome.

CT and MRI scans are useful to image these tumors (Fig. 38-45). The size of the adrenal mass on imaging studies is the single most important criterion to help diagnose malignancy. In the series reported by Copeland, 92% of adrenal cancers were >6 cm in diameter.103 The sensitivity, specificity, and likelihood ratio of tumor size in predicting malignancy (based on Surveillance, Epidemiology, and End Results program data) were reported as 96%, 51%, and 2 for tumors ≥4 cm, and 90%, 78%, and 4.1 for tumors ≥6 cm.106 Other CT imaging characteristics suggesting malignancy include tumor heterogeneity, irregular margins, and the presence of hemorrhage and adjacent lymphadenopathy or liver metastases. Moderately bright signal intensity on T2-weighted images (adrenal mass–to–liver ratio 1.2:2.8), significant lesion enhancement, and slow washout after injection of gadolinium contrast also indicate malignancy, as does evidence of local invasion into adjacent structures such as the liver, blood vessels (IVC), and distant metastases. FDG-PET or PET-CT scans may have some utility in distinguishing benign from malignant lesions, as discussed in the section on incidentalomas. Once adrenal cancer is diagnosed, CT scans of the chest and pelvis or FDG-PET or PET-CT scans are performed for staging. The tumor-node-metastasis (TNM) staging system for adrenocortical carcinoma is depicted in Table 38-19. Up to 70% of patients present with stage III or IV disease.

**Pathology** Most adrenocortical cancers are large, weighing between 100 and 1000 g. On gross examination, areas of
hazard and necrosis often are evident. Microscopically, cells are hyperchromatic and typically have large nuclei and prominent nucleoli. It is very difficult to distinguish benign adrenal adenomas from carcinomas by histologic examination alone. Capsular or vascular invasion is the most reliable sign of cancer. Weiss and associates studied a combination of nine criteria for their usefulness in distinguishing malignant from benign adrenal tumors: nuclear grade III or IV; mitotic rate greater than 5 per 50 high-power fields; atypical mitoses; clear cells comprising 25% or less of the tumor; a diffuse architecture; microscopic necrosis; and invasion of venous, sinusoidal, and capsular structure. Tumors with four or more of these criteria were likely to metastasize and/or recur.107 Rarely, the diagnosis of malignancy of a completely resected adrenal tumor is often made in retrospect by the finding of metastatic disease. However, the therapeutic effectiveness is significantly increased recurrence-free survival in the treatment group, even in long-term follow-up.108,109 However, a study of several centers in the United States failed to show similar results.110 The routine use of this medication awaits evaluation in randomized, controlled trials. Determination of blood mitotane levels is helpful to ascertain whether therapeutic and nontoxic levels are present. Adrenocortical tumors commonly metastasize to the liver, lung, and bone.

Surgical debulking is recommended for isolated, recurrent disease and has been demonstrated to prolong survival. Systemic chemotherapeutic agents used in this tumor include etoposide, cisplatin, doxorubicin, and, more recently, paclitaxel, but consistent responses are rare, possibly due to the expression of the multidrug resistance gene (MDR-1) in tumor cells. In vitro data indicate that mitotane may be able to reverse this resistance when combined with various chemotherapeutic agents. Results from the First International Randomized Trial in Advanced or Metastatic Adrenocortical Carcinoma Treatment (FIRM-ACT) showed that patients receiving etoposide, doxorubicin, cisplatin, and mitotane had better response rates and progression-free survival rates than patients receiving streptozotocin and mitotane.111 There has been recent interest in the use of suramin, a growth factor inhibitor, as therapy for adrenocortical carcinoma; however, this requires further study, particularly because this drug may be associated with significant neurotoxicity. Gossypol, a naturally occurring insecticide (from the cotton plant Gossypium species), also appears to inhibit the growth of adrenocortical cancer cell lines and tumors in vivo. However, poor response rates combined with high death rates in limited clinical studies have reduced enthusiasm for this agent. Adrenocortical cancers also are relatively insensitive to conventional external-beam radiation therapy. However, this modality is used in the adjuvant setting in patients with incomplete resections and palliation of bony metastases. Ketoconazole, metyrapone, or aminglutethimide may also be useful in controlling steroid hypersecretion. Targeted molecular therapies such as VEGF/EGF-receptor inhibitors, tyrosine-kinase inhibitors, and IGF-2 inhibitors have had disappointing results in patients with ACC.

**Sex Steroid Excess.** Adrenal adenomas or carcinomas that secrete adrenal androgens lead to virilizing syndromes. Although women with virilizing tumors develop hirsutism, amenorrhea, infertility, and other signs of masculinization, such as increased muscle mass, deepened voice, and temporal balding, men with these tumors are more difficult to diagnose and, hence, usually present with disease in advanced stages. Children with virilizing tumors have accelerated growth, premature development of facial and pubic hair, acne, genital enlargement, and deepening of their voice. Feminizing adrenal tumors are less common and occur in men in the third to fifth decades of life. These tumors lead to gynecomastia, impotence, and testicular atrophy. Women with these tumors develop irregular menses or dysfunctional uterine bleeding. Vaginal bleeding may occur in postmenopausal women. Girls with these tumors experience precocious puberty with breast enlargement and early menarche.

**Diagnostic Tests** Virilizing tumors produce excessive amounts of the androgen precursor, DHEA, which can be measured

in plasma or urine as 17-ketosteroids. Patients with feminizing tumors also have elevated urinary 17-ketosteroids in addition to increased estrogen levels. Androgen-producing tumors often are associated with production of other hormones such as glucocorticoids.

**Treatment** Virilizing and feminizing tumors are treated by adrenalectomy. Malignancy is difficult to diagnose histologically but is suggested by the presence of local invasion, recurrence, or distal metastases. Adrenolytic drugs such as mitotane, aminoglutethimide, and ketoconazole may be useful in controlling symptoms in patients with metastatic disease.

**Congenital Adrenal Hyperplasia.** CAH refers to a group of disorders that result from deficiencies or complete absence of enzymes involved in adrenal steroidogenesis. 21-Hydroxylase (CYP21A2) deficiency is the most common enzymatic defect, accounting for >90% of cases of CAH. This deficiency prevents the production of 11-deoxycortisol and 11-DOC from progesterone precursors. Deficiency of glucocorticoids and aldosterone leads to elevated ACTH levels and overproduction of adrenal androgens and corticosteroid precursors such as 17-hydroxyprogesterone and Δ4-androstenedione. These compounds are converted to testosterone in the peripheral tissues, thereby leading to virilization. Complete deficiency of 21-hydroxylase presents at birth with virilization, diarrhea, hypovolemia, hyponatremia, hyperkalemia, and hyperpigmentation. Partial enzyme deficiency may present at birth or later with virilizing features. These patients are less prone to the salt wasting that characterizes complete enzyme deficiency. 11β-Hydroxylase deficiency is the second most common form of CAH and leads to hypertension (from 11-DOC accumulation), virilization, and hyperpigmentation. Other enzyme deficiencies include 3β-hydroxydehydrogenase and 17-hydroxylase deficiency. Congenital adrenal lipoid hyperplasia is the most severe form of CAH, which is caused by cholesterol desmolase deficiency. It leads to the disruption of all steroid biosynthetic pathways, thus resulting in a fatal salt-wasting syndrome in phenotypic female patients.

**Diagnostic Tests** The particular enzyme deficiency can be diagnosed by karyotype analysis and measurement of plasma and urinary steroids. The most common enzyme deficiency, absence of 21-hydroxylase, leads to increased plasma 17-hydroxyprogesterone and progesterone levels because these compounds cannot be converted to 11-deoxycortisol and 11-DOC, respectively. 11β-Hydroxylase deficiency is the next most common disorder and results in elevated plasma 11-DOC and 11-deoxycortisol. Urinary 17-hydroxyprogesterone, androgens, and 17-ketosteroids also are elevated. The dexamethasone suppression test (2–4 mg divided four times a day for 7 days) can be used to distinguish adrenal hyperplasia from neoplasia. CT, MRI, and iodocholesterol scans generally are used to localize the tumors.

**Treatment** Patients with CAH traditionally have been managed medically, with cortisol and mineralocorticoid replacement to suppress the hypothalamic-pituitary-adrenal axis. However, the doses of steroids required often are supraphysiologic and lead to iatrogenic hypercortisolism. More recently, bilateral laparoscopic adrenalectomy has been proposed as an alternative treatment for this disease and has been successfully performed in a limited number of patients for various forms of CAH.

---

**Disorders of the Adrenal Medulla**

**Pheochromocytomas.** Pheochromocytomas are rare tumors with prevalence rates ranging from 0.3% to 0.95% in autopsy series and approximately 1.9% in series using biochemical screening. They can occur at any age, with a peak incidence in the fourth and fifth decades of life, and have no gender predilection. Extra-adrenal tumors, also called functional paragangliomas, may be found at sites of sympathetic ganglia in the organ of Zuckerkandl, neck, mediastinum, abdomen, and pelvis. Pheochromocytomas often are called the "10 percent tumor" because 10% are bilateral, 10% are malignant, 10% occur in pediatric patients, 10% are extra-adrenal, and 10% are familial.

Pheochromocytomas occur in families with MEN2A and MEN2B in approximately 50% of patients. Both syndromes are inherited in an autosomal dominant fashion and are caused by germline mutations in the RET proto-oncogene. Another syndrome with an increased risk of pheochromocytomas is von Hippel-Lindau (VHL) disease, which also is inherited in an autosomal dominant manner. This syndrome also includes retinal angioma, hemangioblastomas of the central nervous system, renal cysts and carcinomas, pancreatic cysts, and epilidymal cystadenomas. The incidence of pheochromocytomas in the syndrome is approximately 14%. The gene causing VHL has been mapped to chromosome 3p and is a tumor suppressor gene. Pheochromocytomas also are included within the tumor spectrum of neurofibromatosis type 1 (NF1 gene) and other neuroectodermal disorders (Sturge-Weber syndrome and tuberous sclerosis), Carney’s syndrome (gastric epithelioid leiomyosarcoma, pulmonary chondroma, and extra-adrenal paraganglioma), MEN1 syndrome, and the familial paraganglioma and pheochromocytoma syndrome are caused by mutations in the succinyl dehydrogenase family of genes (SDHB, SDHC, and SDHD), which comprise portions of the mitochondrial complex II. More recently, mutations in SDHA and SDHB have also been identified. Additional susceptibility loci include TMEM127 (involved in the mTORC1-signaling pathway) and MAX (myc-associated factor X).

**Symptoms and Signs** Headache, palpitations, and diaphoresis constitute the “classic triad” of pheochromocytomas. Symptoms such as anxiety, tremulousness, paresthesias, flushing, chest pain, shortness of breath, abdominal pain, nausea, vomiting, and others are nonspecific and may be episodic in nature. Cardiovascular complications such as myocardial infarction and cerebrovascular accidents may ensue. These symptoms can be incited by a range of stimuli including exercise, micturition, and defecation. The most common clinical sign is hypertension. Pheochromocytomas are one of the few curable causes of hypertension and are found in 0.1% to 0.2% of hypertensive patients. Hypertension related to this tumor may be paroxysmal with intervening normotension, sustained with paroxysms or sustained hypertension alone. Sudden death may occur in patients with undiagnosed tumors who undergo other surgeries or biopsy.

**Diagnostic Tests**

**Biochemical Studies.** Pheochromocytomas are diagnosed by testing 24-hour urine samples for catecholamines and their metabolites as well as by determining plasma metanephrine levels. Urinary metanephrines are 98% sensitive and also about 98% specific for pheochromocytomas, whereas VMA measurements are slightly less sensitive and specific. False-positive VMA tests may result from ingestion of caffeine, raw fruits,
or medications (α-methyldopa). Fractionated urinary catecholamines (norepinephrine, epinephrine, and dopamine) also are very sensitive but less specific for pheochromocytomas. Because extra-adrenal sites lack phenylethanolamine N-methyltransferase, these tumors secrete norepinephrine, whereas epinephrine is the main hormone secreted from adrenal pheochromocytomas. Many physiologic and pathologic states can alter the levels of plasma catecholamines. Hence, they often are thought to be less accurate than urinary tests. Both epinephrine and norepinephrine should be measured, as tumors often secrete one or the other hormone. Sensitivities of 85% and specificities of 95% have been reported using cutoff values of 2000 pg/mL for norepinephrine and 200 pg/mL for epinephrine. Clonidine is an agent that suppresses neurogenically mediated catecholamine excess but not secretion from pheochromocytomas. A normal clonidine suppression test is defined by a decrease of basal catecholamine levels to <500 pg/mL within 2 to 3 hours after an oral dose of 0.3 mg of clonidine. Chromogranin A is a monomeric, acidic protein, which is stored in the adrenal medulla and other neuroendocrine tumors and released along with catecholamine hormones. It has been reported to have a sensitivity of 83% and a specificity of 96% and is useful in conjunction with catecholamine measurement for diagnosing pheochromocytomas. Some studies have shown that plasma metanephrines should be the first-line test to identify pheochromocytomas, as the predictive value of a negative test is very high and normal levels exclude pheochromocytoma in patients with preclinical disease or dopamine secreting tumors. Although sensitivities of 96% to 100% have been reported, specificity is lower at 85% to 89% and may be much lower at 77% in elderly patients. Although attractive because of the simplicity of a blood test, measurement of plasma metanephrines is generally reserved for cases for which there is a high index of suspicion. 

Radiologic Studies. Radiologic studies are useful to localize tumors and to assess the extent of spread once the diagnosis has been made with biochemical tests. CT scans are 85% to 95% sensitive and 70% to 100% specific for pheochromocytomas (Fig. 38-46A). The scans should be performed without contrast to minimize the risk of precipitating a hypertensive crisis, although some recent studies suggest that intravenous contrast may be used. Images should include the region from the diaphragm to the aortic bifurcation so as to include the organ of Zuckerkandl. CT scans do not provide functional information and cannot definitively diagnose pheochromocytomas. MRI scans are 95% sensitive and almost 100% specific for pheochromocytomas because these tumors have a characteristic appearance on T2-weighted images or after gadolinium. MRI is also the study of choice in pregnant women as there is no risk of radiation exposure. Metaiodobenzylguanidine (MIBG) is taken up and concentrated by vesicles in the adrenal medullary cells because its structure is similar to norepinephrine. Normal adrenal medullary tissue does not take up appreciable MIBG. 131I-radiolabeled MIBG is, therefore, useful for localizing pheochromocytomas (Fig. 38-46B), especially those in ectopic positions. This test has a reported sensitivity of 77% to 89% and a specificity ranging from 88% to 100%.

Treatment. The medical management of pheochromocytomas is aimed chiefly at blood pressure control and volume repletion. Irreversible, long-acting α-blockers such as phenoxycyzbenzamine are started 1 to 3 weeks before surgery at doses of 10 mg twice daily, which may be increased to 300 to 400 mg/d with rehydration. Patients should be warned about orthostatic hypotension. β-Blockers such as propranolol at doses of 10 to 40 mg every 6 to 8 hours often need to be added preoperatively in patients who have persistent tachycardia and arrhythmias. β-Blockers should only be instituted after adequate α-blockade and hydration to avoid the effects of unopposed α-stimulation (i.e., hypertensive crisis and congestive heart failure) and are typically initiated 3 to 4 days preoperatively. Patients also should be volume repleted preoperatively to avoid postoperative hypotension, which ensues with the loss of vasoconstriction after tumor removal. Other α-blockers such as prazosin, terazosin, and doxazosin, which are selective α1-adrenergic blockers, have a better side effect profile and are preferable to phenoxybenzamine when long-term

**Figure 38-46.** A left-sided pheochromocytoma (arrows) imaged by a computed tomography scan of the abdomen (A) and a metaiodobenzylguanidine scan viewed posteriorly (B).
pharmacologic therapy is needed, as in patients with metastatic pheochromocytoma. Nicardipine is the most commonly used calcium channel blocker and inhibits norepinephrine-mediated calcium transport into vascular smooth muscle. When used as the primary mode of treatment, it appears to be just as effective as α- and β-blockade preoperatively and for intraoperative hemodynamics.[113] In some patients, catecholamine-synthesis inhibitors such as α-methyl-p-l-tyrosine (methyrosine) may need to be added if standard α- and β-blockade is poorly tolerated or is ineffective in reaching target blood pressure and when moderate intraoperative tumor manipulation is anticipated.

Adrenalectomy is the treatment of choice for patients with pheochromocytoma. The chief goal of surgery is to resect the tumor completely with minimal tumor manipulation or rupture of the tumor capsule. Surgery should be performed with both noninvasive and invasive monitors, including an arterial line and central venous lines. In patients with congestive heart failure or underlying coronary artery disease, Swan-Ganz catheters may be necessary. Stress must be avoided during anesthesia induction, and use of inhaled agents like isoflurane and enflurane are preferred because they have minimal cardiac depressant effects. Fentanyl, ketamine, and morphine should be avoided as they can potentially stimulate catecholamine release from the tumor. The common medications used for intraoperative blood pressure control include nitroprusside, nitroglycerin, phentolamine, and nicardipine. Intraoperative arrhythmias are best managed by short-acting β-blockers such as esmolol. Adrenalectomy usually was performed via an open anterior approach to facilitate detection of bilateral tumors, extra-adrenal lesions, or metastatic lesions. However, most pheochromocytomas <5 cm in diameter can be safely resected laparoscopically. Postoperatively, these patients are prone to hypotension due to loss of adrenergic stimulation and consequent vasodilatation and therefore need large volume resuscitation.

Hereditary Pheochromocytomas. Inherited pheochromocytomas tend to be multiple and bilateral. Generally, unilateral adrenalectomy is recommended in the absence of obvious lesions in the contralateral adrenal gland because of Addison’s disease, requiring lifelong steroid replacement in patients undergoing bilateral adrenalectomy. For patients with tumors in both adrenal glands, cortical-sparing subtotal adrenalectomy may preserve adrenocortical function and avoid the morbidity of bilateral total adrenalectomy. Laparoscopic subtotal adrenalectomy has been shown to provide short-term clinical results comparable to total adrenalectomy, with reduced surgical morbidity and may be done as a unilateral or bilateral subtotal procedure.[114] However, these patients remain at risk for recurrent pheochromocytoma, which has been reported in 20% of patients with VHL disease a median of 40 months after partial adrenalectomy, and in 33% of MEN2 patients followed for 54 to 88 months after surgery. Autotransplantation of adrenocortical tissue after total adrenalectomy may be another option for these patients. However, the transplanted cortical tissue rarely provides full function, and steroid replacement usually is required.

Malignant Pheochromocytomas. Approximately 12% to 29% of pheochromocytomas are malignant, and these tumors are associated with decreased survival. There are no definitive histologic criteria defining malignant pheochromocytomas. In fact, pleomorphism, nuclear atypia, and abundant mitotic figures are seen in benign tumors. Capsular and vascular invasion may be seen in benign lesions as well. Malignancy usually is diagnosed when there is evidence of invasion into surrounding structures or distant metastases. The most common sites for metastatic disease are bone, liver, regional lymph nodes, lung, and peritoneum, although the brain, pleura, skin, and muscles may also occasionally be involved. Some studies also suggest that older patient age and larger tumors are associated with a higher risk of malignancy. Although risk of malignancy increases with size for all pheochromocytomas, size does not seem to reliably predict malignancy in pheochromocytomas with local disease only.[115] Given this difficulty of defining malignancy clinically (in the absence of metastatic disease), a number of other features such as DNA ploidy, tumor size, and necrosis, neuropeptide Y mRNA expression, and serum neuron-specific enolase expression have been studied. Malignant pheochromocytomas are more likely to express p53 and bcl-2 and have activated telomerase. Recent data suggest that flow cytometry and molecular markers such as expression of Ki-67, tissue inhibitor of metalloproteinase, and COX-2 also have shown some use in determining malignancy. When pheochromocytomas develop in the MEN syndromes, they rarely are malignant. In contrast, patients with germline SDHB mutations appear to have a higher propensity for extra-adrenal and malignant tumors. In general, soft tissue lesions are treated with resection if feasible. External-beam radiation can be used for unresectable lesions or symptomatic skeletal metastases. Therapeutic 131I-MIBG irradiation may be useful in patients with diffuse disease showing 123I-MIBG uptake on a diagnostic scan. Chemotherapy regimens typically use cyclophosphamide, vincristine, and dacarbazine with variable response rates. However, molecular targeted therapies such as sunitinib have shown some promising results.

The Adrenal Incidentaloma
Adrenal lesions discovered during imaging performed for unrelated reasons are referred to as incidentalomas. This definition excludes tumors discovered on imaging studies performed for evaluating symptoms of hormone hypersecretion or staging patients with known cancer. The incidence of these lesions identified by CT scans ranges from 0.4% to 4.4%.

Differential Diagnosis. The differential diagnosis of adrenal incidentalomas is shown in Table 38-20. Nonfunctional cortical adenomas account for the majority (36–94%) of adrenal incidentalomas in patients without a history of cancer. In a series of patients from the Mayo Clinic, no nonfunctional

lesion progressed to cause clinical or biochemical abnormalities. However, other studies indicate that 5% to 20% of patients with apparently nonfunctioning cortical adenomas have underlying, subtle abnormalities of glucocorticoid secretion, and a rare benign-appearing incidentaloma is a cancer.

By definition, patients with incidentalomas do not have clinically overt Cushing’s syndrome, but subclinical Cushing’s syndrome is estimated to occur in approximately 8% of patients. This disorder is characterized by subtle features of cortisol excess, such as weight gain, skin atrophy, facial fullness, diabetes, and hypertension, accompanied by loss of normal diurnal variation in cortisol secretion, autonomous cortisol secretion, and resistance to suppression by dexamethasone. Total cortisol produced and 24-hour urinary cortisol levels may be normal. Examination of the natural history of subclinical Cushing’s syndrome indicates that, although most patients remain asymptomatic, some do progress to clinically evident Cushing’s syndrome. Furthermore, cases of postoperative adrenal crisis from unrecognized suppression of the contralateral adrenal have been reported, making preoperative identification of this condition imperative, particularly in the era of early discharge following laparoscopic adrenalectomy.

The adrenal is a common site of metastases of lung and breast tumors, melanoma, renal cell cancer, and lymphoma. In patients with a history of nonadrenal cancer and a unilateral adrenal mass, the incidence of metastatic disease has been reported to range from 32% to 73%. Myelolipomas are benign, biochemically nonfunctioning lesions composed of elements of hematopoietic and mature adipose tissue, which are rare causes of adrenal incidentaloma. Other less commonly encountered lesions include adrenal cysts, ganglioneuromas, and hemorrhage.

**Diagnostic Investigations.** The diagnostic workup of an adrenal incidentaloma is aimed at identifying patients who would benefit from adrenalectomy (i.e., patients with functioning tumors and tumors at increased risk of being malignant). It is not necessary for asymptomatic patients whose imaging studies are consistent with obvious cysts, hemorrhage, myelolipomas, or diffuse metastatic disease to undergo additional investigations. All other patients should be tested for underlying hormonally active tumors using (a) a low-dose (1 mg) overnight dexamethasone suppression test to rule out subclinical Cushing’s syndrome and 17-ketosteroids (if sex steroid excess is suspected); (b) a 24-hour urine collection for catecholamines, metanephrines, VMA, or plasma metanephrine to rule out pheochromocytoma; and (c) in hypertensive patients, serum electrolytes, plasma aldosterone, and plasma renin to rule out an aldosteronoma. In patients with a high index of suspicion for subclinical Cushing’s (those with hypertension, obesity, or diabetes), three tests (i.e., dexamethasone suppression test, salivary cortisol, and 24-hour urine free cortisol) may be used. Confirmatory tests can be performed based on the results of the initial screening studies.

Determination of the malignant potential of an incidentaloma is more difficult. The risk of malignancy in an adrenal lesion is related to its size. Lesions >6 cm in diameter have an approximate risk of malignancy of about 25%. However, this size cutoff is not absolute because adrenal carcinomas also have been reported in lesions <6 cm. Carcinomas account for 2% of lesions <4 cm and 6% of lesions 4.1 to 6 cm in size. This has led to increased use of the imaging characteristics of incidentalomas to predict malignancy. Benign adrenal adenomas tend to be homogeneous, well encapsulated, and have smooth and regular margins. They also tend to be hypoattenuating lesions (<10 Hounsfield units) on CT scanning. In contrast, adrenal cancers tend to be hyperattenuating (>18 Hounsfield units) and inhomogeneous, have irregular borders, and may show evidence of local invasion or adjacent lymphadenopathy. On MRI T2-weighted imaging, adenomas demonstrate low signal intensity when compared to the liver (adrenal mass-to-liver ratio <1.4), whereas carcinomas and metastases have moderate intensity (mass-to-liver ratio 1.2:2.8). Pheochromocytomas are extremely bright, with mass-to-liver ratios >3. Unfortunately, the ranges overlap, and signal intensity is not 100% reliable for determining the nature of the lesion. Radionuclide imaging with NP-59 also has been used to distinguish between various adrenal lesions, with some investigators suggesting that uptake of NP-59 was 100% predictive of a benign lesion (adenoma), whereas absence of imaging was 100% predictive of a nonadenomatous lesion. However, the technique has not gained widespread acceptance because patients need to be given cold iodine 1 week before the study to prevent thyroid uptake, imaging needs to be delayed by 5 to 7 days after administration of the contrast, and false-positive and false-negative results occur. FDG-PET or PET-CT scans may have some utility in distinguishing potentially malignant from benign lesions in cases of inconclusive CT densitometry. However, caution must be exercised for false-positive (some adenomas and pheochromocytomas) and false-negative results (small lesions or those with hemorrhage or necrosis). FNAB cannot be used to distinguish adrenal adenomas from carcinomas. This being said, FNAB is useful in the setting of a patient with a history of cancer and a solitary adrenal mass. The positive predictive value of FNAB in this situation has been shown to be almost 100%, although false-negative rates of up to 33% have been reported. Biopsies usually are performed under CT guidance, and appropriate testing to rule out pheochromocytomas should be undertaken before the procedure to avoid precipitating a hypertensive crisis.

**Management.** An algorithm for the management of patients with incidentalomas is shown in Fig. 38-47. The AACE and American Association of Endocrine Surgeons (AAES) have published management guidelines for patients with adrenal incidentalomas. Patients with functional tumors or obviously malignant lesions should undergo adrenalectomy. The optimal management of patients with subclinical Cushing’s syndrome is controversial, especially due to the paucity of data from high-quality prospective trials. In general, operative intervention is advised in patients with subclinical Cushing’s syndrome with suppressed plasma ACTH levels and elevated urinary cortisol levels because these patients are at high risk for progression to overt Cushing’s syndrome. The adrenal incidentaloma guidelines also recommend adrenalectomy in patients with worsening hypertension, abnormal glucose tolerance, or osteoporosis.

For nonfunctional lesions, the risk of malignancy needs to be balanced with operative morbidity and mortality. The AACE/AAES guidelines recommend that lesions with suspicious features on imaging studies such as heterogeneity, irregular capsule, or adjacent nodes should be treated by adrenalectomy. Nonoperative therapy, with close periodic follow-up, is advised for lesions <4 cm in diameter with benign imaging characteristics, whereas adrenalectomy is recommended for lesions ≥4 cm in size due to the increased risk of cancer.
Questions
1) Low dose DST
2) Plasma metanephrines or 24 h urine catecholamines, VMA, metanephrines
3) Plasma aldosterone, renin activity, electrolytes

Adrenalectomy
Yes
No
Past history of cancer?
Yes
Solitary metastasis
Consider adrenalectomy

However, several important points must be considered in the management of these patients. First, size criteria for malignancy are not definitive and are derived from a selected series of patients. Second, the actual size of adrenal tumors can be underestimated by at least 1 cm by modalities such as CT and MRI scans because tumors are larger in a cephalocaudal axis. Third, the natural history of incidentalomas is variable and depends on the underlying diagnosis, age of the study population, and the size of the mass. Older patients are more likely to have nonfunctioning adenomas. Existing data in terms of the long-term behavior of these nonfunctional lesions, although limited, indicate that malignant transformation is uncommon. Furthermore, tumors that increase in size by at least 1 cm over a 2-year follow-up period and those with subtle hormonal abnormalities appear to be more likely to enlarge. Overt hormone overproduction is more likely in tumors >3 cm and those with increased NP-59 uptake. Surgeons are more likely to operate on a 40-year-old patient with a 4-cm lesion, while electing to follow an 80-year-old patient with a similar lesion but multiple concurrent comorbidities. Based on the above considerations, some surgeons use a size threshold for adrenalectomy with a nonfunctioning homogeneous tumor of 3 to 4 cm in young patients with no comorbidities and 5 cm in older patients with significant comorbidity.

Lesions that grow during follow-up also are treated by adrenalectomy. Myelolipomas generally do not warrant adrenalectomy unless there is concern regarding malignancy, which is rare, or bleeding into the lesion, which is more likely in myelolipomas >4 cm in size. These tumors, even when large, can be removed laparoscopically. Resection of solitary adrenal metastases in patients with a history of nonadrenal cancer has been demonstrated to lead to prolonged patient survival. Suspected adrenal metastases also may be resected for diagnosis.

There is no consensus regarding the follow-up of patients with adrenal incidentaloma. The AACE/AAES guidelines recommend repeating hormonal screening with a 1-mg dexamethasone suppression test and urinary catecholamines and metabolites yearly for 5 years as the risk of hypersecretion appears to plateau after this time period. It also recommends repeat imaging at 3 to 6 months and then annually for 1 to 2 years. Less frequent imaging is reasonable or small (<2 cm), uniform, hypodense cortical nodules in patients without a history of malignant disease. Adrenalectomy is recommended for lesions that grow ≥1 cm or if autonomous hormone secretion develops during follow-up.

Adrenal Insufficiency
Adrenal insufficiency may be primary, resulting from adrenal disease, or secondary, due to a deficiency of ACTH (Table 38-21). The most commonly encountered causes of primary adrenal insufficiency are autoimmune disease, infections, and metastatic deposits. Spontaneous adrenal hemorrhage can occur in patients with fulminant meningococcal septicemia (Waterhouse-Friderichsen syndrome). Bilateral adrenal hemorrhage also can occur secondary to trauma, severe stress, infection, and coagulopathies and, if unrecognized, is lethal. Exogenous glucocorticoid therapy with suppression of the adrenal glands is the most common cause of secondary adrenal insufficiency.

Symptoms and Signs. Acute adrenal insufficiency should be suspected in stressed patients with any of the relevant risk factors. It may mimic sepsis, myocardial infarction, or pulmonary embolus and presents with fever, weakness, confusion, nausea, vomiting, lethargy, abdominal pain, or severe hypotension. Chronic adrenal insufficiency, such as that occurring in patients with metastatic tumors, may be more subtle. Symptoms include fatigue, salt craving, weight loss, nausea, vomiting, and
abdominal pain. These patients may appear hyperpigmented from increased secretion of CRH and ACTH, with increased α-melanocyte-stimulating hormone side-products.

**Diagnostic Studies.** Characteristic laboratory findings include hyponatremia, hyperkalemia, eosinophilia, mild azotemia, and fasting or reactive hypoglycemia. The peripheral blood smear may demonstrate eosinophilia in approximately 20% of patients. Adrenal insufficiency is diagnosed by the ACTH stimulation test. ACTH (250 μg) is infused intravenously, and cortisol levels are measured at 0, 30, and 60 minutes. Peak cortisol levels <20 μg/dL suggest adrenal insufficiency. ACTH levels also allow primary insufficiency to be distinguished from secondary causes. High ACTH levels with low plasma cortisol levels are diagnostic of primary adrenal insufficiency.

**Treatment.** Treatment must be initiated based on clinical suspicion alone, even before test results are obtained, or the patient is unlikely to survive. Management includes volume resuscitation with at least 2 to 3 L of a 0.9% saline solution or 5% dextrose in saline solution. Blood should be obtained for electrolyte (decreased Na+ and increased K+), glucose (low), and cortisol (low) levels; ACTH (increased in primary and decreased in secondary); and quantitative eosinophilic count. Dexamethasone (4 mg) should be administered intravenously. Hydrocortisone (100 mg intravenously every 8 hours) also may be used, but it interferes with testing of cortisol levels. Once the patient has been stabilized, underlying conditions such as infection should be sought, identified, and treated. The ACTH stimulation test should be performed to confirm the diagnosis. Glucocorticoids can then be tapered to maintenance doses (oral hydrocortisone 15–20 mg in the morning and 10 mg in the evening). Mineralocorticoids (fludrocortisone 0.05–0.1 mg daily) may be required once the saline infusions are discontinued.

**Adrenal Surgery**

**Choice of Procedure.** Adrenalectomy may be performed via a laparoscopic or open approach. In either approach, the gland may be approached anteriorly, laterally, or posteriorly via the retroperitoneum. The choice of approach depends on the size and nature of the lesion and expertise of the surgeon. Laparoscopic adrenalectomy has rapidly become the standard procedure of choice for the excision of most benign-appearing adrenal lesions <6 cm in diameter. The role of laparoscopic adrenalectomy in the management of adrenocortical cancers is controversial. The data with respect to local tumor recurrence and intra-abdominal carcinomatosis from laparoscopic adrenalectomy for malignant adrenal tumors that were not appreciated as such, preoperatively or intraoperatively, are conflicting. Although laparoscopic adrenalectomy appears to be feasible and safe for solitary adrenal metastasis116 (provided there is no local invasion and the tumor can be resected intact), open adrenalectomy or laparoscopic-assisted open adrenalectomy is the safest option for suspected or known adrenocortical cancers and malignant pheochromocytomas. Technical considerations and surgeon experience, rather than absolute tumor size, usually determine the size threshold for laparoscopic resection. Hand-assisted laparoscopic adrenalectomy may provide a bridge between laparoscopic adrenalectomy and conversion to an open procedure. There have been no randomized trials directly comparing open vs. laparoscopic adrenalectomy. However, studies have shown that laparoscopic adrenalectomy is associated with decreased blood loss, postoperative pain, and narcotic use; reduced length of hospital stay; and faster return to work.

**Laparoscopic Adrenalectomy.** The procedure is performed under general anesthesia. Arterial lines are used routinely, and central lines are necessary for patients in whom massive fluid shifts are anticipated (e.g., those with large, active pheochromocytomas). A nasogastric tube and Foley catheter are recommended. Routine preoperative antibiotics are not needed, except in patients with Cushing’s syndrome. The adrenals can be removed laparoscopically via a transabdominal (anterior or lateral) or retroperitoneal (lateral or posterior) approach. The lateral approach is preferred by most laparoscopic surgeons and uses gravity to aid retraction of surrounding organs. Patients, however, need to be repositioned for a bilateral procedure. The anterior transabdominal approach offers the advantage of a conventional view of the abdominal cavity and allows a bilateral adrenalectomy to be performed without the necessity of repositioning the patient. The posterior retroperitoneal approach has also been gaining popularity in recent years, particularly in patients with previous anterior abdominal surgery and peritoneal adhesions. In addition, several centers have successfully utilized robotic approaches for both lateral transabdominal and retroperitoneal laparoscopic adrenal surgery. Single incision laparoscopic adrenalectomy is another option. While these latter approaches are feasible,119 their widespread use awaits analysis of long-term outcomes data and cost analyses. The lateral transabdominal approach is widely used and described in detail in the following section.
Lateral Transabdominal Approach  The patient is placed in the lateral decubitus position, and the operating table is flexed at the waist to open the space between the lower rib cage and the iliac crest (Fig. 38-48). The surgeon and assistant both stand on the same side, facing the front of the patient. Pneumoperitoneum is created using a Veress needle or insufflation via a Hasson port. In general, four 10-mm trocars are placed between the midclavicular line medially and anterior axillary line laterally, one to two fingerbreadths below the costal margin (see Fig. 38-48), although additional ports may be placed, if needed. A 30° laparoscope is inserted through the second or midclavicular port. Most of the dissection is carried out via the two most lateral ports. However, the instruments and ports may be changed to provide optimum exposure, as needed.

For a right adrenalectomy, a fan retractor is inserted through the most medial port to retract the liver. An atraumatic grasper and an L-hook cautery are inserted via the two lateral ports for the dissection. The right triangular ligament is divided, and the liver is rotated medially (Fig. 38-49A). Rarely, the hepatic flexure of the colon may need mobilization during a right adrenalectomy. The right kidney is identified visually and by palpation with an atraumatic grasper. The adrenal gland is identified on the superomedial aspect of the kidney. Gerota’s fascia is incised with the hook cautery. Dissection of the adrenal is started superomedially and then proceeds inferiorly, dissecting around the adrenal in a clockwise manner. The periadrenal tissues are grasped or moved with a blunt grasper to facilitate circumferential dissection. The right adrenal vein is identified at its junction with the IVC, ligated with clips, and divided using endoscopic scissors. Alternatively, a vascular stapler may be used to divide the vein endoscopically. There may be a second adrenal vein on the right. Generally, two clips are left on the vena cava side. Although early identification of the adrenal vein is helpful to facilitate mobilization and prevent injury, it can be dissected whenever it is safe to do so. Early ligation of the adrenal vein makes it easier to mobilize the gland but may make subsequent dissection more difficult due to venous congestion. The arterial branches to the adrenal gland can be electrocoagulated if small or clipped and divided.

For a left adrenalectomy, the fan retractor is used to retract the spleen. The splenic flexure is mobilized early, and the lateral attachments to the spleen and the tail of the pancreas are divided using the electrocautery (Fig. 38-49B). Gravity allows the spleen and the pancreatic tail to fall medially. The remainder of the dissection proceeds similarly to that described for the right adrenal. In addition to the adrenal vein, the inferior phrenic vein, which joins the left adrenal vein medially, also needs to be
dissected, doubly clipped, and divided. As with the right adrenal vein, the left-sided veins also can be divided with a vascular stapler. Once the dissection is complete, the area of the adrenal bed can be irrigated and suctioned. A drain is rarely necessary. The gland is placed in a nylon specimen bag, which is brought out via one of the ports after morcellation, if necessary.

**Posterior Retroperitoneal Approach** The retroperitoneal approach provides a more direct access to the adrenal gland and avoids abdominal adhesions in patients who have had previous abdominal surgery. Furthermore, bilateral adrenalectomy can be performed without repositioning the patient. Intraoperative ultrasound is helpful for identifying the adrenal, but the dissection and exposure are more difficult because the working space is limited. This makes vascular control difficult and also renders it unsuitable for large (>5 cm) lesions. This technique is being increasingly used for small adenomas causing hyperaldosteronism.

The patient is placed in the prone-jackknife position, and the operating table is flexed at the waist to open the space between the posterior costal margin and the pelvis. Palpation is used to identify the position of the twelfth rib. Percutaneous ultrasound is performed to determine the outline of the underlying kidney and adrenal. When done laparoscopically, the surgeon stands on the side of the adrenal to be removed, and the assistant stands on the opposite side. A 1.5-cm incision is placed 2 cm inferior and parallel to the twelfth rib, laterally at the level of the inferior pole of the kidney. Gerota’s space is entered under direct vision using a 12-mm direct viewing trocar with a 0° laparoscope through the muscle layers of the posterior abdominal wall. Alternatively, blunt dissection with the surgeon’s finger also can identify the space behind Gerota’s fascia. The trocar is then replaced by a dissecting balloon, which is manually inflated using a hand pump under direct vision through the laparoscope. A 12-mm trocar is then reinserted into this space, and CO₂ is insufflated to 12 to 15 mmHg pressure. The 0° laparoscope is replaced by a 45° laparoscope. Two additional 5- or 10-mm trocars are placed, one each on either side of the first port. Laparoscopic ultrasound then is used to help locate the adrenal gland and vessels. The adrenal dissection is begun at the superior pole and then proceeds to the lateral and inferior aspect. The medial dissection usually is performed last, and the vessels are identified and divided as described in the earlier “Lateral Transabdominal Approach” section.

**Open Adrenalectomy.** Open adrenalectomy may be performed via four approaches, each with specific advantages and disadvantages. The anterior approach allows examination of the abdominal cavity and resection of bilateral tumors via a single incision. The posterior approach avoids the morbidity of a laparotomy incision, especially in patients with cardiopulmonary disease and those prone to wound complications (Cushing’s syndrome) and avoids abdominal adhesions in patients who have undergone previous abdominal surgery. Recovery time is also quicker and hospitalization shorter. However, the retroperitoneal exposure is difficult, particularly in obese patients, and the small working space makes it unsuitable for tumors >6 cm in diameter. The lateral approach is best for obese patients and for large tumors because it provides a bigger working space. The thoracoabdominal approach is most useful for en bloc resection of large (>10 cm), malignant lesions. However, it is associated with significant morbidity and should be used selectively.

**Anterior Approach** The adrenals may be removed via a midline incision or bilateral subcostal incision (Fig. 38-50). The former allows adequate infraumbilical exposure for examination of extra-adrenal tumors, whereas the latter provides better superior and lateral exposure. For the right side, the hepatic flexure of the colon is mobilized inferiorly, and the triangular ligament is incised to retract the liver medially and superiorly. A generous Kocher maneuver is used to mobilize the duodenum anteriorly and expose the retroperitoneal fat and the IVC (Fig. 38-51A). Gerota’s fascia is incised, and the gland is freed of surrounding fibro-fatty tissue and the kidney inferiorly. The lateral and superior surfaces usually are mobilized first. Then, the short, right adrenal vein is dissected, ligated, and divided, taking care not to injure the hepatic veins and IVC. On the left side, the adrenal is located cephalad to the pancreatic tail and just lateral to the aorta. For large tumors, the adrenal is best approached by medial visceral rotation to mobilize the spleen, colon, and pancreas toward the midline (Fig. 38-51B). An alternative approach is to enter the lesser sac by division of the gastrocolic ligament. The pancreas is mobilized superiority by incision of its inferior
peritoneal attachments, thus exposing the left kidney and adrenal. The gland is then mobilized as on the right side.

**Posterior Approach** The patient is placed prone on the operating table, similar to the laparoscopic approach. A hockey stick or curvilinear incision may be used, and extended through the latissimus dorsi and sacrospinalis fascia. The twelfth rib generally is excised at its base, and the eleventh rib is retracted superiorly to reveal the pleura and the lateral arcuate ligament of the liver on the right side. The pleura also is mobilized cephalad, and the adrenal and kidney are identified. The superior aspect of the gland is dissected first, and the superior vessels are identified and ligated. This prevents superior retraction of the adrenal gland. The remainder of the gland is then dissected and the adrenal gland and tumor removed. The resulting space generally is filled with perinephric fat and closed in layers. A chest X-ray is obtained postoperatively to rule out a pneumothorax.

**Lateral Approach** The patient is placed in a lateral position with the table flexed, and an incision is made between the eleventh and twelfth ribs or subcostally. The dissection then is performed as indicated previously in “Anterior Approach.”

**Complications of Adrenal Surgery.** Patients with Cushing’s syndrome are more prone to infectious (incisional and intra-abdominal abscess) and thrombotic complications. Creation of pneumoperitoneum may result in injury to various organs from Veress needle and trocar insertion, subcutaneous emphysema, pneumothorax, and hemodynamic compromise. Excessive retraction and dissection may lead to bleeding from injury to the IVC and renal vessels, or from injury to surrounding organs such as the liver, pancreas, spleen, and stomach. Postoperative hemodynamic instability may be evident in patients with pheochromocytomas, and patients are at risk of adrenal insufficiency after bilateral adrenalectomy and sometimes after unilateral adrenalectomy (unrecognized Cushing’s syndrome or, very rarely, Conn’s syndrome). Long-term morbidity results mainly from injury to nerve roots during trocar insertion, which can lead to chronic pain syndromes or muscle weakness, although this is more of an issue in case of open procedures.

Approximately 30% of patients who undergo bilateral adrenalectomy for Cushing’s disease are at risk of developing Nelson’s syndrome from progressive growth of the preexisting pituitary tumor. This leads to increased ACTH levels, hyperpigmentation, visual field defects, headaches, and extraocular muscle palsies. Transsphenoidal pituitary resection is the initial mode of therapy, and external-beam radiotherapy is used in patients with residual tumor or extrasellar invasion.

INTRODUCTION

In his 1953 classic textbook entitled The Surgery of Infancy and Childhood, Dr. Robert E. Gross summarized the essential challenge of pediatric surgery: “Those who daily operate upon adults, even with the greatest of skill, are sometimes appalled—or certainly are not at their best—when called upon to operate upon and care for a tiny patient. Something more than diminutive instruments or scaled-down operative manipulations are necessary to do the job in a suitable manner.” To this day, surgical residents and other trainees often approach the pediatric surgical patient with the same mix of fear, trepidation, and anxiety. These same trainees often complete their pediatric surgical rotations with a profound respect for the resilience of young children to undergo complex operations and an appreciation for the precision required from their caregivers, both in the operating room and during the perioperative period. Over the decades, the specialty of pediatric surgery has evolved considerably in its care for the smallest of surgical patients, such that in utero surgery is now an option in an increasing number of circumstances. Similarly, our understanding of the pathophysiology of the diseases that pediatric surgeons face has increased to the point that some pediatric surgical diseases are now understood at the level of molecular or cellular signaling pathways. Pediatric surgery provides the opportunity to intervene in a wide array of diseases and to exert a long-lasting impact on the lives of children and their grateful parents. The scope of diseases encountered in the standard practice of pediatric surgery is immense, with patients...
Key Points

1. In infants with Bochdalek-type congenital diaphragmatic hernia, the severity of pulmonary hypoplasia and the resultant pulmonary hypertension are key determinants of survival. Barotrauma and hypoxia should be avoided.

2. During initial management of an infant with esophageal atresia and distal tracheoesophageal fistula, every effort should be made to avoid distending the gastrointestinal tract, especially when using mechanical ventilation. The patient should be evaluated for components of the VACTERL (vertebral, anorectal, cardiac, tracheoesophageal, renal, radial limb) anomalies. Timing and extent of surgery are dictated by the stability of the patient.

3. Although malrotation with midgut volvulus occurs most commonly within the first few weeks of life, it should always be considered in the differential diagnosis in a child with bilious emesis. Volvulus is a surgical emergency; therefore, in a critically ill child, prompt surgical intervention should not be delayed for any reason.

4. When evaluating a newborn infant for vomiting, it is critical to distinguish between proximal and distal causes of intestinal obstruction using both prenatal and postnatal history, physical examination, and abdominal radiographs.

5. Risk factors for necrotizing enterocolitis (NEC) include prematurity, formula feeding, bacterial infection, and intestinal ischemia. Critical to the management of infants with advanced (Bell stage III) or perforated NEC is timely and adequate source control of peritoneal contamination. Early sequelae of NEC include perforation, sepsis, and death. Later sequelae include short bowel syndrome and stricture.

6. In patients with intestinal obstruction secondary to Hirschsprung’s disease, a leveling ostomy or endorectal pull-through should be performed using ganglionated bowel, proximal to the transition zone between ganglionic and aganglionic intestine.

7. Prognosis of infants with biliary atresia is directly related to age at diagnosis and timing of portoenterostomy. Infants with advanced age at the time of diagnosis or infants who fail to demonstrate evidence of bile drainage after portoenterostomy usually require liver transplantation.

8. Infants with omphaloceles have greater associated morbidity and mortality than infants with gastroschisis due to a higher incidence of congenital anomalies and pulmonary hypoplasia. Gastroschisis can be associated with intestinal atresia, but not with other congenital anomalies. An intact omphalocele can be repaired electively, whereas gastroschisis requires urgent intervention to protect the exposed intestine.

9. Prognosis for children with Wilms’ tumor is defined by the stage of disease at the time of diagnosis and the histologic type (favorable vs. unfavorable). Preoperative chemotherapy is indicated for bilateral involvement, a solitary kidney, or tumor in the inferior vena cava above the hepatic veins. Gross tumor rupture during surgery automatically changes the stage to 3 (at a minimum).

10. Injury is the leading cause of death in children older than 1 year of age. Blunt mechanisms account for the majority of pediatric injuries. The central nervous system is the most commonly injured organ system and the leading cause of death in injured children.

PEDIATRIC SURGICAL THEMES: PITFALLS AND PEARLS

This chapter focuses on the unique considerations regarding the diagnosis and management of surgical diseases in the pediatric population. Many surgical trainees approach the surgical care of children with some degree of fear and trepidation. As any pediatric caregiver will attest to, the surgical management of infants and children requires delicate, careful, and professional interactions with their parents. The stress that the parents of sick children experience in the hospital setting can, at times, be overwhelming. It is due, in part, to the uncertainty regarding a particular prognosis, the feeling of helplessness that evolves when one is unable to care for one’s own child, and in certain cases, the guilt or remorse that one feels for not seeking medical care earlier, or for consenting to a particular procedure. Management of the sick child and his or her family requires not only a certain set of skills but also a unique knowledge base. This section is included to summarize some important general principles in accomplishing this task.

1. Children are not little adults, but they are little people. In practical terms, this often-heard refrain implies that children have unique fluid, electrolyte, and medication needs. Thus, the dosage of medications and the administration of IV fluids should at all times be based on their weight. The corollary of this point is that infants and young children are extremely sensitive to perturbations in their normal physiology and may be easily tipped into fluid overload or dehydration.

2. Sick children whisper before they shout. Children with surgical diseases can deteriorate very quickly. But before they deteriorate, they often manifest subtle physical findings. These findings—referred to as “whispers”—may include signs such as tachycardia, bradycardia, hypothermia, fever, recurrent emesis, or feeding intolerance. Meticulous attention to these subtle findings may unmask the development of potentially serious, life-threatening physiological disturbances.

3. Always listen to the mother and the father. Surgical diseases in children can be very difficult to diagnose because children are often minimally communicative, and information that they communicate may be confusing, conflicting, or both. In all cases, it is wise to listen to the child’s parents, who have closely observed their child and know him or her best. Most importantly, the child’s parents know with certainty...
whether or not the child is sick or not, despite not always knowing the precise diagnosis.

4. Pediatric tissue must be handled delicately and with profound respect.

6. Pay particular attention to the postoperative pediatric patient whose pain cannot be soothed by the administration of standard amounts of analgesic agents. Ask yourself whether a significant yet unrecognized postoperative complication exists.

**GENERAL CONSIDERATIONS**

**Fluid and Electrolyte Balance**

In managing the pediatric surgical patient, an understanding of fluid and electrolyte balance is critical as the margin between dehydration and fluid overload is small. This is particularly true in infants, who have little reserve at baseline and even less when ill. Failure to pay meticulous attention to their hydration status can result in significant fluid overload or dehydration. Several surgical diagnoses such as gastrochisis or short-gut syndrome are characterized by a predisposition to fluid loss. Others require judicious restoration of intravascular volume in order to prevent cardiac failure as is the case in patients with congenital diaphragmatic hernia and associated pulmonary hypertension.

The infant’s physiologic day is approximately eight hours in duration. Accordingly, careful assessment of the individual patient’s fluid balance, including fluid intake and output for the previous eight hours, is essential to prevent dehydration or fluid overload. Clinical signs of dehydration include tachycardia, decreased urine output, reduced skin turgor, depressed fontanelle, absent tears, lethargy, and poor feeding. Fluid overload is often manifested by the onset of a new oxygen requirement, respiratory distress, tachypnea, and tachycardia. The physical assessment of the fluid status of each child must include a complete head-to-toe evaluation, with emphasis on determining whether perturbations in normal physiology are present.

At 12 weeks’ gestation, the total body water of a fetus is approximately 94 cc/kg. By the time the fetus reaches full term, the total body water has decreased to approximately 80 cc/kg. Total body water drops an additional 5% within the first week of life, and by 1 year of life, total body water approaches adult levels, around 60 to 65 cc/kg. Parallel to the drop in total body water is the reduction in extracellular fluid. These changes are accelerated in the preterm infant who may face additional fluid losses due to coexisting congenital anomalies or surgery. Normal daily maintenance fluids for most children can be estimated using the following formula:

\[
100 \text{ mL/kg for the first } 10 \text{ kg, plus } 50 \text{ mL/kg for each additional kilogram of body weight thereafter.}
\]

Because IV (I.V.) fluid orders are written as milliliters per hour, this can be conveniently converted to:

\[
4 \text{ mL/kg/h up to } 10 \text{ kg, add } 2 \text{ mL/kg/h for each additional kilogram body weight thereafter.}
\]

For example, a 26-kg child has an estimated maintenance fluid requirement of \((10 \times 4) + (10 \times 2) + (6 \times 1) = 66 \text{ mL/h in the absence of massive fluid losses or shock. A newborn infant with gastrochisis will manifest significant evaporative losses from the exposed bowel such that fluid requirements can be on the order of 150 to 180 cc/kg/day.}

Precise management of a neonate’s fluid status requires an understanding of changes in the glomerular filtration rate (GFR) and tubular function of the kidney. The term newborn’s GFR is approximately 21 mL/min/1.73 m² compared to 70 mL/min/1.73 m² in an adult. Within the first 2 weeks of life GFR increases to approximately 60, and by 2 years of age it is essentially at adult levels. The capacity to concentrate urine is very limited in preterm and term infants. In comparison to an adult who can concentrate urine to 1200 mosm/kg, infants can concentrate urine at best to 600 mosm/kg. While infants are capable of secreting antidiuretic hormone, ADH, the aquaporin water channel-mediated osmotic water permeability of the infant’s collecting tubules is severely limited compared to that of adults, leading to an insensitivity to ADH.

Sodium requirements range from 2 mEq/kg per day in term infants up to 5 mEq/kg per day in critically ill preterm infants as a consequence of salt wasting. Potassium requirements are on the order of 1 to 2 mEq/kg per day. Calcium and magnesium supplementation of IV fluids is essential to prevent laryngospasm, dysrhythmias, and tetany.

**Acid-Base Equilibrium**

Acute metabolic acidosis usually implies inadequate tissue perfusion and is a serious disorder in children. Potentially life-threatening causes that are specific for the pediatric population must be sought; they include intestinal ischemia from necrotizing enterocolitis (in the neonate), midgut volvulus, or incarcerated hernia. Other causes include chronic bicarbonate loss from the gastrointestinal tract or acid accumulation as in chronic renal failure. Respiratory acidosis implies hypoventilation, the cause of which should be apparent. Treatment of acute metabolic acidosis should be aimed at restoring tissue perfusion by addressing the underlying abnormality first. For severe metabolic acidemia where the serum pH is less than 7.25, sodium bicarbonate should be administered using the following guidelines: base deficit × weight in kilograms × 0.5 (in newborns). The last factor in the equation should be 0.4 for smaller children and 0.3 for older children. The dose should be diluted to a concentration of 0.5 mEq/mL because full-strength sodium bicarbonate is hyperosmolar. One-half the corrective dose is given, and the serum pH is measured again. During cardiopulmonary resuscitation (CPR), one-half the corrective dose can be given as an intravenous bolus and the other half given slowly intravenously.

Respiratory alkalosis is usually caused by hyperventilation, which is readily correctable. Metabolic alkalosis most commonly implies gastric acid loss, as in the child with pyloric stenosis, or aggressive diuretic therapy. In the child with gastric fluid loss, IV fluids of 5% dextrose, 0.5% normal saline, and 20 mEq KCl/L usually correct the alkalosis.

**Blood Volume and Blood Replacement**

Criteria for blood transfusion in infants and children remain poorly defined. The decision to transfuse a critically ill pediatric patient may depend on a number of clinical features that include the patient’s age, primary diagnosis, the presence of ongoing bleeding, coagulopathy, hypoxia, hemodynamic compromise, lactic acidosis, cyanotic heart disease, and overall severity of illness. A recent survey of transfusion practices among pediatric intensivists showed that the baseline hemoglobin levels that would prompt them to recommend RBC transfusion ranged from 7 to 13 g/dL. Patients with cyanotic heart disease are often transfused to
higher hemoglobin values, although the threshold for transfusion in this population remains to be defined. In general terms, there is a trend towards an avoidance of the use of RBC products whenever possible as current studies suggest that lower hemoglobin concentrations are well tolerated by many groups of patients and that administration of RBCs may have unintended negative consequences, including perhaps an increase in predisposition to the development of necrotizing enterocolitis, although this finding is controversial. In addition, there is increasing evidence that PRBC transfusion may have adverse effects on the host immune in both children and adults. These effects are poorly understood but may include effects due to RBC storage and due to factors that are particular to the individual RBC donor. The TRIPICU randomized controlled trial by Lacroix et al in 2007, which was performed in stable critically ill children, determined that a restrictive Hb transfusion trigger (70 g/L) was as safe as a liberal Hb trigger (95 g/L) and was associated with reduced blood use. It remains uncertain whether this can be extrapolated to unstable patients. Expert opinion now generally favors an Hb transfusion trigger of 70 g/L in stable critically ill children, which is the same as the recommendation for adult patients (see Chapter 7).

A higher threshold should be considered if the child has symptomatic anemia or impaired cardiorespiratory function. A useful guideline for estimating blood volume for the newborn infant is approximately 80 mL/kg of body weight. When packed red blood cells are required, the transfusion requirement is usually administered in 10 mL/kg increments, which is roughly equivalent to a 500-mL transfusion for a 70-kg adult. The following formula may be used to determine the volume (ml) of PRBC to be transfused:

\[(\text{Target hematocrit} - \text{Current Hematocrit}) \times \text{weight (kg)} \times \frac{80}{65}\] (65 represents the estimated hematocrit of a unit of PRBC)

As a general rule, blood is recommended for replacement of volume loss if the child’s perfusion is inadequate despite administration of 2 to 3 boluses of 20 mL/kg of isotonic crystalloid. Consideration should be given for the administration of 10 mL/kg of packed red blood cells as soon as possible. Type O blood can be administered without a cross-match and is relatively safe; type-specific blood can be obtained quite quickly; however, unlike fully cross-matched blood, incompatibilities other than ABO and Rh may exist.

In the child, coagulation deficiencies may rapidly assume clinical significance after extensive blood transfusion. It is advisable to have fresh frozen plasma and platelets available if more than 30 mL/kg have been transfused. Plasma is given in a dose of 10 to 20 mL/kg, and platelets are given in a dose of 1 unit/5 kg. Each unit of platelets consists of 40 to 60 mL of fluid (plasma plus platelets). Following transfusion of PRBCs to neonates with tenuous fluid balance, a single dose of a diuretic (such as furosemide 1 mg/kg) may help to facilitate excretion of the extra fluid load. Many clinicians prefer to administer fresh products to minimize the deleterious effects of red cell storage.

In pediatric patients who have lost greater than 30 mL/kg with ongoing bleeding, consideration should be given to initiation of a massive transfusion protocol. Such a protocol involves transfusion, based on weight, of 1:1:1 transfusion of RBCs, plasma, and platelets.

Parenteral Alimentation and Nutrition
The nutritional requirements of the surgical neonate must be met in order for the child to grow and to heal surgical wounds. If inadequate protein and carbohydrate calories are given, the child may not only fail to recover from surgery but may also exhibit growth failure and impaired development of the central nervous system. In general terms, the adequacy of growth must be assessed frequently by determining both total body weight as well as head circumference. Neonates that are particularly predisposed to protein-calorie malnutrition include those with gastroschisis, intestinal atresia, or intestinal insufficiency from other causes, such as necrotizing enterocolitis. The protein and caloric requirements for the surgical neonate are shown in Table 39-1.

Nutrition can be provided via either the enteral or parenteral routes. Whenever possible, the enteral route is preferred because it not only promotes the growth and function of the gastrointestinal system, it also ensures that the infant learns how to feed. There are various enteral feeding preparations available; these are outlined in Table 39-2. The choice of formula is based upon the individual clinical state of the child. Pediatric surgeons are often faced with situations where oral feeding is not possible. This problem can be seen in the extremely premature infant who has not yet developed the feeding skills, or in the infant with concomitant craniofacial anomalies that impair sucking, for example. In these instances, enteral feeds can be administered either a nasojejunal or a gastrostomy tube.

When the gastrointestinal tract cannot be used because of mechanical, ischemic, inflammatory, or functional disorders, parenteral alimentation must be given. Prolonged parenteral nutrition is delivered via a central venous catheter. Peripheral IV alimentation can be given, utilizing less concentrated but greater volumes of solutions. Long-term parenteral nutrition should include supplemental copper, zinc, and iron to prevent the development of trace metal deficiencies. A major complication of long-term total parenteral nutrition (TPN) is the development of parenteral nutrition–associated cholestasis, which can eventually progress to liver failure. To prevent this major complication, concomitant enteral feedings should be instituted, and the gastrointestinal tract should be used as soon as possible. When proximal stomas are in place, gastrointestinal continuity should be restored as soon as possible. Where intestinal insufficiency is associated with dilation of the small intestine, tapering or intestinal lengthening procedures may be beneficial.

Other strategies to minimize the development of TPN-related liver disease include meticulous catheter care to avoid infection, which increases cholestatic symptoms, aggressive treatment of any infection, and early cycling of parenteral nutrition in older children who can tolerate not receiving continuous dextrose solution for a limited period. Evidence suggests that cholestasis eventually resolves in most cases after parenteral nutrition is discontinued, as measured by levels of total bilirubin. Preliminary evidence suggests that substituting omega-3 fish oil lipid emulsion in parenteral nutrition for the standard soybean-based emulsions may prevent the development of TPN-related cholestasis and reverse the effects of established liver disease. A phase 2 trial to determine whether parenteral nutrition–associated liver disease can be reversed or its progression halted by using a parenteral fat emulsion prepared from fish oil as measured by normalization of serum levels of hepatic enzymes and bilirubin is ongoing (ClinicalTrials.gov, identifier NCT00826020).

**Venous Access**

Obtaining reliable vascular access in an infant or child is an important task that often becomes the responsibility of the pediatric surgeon. The goal should always be to place the catheter in the least invasive, least risky, and least painful manner, and in a location that is most accessible and allows for use of the catheter without complications for as long as it is needed. In infants, central venous access may be established using a cutdown approach, either in the antecubital fossa, external jugular vein, facial vein, or proximal saphenous vein. If the internal jugular vein is used, care is taken to prevent venous occlusion. In infants over 3 kg and in older children, percutaneous access of the subclavian, internal jugular, or femoral veins is possible in most cases, and central access is achieved using the Seldinger technique. The use of ultrasound (US) is considered standard of care for placement of central lines in this population for the internal jugular vein and femoral veins, and it significantly improves the safety of the insertion procedure. The catheters are tunneled to an exit site separate from the venotomy site. Where available, PICC lines (peripherally inserted central catheters) may be placed, typically via the antecubital fossa. Regardless of whether the catheter is placed by a cutdown approach or percutaneously, a chest X-ray to confirm central location of the catheter tip and to exclude the presence of a pneumothorax or hemothorax is mandatory. When discussing the placement of central venous catheters with parents, it is important to note that the complication rate for central venous lines in children can be high. The incidence of catheter-related sepsis or infection remains a problem, yet should be less than 1% with meticulous attention to catheter insertion care and exit site management. Superior or inferior vena cava occlusion is a significant risk after the placement of multiple lines, particularly in the smallest premature patients.

**Thermoregulation**

Careful regulation of the ambient environment of infants and children is crucial as these patients are extremely thermolabile. Premature infants are particularly susceptible to changes in environmental temperature. Because they are unable to shiver and lack stores of fat, their potential for thermogenesis is impaired. The innate inability to regulate temperature is compounded by the administration of anesthetic and paralyzing agents. Since these patients lack adaptive mechanisms to cope with the environment, the environment must be carefully regulated. Attention to heat conservation during transport of the infant to and from the operating room is essential. Transport systems incorporating heating units are necessary for premature infants. In the operating room, the infant is kept warm by the use of overhead heating lamps, a heating blanket, warming of inspired gases, and coverage of the extremities and head with occlusive materials. During abdominal surgery, extreme care is taken to avoid wet and cold drapes. All fluids used to irrigate the chest or abdomen must be warmed to body temperature. Laparoscopic approaches for abdominal operations may result in more stable thermoregulation due to decreased heat loss from the smaller wound size. Constant monitoring of the child’s temperature is critical in a lengthy procedure, and the surgeon should continuously communicate with the anesthesiologist regarding the temperature of the patient. The development of hypothermia in infants and children can result in cardiac arrhythmias or coagulopathy. These potentially life-threatening complications can be avoided by careful attention to thermoregulation.
Pain Control

All children including neonates experience pain; the careful recognition and management of pediatric pain represents an important component of the perioperative management of all pediatric surgical patients. There is a range of pain management options that can improve the child’s well-being, as well as the parents’ sense of comfort. Given that morphine and fentanyl have an acceptable safety margin, they should be administered to neonates and children when indicated, bearing in mind that withholding analgesia poses a significant risk, as does administration of excessive analgesic agents. A recent randomized trial of neonates on ventilators showed that the use of a morphine infusion decreased the incidence of intraventricular hemorrhage by 50%. Additional analgesic modalities include the use of topical anesthetic ointment (EMLA cream) and the use of regional anesthesia, such as caudal blocks for hernias and epidural or incisional catheter infusions (On-Q) for large abdominal or thoracic incisions. In surgical neonates that have been administered large concentrations of narcotics over a prolonged period, transient physical dependence should not only be expected but also anticipated. When narcotics are discontinued, symptoms of narcotic withdrawal may develop, including irritability, restlessness, and episodes of hypertension and tachycardia. Early recognition of these signs is essential, as is timely treatment using nalaxone and other agents. It is important to administer pain control in concert with a well-qualified and collaborative pediatric pain-management team, which typically includes anesthesiologists with expertise in pain management, as well as advance practice nurses who can respond rapidly when the pain control is inadequate or excessive. By ensuring that the pediatric surgical patient has adequate analgesia, the surgeon ensures that the patient receives the most humane and thorough treatment and provides important reassurance to all other members of the healthcare team and to the family that pain control is a very high priority.

NECK MASSES

The management of neck masses in children is determined by their location and the length of time that they have been present. Neck lesions are found either in the midline or lateral compartments. Midline masses include thyroglossal duct remnants, thyroid masses, thymic cysts, or dermoid cysts. Lateral lesions include branchial cleft remnants, cystic hygromas, vascular malformations, salivary gland tumors, torticolli, and lipoblastoma (a rare benign mesenchymal tumor of embryonal fat occurring in infants and young children). Enlarged lymph nodes and rare malignancies such as rhabdomyosarcoma can occur either in the midline or laterally.

Lymphadenopathy

The most common cause of a neck mass in a child is an enlarged lymph node, which typically can be found laterally or in the midline. The patient is usually referred to the pediatric surgeon for evaluation after the mass has been present for several weeks. A detailed history and physical examination often helps determine the likely etiology of the lymph node and the need for excisional biopsy. Enlarged tender lymph nodes are usually the result of a bacterial infection (Staphylococcus or Streptococcus). Treatment of the primary cause (e.g., otitis media or pharyngitis) with antibiotics often is all that is necessary. However, when the involved nodes become fluctuant, incision and drainage are indicated. In many North American institutions, there has been an increasing prevalence of methicillin-resistant Staphylococcus aureus infection of the skin and soft tissues, leading to increased staphylococcal lymphadenitis in children. More chronic forms of lymphadenitis, including infections with atypical mycobacteria, as well as cat-scratch fever, are diagnosed based on serologic findings or excisional biopsy. The lymphadenopathy associated with infectious mononucleosis can be diagnosed based on serology. When the neck nodes are firm, fixed, and others are also present in the axillae or groin, or the history suggests lymphoma, excisional biopsy is indicated. In these cases, it is essential to obtain a chest radiograph to look for the presence of a mediastinal mass. Significant mediastinal load portends cardiopulmonary collapse due to loss of venous return and compression of the tracheobronchial tree with general anesthesia.

Thyroglossal Duct Remnants

Pathology and Clinical Manifestations. The thyroid gland buds off the foregut diverticulum at the base of the tongue in the region of the future foramen cecum at 3 weeks of embryonic life. As the fetal neck develops, the thyroid tissue becomes more anterior and caudal until it rests in its normal position. The “descent” of the thyroid is intimately connected with the development of the hyoid bone. Residual thyroid tissue left behind during the migration may persist and subsequently present in the midline of the neck as a thyroglossal duct cyst. The mass is most commonly appreciated in the 2- to 4-year-old child when the baby fat disappears and irregularities in the neck become more readily apparent. Usually the cyst is encountered in the midline at or below the level of the hyoid bone and moves up and down with swallowing or with protrusion of the tongue. Occasionally it presents as an intrathyroidal mass. Most thyroglossal duct cysts are asymptomatic. If the duct retains its connection with the pharynx, infection may occur, and the resulting abscess will necessitate incision and drainage, occasionally resulting in a salivary fistula. Submental lymphadenopathy and midline dermoid cysts can be confused with a thyroglossal duct cyst. Rarely, midline ectopic thyroid tissue masquerades as a thyroglossal duct cyst and may represent the patient’s only thyroid tissue. Therefore, if there is any question regarding the diagnosis or if the thyroid gland cannot be palpated in its normal anatomic position, it is advisable to obtain a nuclear scan to confirm the presence of a normal thyroid gland. Although rarely the case in children, in adults the thyroglossal duct may contain thyroid tissue that can undergo malignant degeneration. The presence of malignancy in a thyroglossal cyst should be suspected when the cyst grows rapidly or when US demonstrates a complex anechoic pattern or the presence of calcification.

Treatment. If the thyroglossal duct cyst presents with an abscess, treatment should first consist of drainage and antibiotics. Following resolution of the inflammation, resection of the cyst in continuity with the central portion of the hyoid bone and the tract connecting to the pharynx in addition to ligation at the foramen cecum (the Sistrunk operation), is curative in over 90% of patients. Lesser operations result in unacceptably high recurrence rates, and recurrence is more frequent following infection. According to a recent review, factors predictive of recurrence included more than two infections prior to surgery, age under 2 years, and inadequate initial operation.
Paired branchial clefts and arches develop early in the fourth gestational week. The first cleft and the first, second, third, and fourth pouches give rise to adult organs. The embryologic communication between the pharynx and the external surface may persist as a fistula. A fistula is seen most commonly with the second branchial cleft, which normally disappears, and extends from the anterior border of the sternocleidomastoid muscle superiorly, inward through the bifurcation of the carotid artery, and enters the posterolateral pharynx just below the tonsillar fossa. In contrast, a third branchial cleft fistula passes posterior to the carotid bifurcation. The branchial cleft remnants may contain small pieces of cartilage and cysts, but internal fistulas are rare. A second branchial cleft sinus is suspected when clear fluid is noted draining from the external opening of the tract at the anterior border of the lower third of the sternomastoid muscle. Rarely, branchial cleft anomalies occur in association with biliary atresia and congenital cardiac anomalies, an association that is referred to as Goldenhar’s complex.

**Treatment.** Complete excision of the cyst and sinus tract is necessary for cure. Dissection of the sinus tract is facilitated with passage of a fine lacrimal duct probe through the external opening into the tract and utilizing it as a guide for dissection. Injection of a small amount of methylene blue dye into the tract also may be useful. A series of two or sometimes three small transverse incisions in a “stepladder” fashion is preferred to a long oblique incision in the neck, which is cosmetically undesirable. Branchial cleft cysts can present as abscesses. In these cases, initial treatment includes incision and drainage with a course of antibiotics to cover *Staphylococcus* and *Streptococcus* species, followed by excision of the cyst after the infection resolves.

**Lymphatic Malformation**

**Etiology and Pathology.** Lymphatic malformation (cystic hygroma or lymphangioma) occurs as a result of sequestration or obstruction of developing lymph vessels in approximately 1 in 12,000 births. Although the lesion can occur anywhere, the most common sites are in the posterior triangle of the neck, axilla, groin, and mediastinum. The cysts are lined by endothelium and filled with lymph. Occasionally unilocular cysts occur, but more often there are multiple cysts “infiltrating” the surrounding structures and distorting the local anatomy. A particularly troublesome variant of lymphatic malformation is that which involves the tongue, floor of the mouth, and structures deep in the neck. Adjacent connective tissue may show extensive lymphocytic infiltration. The mass may be apparent at birth or may appear and enlarge rapidly in the early weeks or months of life as lymph accumulates; most present by age 2 years (Fig. 39-1A). Extension of the lesion into the axilla or mediastinum occurs about 10% of the time and can be demonstrated preoperatively by chest X-ray, US, or computed tomographic (CT) scan, although magnetic resonance imaging (MRI) is preferable. Occasionally lymphatic malformations contain nests of vascular tissue. These poorly supported vessels may bleed and produce rapid enlargement and discoloration of the lesion. Infection within the lymphatic malformations, usually caused by *Streptococcus* or *Staphylococcus*, may occur. In the neck, this can cause rapid enlargement, which may result in airway compromise. Rarely, it may be necessary to carry out percutaneous aspiration of a cyst to relieve respiratory distress.

The diagnosis of lymphatic malformation by prenatal US, before 30 weeks’ gestation, has detected a “hidden mortality” as well as a high incidence of associated anomalies, including abnormal karyotypes and hydrops fetalis. Occasionally, very large lesions can cause obstruction of the fetal airway. Such obstruction can result in the development of polyhydramnios by impairing the ability of the fetus to swallow amniotic fluid. In these circumstances, the airway is usually markedly distorted, which can result in immediate airway obstruction unless the airway is secured at the time of delivery. Orotracheal intubation or emergency tracheostomy while the infant remains attached to the placenta, the so-called EXIT procedure (ex utero intrapartum technique) may be necessary to secure the airway.

**Treatment.** The modern management of most lymphatic malformations includes image-guided sclerotherapy as first-line therapy, which often involves multiple injections. Cyst excision may be used in cases where injection is inadequate.

---

**Figure 39-1.** A. Left cervical cystic hygroma in a 2-day old baby. B. Intraoperative photograph showing a vessel loop around the spinal accessory nerve.
Total removal of all gross disease is often not possible because of the extent of the lymphatic malformation and its proximity to, and intimate relationship with, adjacent nerves, muscles, and blood vessels (Fig. 39-1B). Radical ablative surgery is not indicated for these lesions, which are always benign. Conservative excision and unroofing of remaining cysts is advised, with repeated partial excision of residual cysts and sclerotherapy if necessary, preserving all adjacent crucial structures. In cases in which surgical excision is performed, closed-suction drainage is recommended. Nevertheless, fluid may accumulate beneath the surgically created flaps in the area from which the lymphatic malformation was excised, requiring multiple needle aspirations. A combined sclerotherapy/resectional approach is particularly useful for masses that extend to the base of the tongue or the floor of the mouth.

**Torticollis**

The presence of a lateral neck mass in infancy in association with rotation of the head towards the opposite side of the mass indicates the presence of congenital torticollis. This lesion results from fibrosis of the sternocleidomastoid muscle. The mass may be palpated in the affected muscle in approximately two-thirds of cases, or it may be diagnosed by US. Histologically, the lesion is characterized by the deposition of collagen and fibroblasts around atrophied muscle cells. In the vast majority of cases, physical therapy based on passive stretching of the affected muscle is of benefit. Rarely, surgical transection of the sternocleidomastoid may be indicated.

**RESPIRATORY SYSTEM**

### Congenital Diaphragmatic Hernia (Bochdalek)

**Pathology.** The septum transversum extends to divide the pleural and coelomic cavities during fetal development. This precursor of the diaphragm normally completes separation of these two cavities at the posterolateral aspects of this mesenchymally derived structure. The most common variant of a congenital diaphragmatic hernia is a posterolateral defect, also known as a Bochdalek hernia. Diaphragmatic defects allow abdominal viscera to fill the chest cavity. The abdominal cavity is small and underdeveloped and remains seaploid after birth. Both lungs are hypoplastic, with decreased bronchial and pulmonary artery branching. Lung weight, lung volume, and DNA content are also decreased, and these findings are more striking on the ipsilateral side. This anomaly is encountered more commonly on the left (80–90%). Linkage analyses have recently implicated genetic mutations in syndromic variants of congenital diaphragmatic hernias. In many instances, there is a surfactant deficiency, which compounds the degree of respiratory insufficiency. Amniocentesis with karyotype may identify chromosomal defects, especially trisomy 18 and 21. Associated anomalies, once thought to be uncommon, were identified in 65 of 166 patients in one study, predominately of the heart, followed by abdominal wall defects, chromosomal changes, and other defects.

Prenatal ultrasonography is successful in making the diagnosis of congenital diaphragmatic hernia (CDH) as early as 15 weeks’ gestation, and early antenatal diagnosis is associated with worse outcomes. US findings include herniated abdominal viscera in the chest that may also look like a mass or lung anomaly, changes in liver position, and mediastinal shift away from the herniated viscera (Fig. 39-2). Accurate prenatal prediction of outcome for fetuses who have CDH remains a challenge. One index of severity for patients with left CDH is the lung-to-head ratio (LHR), which is the product of the length and the width of the right lung at the level of the cardiac atria divided by the head circumference (all measurements in millimeters). An LHR value of less than 1.0 is associated with a very poor prognosis, whereas an LHR greater than 1.4 predicts a more favorable outcome. The utility of the LHR in predicting outcome in patients with CDH has recently been questioned because of the tremendous interobserver variability in calculating this ratio for a particular patient, as well as the lack of reliable measures to determine postnatal disease severity. Because the LHR is not gestational age independent, Jani and colleagues proposed the introduction of a new measurement: the observed (o/e) LHR, to correct for gestational age. The observed LHR may be expressed as a percentage of the expected mean for gestational age of the observed/expected lung-to-head ratio (o/e LHR), which is considered extreme if <15%, severe at 15% to 25%, moderate at 26% to 35%, and mild at 36% to 45%. The most reliable prenatal predictor of postnatal survival is absence of liver herniation, where in 710 fetuses, there was significantly higher survival rate in fetuses without herniation (74% without herniation vs. 45% with herniation).

Following delivery, the diagnosis of CDH is made by CXR (Fig. 39-3). The differential diagnosis includes bronchopulmonary foregut malformations, in which the intrathoracic loops of bowel may be confused for lung or foregut pathology. The vast majority of infants with CDH develop immediate respiratory distress, which is due to the combined effects of three factors. First, the air-filled bowel in the chest compresses the mobile mediastinum, which shifts to the opposite side of the chest, compromising air exchange in the contralateral lung. Second, pulmonary hypertension develops. This phenomenon results in persistent fetal circulation with resultant decreased pulmonary perfusion and impaired gas exchange. Finally, the lung on the affected side is often hypoplastic, such that it is essentially nonfunctional. Varying degrees of pulmonary hypoplasia on the opposite side may compound these effects. The second and third factors are thought to be the most important. Neonates with CDH are usually in respiratory distress requiring
ventilation and intensive care, and the overall mortality in most series is around 50%.

**Treatment.** CDH care has been improved through effective use of improved methods of ventilation and timely cannulation for extracorporeal membrane oxygenation (ECMO). Many infants are symptomatic at birth due to hypoxia, hypercarbia, and metabolic acidosis. Prompt cardiorespiratory stabilization is mandatory. It is noteworthy that the first 24 to 48 hours after birth are often characterized by a period of relative stability with high levels of PaO₂ and relatively good perfusion. This has been termed the “ honeymoon period” and is often followed by progressive cardiorespiratory deterioration. In the past, correction of the hernia was believed to be a surgical emergency, and patients underwent surgery shortly after birth. It is now accepted that the presence of persistent pulmonary hypertension that results in right-to-left shunting across the open foramen ovale or the ductus arteriosus, and the degree of pulmonary hypoplasia, are the leading causes of cardiorespiratory insufficiency. Current management is directed toward managing the pulmonary hypertension, and minimizing barotrauma while optimizing oxygen delivery. To achieve this goal, infants are placed on mechanical ventilation using relatively low or “gentle” settings that prevent overinflation of the noninvolved lung. Levels of PaCO₂ in the range of 50 to 60 mmHg or higher are accepted as long as the pH remains ≥7.25. If these objectives cannot be achieved using conventional ventilation, high frequency oscillatory ventilation (HFOV) may be employed to avoid the injurious effects of conventional tidal volume ventilation. Echocardiography will assess the degree of pulmonary hypertension and identify the presence of any coexisting cardiac anomaly. ICU goals include minimal sedation, meticulous attention to endotracheal tube secretions, and gradual changes to ventilator settings to avoid inducing pulmonary hypertension via hypoxia. To minimize the degree of pulmonary hypertension, inhaled nitric oxide may be administered, and in some patients, this improves pulmonary perfusion. Nitric oxide is administered into the ventilation circuit and is used in concentrations up to 40 parts per million. Correction of acidosis using bicarbonate solution may minimize the degree of pulmonary hypertension. As the degree of pulmonary hypertension becomes hemodynamically significant, right-sided heart failure develops, and systemic perfusion is impaired. Administration of excess IV fluid will compound the degree of cardiac failure and lead to marked peripheral edema. Inotropic support using epinephrine, dopamine, and milrinone alone or in combination may be useful in optimizing cardiac contractility and maintaining mean arterial pressure.

Infants with CDH who remain severely hypoxic despite maximal ventilatory care may be candidates for treatment of their respiratory failure ECMO, with access via venovenous (VV) or venoarterial (VA) routes. VV bypass is established with a single cannula through the right internal jugular vein, with blood removed from and infused into the right atrium by separate ports. VA bypass provides additional cardiac support, whereas VV bypass requires a well-functioning heart and relies on the lungs for some oxygenation as well. In VA ECMO, the right atrium is cannulated by means of the internal jugular vein and the aortic arch through the right common carotid artery. As much of the cardiac output is directed through the membrane oxygenator as is necessary to provide oxygenated blood to the infant and remove carbon dioxide. The infant is maintained on bypass until the pulmonary hypertension is resolved and lung function, as measured by compliance and the ability to oxygenate and ventilate, is improved. This is usually seen within 7 to 10 days, but in some infants, it may take up several weeks to occur. Complications associated with ECMO increase after 14 days and include cannula malposition, bleeding in multiple locations, and infection. The use of ECMO is associated with significant risk. Because patients require systemic anticoagulation, bleeding complications are the most significant. They may occur intracranially or at the site of cannula insertion, and they can be life-threatening. Systemic sepsis is a significant problem and may necessitate decannulation. Criteria for placing infants on ECMO include the presence of normal cardiac anatomy by echocardiography, the absence of fatal chromosome anomalies, and the expectation that the infant would die without ECMO. Traditionally, a threshold of weight greater than 2 kg and gestational age greater than 34 weeks has been applied, although success has been achieved at weights as low as 1.8 kg. Upon decannulation, some centers repair the carotid artery. In instances in which the child is cannulated for a brief period (5 days or less) this may be feasible. A recent study failed to show any benefit from repairing the carotid artery, although this finding remains to be studied further.

A strategy that does not involve the use of ECMO but instead emphasizes the use of permissive hypercapnia and the avoidance of barotrauma may provide equal overall outcome in patients with CDH. This likely reflects the fact that mortality is related to the degree of pulmonary hypoplasia and the presence of congenital anomalies, neither of which are correctable by ECMO.
The timing of diaphragmatic hernia repair still varies from center to center, particularly when the infant is on ECMO. In patients that are not on ECMO, repair should be performed once the hemodynamic status has been optimized. In neonates that are on ECMO, some surgeons perform early repair on bypass; others wait until the infant’s lungs are improved and the pulmonary hypertension has subsided and then repair the diaphragm and discontinue bypass within hours of surgery. Still others repair the diaphragm only after the infant is off bypass. Operative repair of the diaphragmatic hernia may be accomplished either by an abdominal or transthoracic approach and can be performed either via open or minimally invasive techniques. Through a subcostal incision the abdominal viscera are withdrawn from the chest, exposing the defect in the diaphragm. Care must be taken when reducing the spleen and liver, as bleeding from these structures can be fatal. The anterior margin is often apparent, while the posterior muscular rim is attenuated. If the infant is heparinized on bypass, minimal dissection of the muscular margins is performed. Electrocautery is used liberally to minimize postoperative bleeding. Most infants who require ECMO support prior to hernia repair have large defects, often lacking the medial and posterior margins. About three-fourths of infants repaired on bypass require prosthetic material to patch the defect, suturing it to the diaphragmatic remnant or around ribs or costal cartilages for the large defects. If there is adequate muscle for closure, a single layer of nonabsorbable horizontal mattress suture, pledgeted or not, closes the defect. Just before the repair is complete, a chest tube may be positioned in the thoracic cavity but is not mandatory. Patients repaired on ECMO are at risk for developing a hemotherax, which can significantly impair ventilation. Anatomic closure of the abdominal wall may be impossible after reduction of the viscera. Occasionally, a prosthetic patch or acellular material may be sutured to the fascia to facilitate closure. The patch can be removed at a later time, and the ventral hernia can be closed at that time or subsequently. In patients who are deemed to be candidates for a minimally invasive approach (stable patients, >2 kg, no pulmonary hypertension), a thorascoscopic repair may be safely performed although concerns have been raised about possible effects of the longer operative time for thorascoscopic repair and higher recurrence rates. If the diaphragm has been repaired on ECMO, weaning and decannulation are accomplished as soon as possible. All infants are ventilated postoperatively to maintain preductal arterial oxygenation of 80 to 100 torr. Very slow weaning from the ventilator is necessary to avoid recurrent pulmonary hypertension.

Fetal tracheal occlusion is an experimental prenatal therapy for the treatment of severe congenital diaphragmatic hernia that reverses lung hypoplasia. The rationale for this approach is that the occlusion of the fetal trachea leads to net accumulation of lung liquid under pressure, which results in the development of large fluid-filled lungs. The balloon may be placed into the trachea under laparoscopic guidance, then removed prior to delivery when maximal lung growth has been achieved. The use of fetal tracheal occlusion remains investigational, although early reports are promising.

**Congenital Lobar Emphysema**

Congenital lobar emphysema (CLE) is a condition manifested during the first few months of life as a progressive hyperexpansion of one or more lobes of the lung. It can be life-threatening in the newborn period if extensive lung tissue is involved, but in the older infant and in cases in which the lesion is less severely distended it causes less respiratory distress. Air entering during inspiration is trapped in the lobe; on expiration, the lobe cannot deflate and progressively overexpands, causing atelectasis of the adjacent lobe or lobes. This hyperexpansion eventually shifts the mediastinum to the opposite side and compromises the other lung. CLE usually occurs in the upper lobes of the lung (left greater than right), followed next in frequency by the right middle lobe, but it also can occur in the lower lobes. It is caused by intrinsic bronchial obstruction from poor bronchial cartilage development or extrinsic compression. Approximately 14% of children with this condition have cardiac defects, with an enlarged left atrium or a major vessel causing compression of the ipsilateral bronchus.

Symptoms range from mild respiratory distress to full-blown respiratory failure with tachypnea, dyspnea, cough, and late cyanosis. These symptoms may be stationary or they may progress rapidly or result in recurrent pneumonia. Occasionally, infants with CLE present with failure to thrive, which likely reflects the increased work associated with the overexpanded lung. A hyperexpanded hemithorax on the ipsilateral side is pathognomonic for CLE. Diagnosis is typically confirmed by chest X-ray that shows a hyperlucent affected lobe with adjacent lobar compression and atelectasis. The mediastinum may be shifted as a consequence of mass effect to the contralateral side causing compression and atelectasis of the contralateral lung (Fig. 39-4). Although chest radiograph is usually sufficient, it is sometimes important to obtain at CT scan of the chest to clearly establish the diagnosis of CLE. This should be done only in the stable patient. Unless foreign body or mucous plugging is suspected as a cause of hyperinflation, bronchoscopy is not advisable because it can lead to more air trapping and cause life-threatening respiratory distress in a stable infant. Treatment is resection of the affected lobe, which can be safely performed using either an open or thorascoscopic approach. Unless symptoms necessitate earlier surgery, resection can usually be performed after the infant is several months of age. The prognosis is excellent.

**Figure 39-4.** Congenital lobar emphysema of the left upper lobe in a 2-week-old boy. Mediastinal shift is present.
Bronchopulmonary Foregut Malformations

Bronchopulmonary foregut malformations include foregut duplication cysts, congenital pulmonary airway malformations, and pulmonary sequestrations as discussed in the following sections.

Congenital Pulmonary Airway Malformations. Previously denoted as congenital cystic adenomatous malformation, (CCAM), congenital pulmonary airway malformations (CPAM) exhibits cystic proliferation of the terminal airway, producing cyst lined by mucus-producing respiratory epithelium, and elastic tissue in the cyst walls without cartilage formation. There may be a single cyst with a wall of connective tissue containing smooth muscle. Cysts may be large and multiple (type I), smaller and more numerous (type II), or they may resemble fetal lung without macroscopic cysts (type III). CPAMs frequently occur in the left lower lobe. However, this lesion can occur in any location and may occur in more than one lobe on more than one side, although this is rare. Clinical symptoms range from none to severe respiratory failure at birth. Over time, these malformations can be subject to repeated infections and produce fever and cough in older infants and children. The diagnosis is usually confirmed by CT for surgical planning and characteristic features that might delineate other bronchopulmonary foregut malformations (Fig. 39-5). Prenatal US may suggest the diagnosis. Resection is curative and may need to be performed urgently in the infant with severe respiratory distress. Long term, there is a risk of malignant degeneration in unresected CPAMs, but this risk occurs over decades and has not been fully defined. As a result, resection of the affected lobe is usually performed (Fig. 39-6). Antenatal resection may be rarely indicated in those instances in which fetal development is complicated by hydrops as a result of the mechanical and vascular effects of the lung lesion.

Pulmonary Sequestration. Pulmonary sequestration is uncommon and consists of a mass of lung tissue, usually in the left lower chest, occurring without the usual connections to the pulmonary artery or tracheobronchial tree, yet with a systemic blood supply from the aorta. There are two kinds of sequestration. Extralobar sequestration is usually a small area of nonaerated lung separated from the main lung mass, with a systemic blood supply, located immediately above the left diaphragm. It is commonly found in cases of CDH. Intralobar sequestration more commonly occurs within the parenchyma of the left lower lobe but can occur on the right. There is no major connection to the tracheobronchial tree, but a secondary connection may be established, perhaps through infection or via adjacent intrapulmonary shunts. The blood supply frequently originates from the aorta below the diaphragm; multiple vessels may be present (Fig. 39-7). Venous drainage of both types can be systemic or pulmonary. The cause of sequestration is unknown but most probably involves an abnormal budding of the developing lung that picks up a systemic blood supply and never becomes connected with the bronchus or pulmonary vessels. Sequestrations may, in some cases, exhibit mixed pathology with components consistent with CCAMs. Extralobar sequestration is asymptomatic and is usually discovered incidentally on chest X-ray. If the diagnosis can be confirmed, e.g., by CT scan, resection is not necessary. Diagnosis of intralobar sequestration may be made prenatally and confirmed on postnatal CT scan. Alternatively, the diagnosis of intralobar sequestration may be established after repeated infections manifested by cough, fever, and consolidation in the posterior basal segment of the left lower lobe. Increasingly the diagnosis is being made in the early months of life by US, and color Doppler often can be helpful in delineating the systemic arterial supply. Removal of the entire left lower lobe is usually necessary since the diagnosis often is made late after multiple infections. Occasionally segmental resection

of the sequestered part of the lung can be performed using an open, or ideally, a thoracoscopic approach. If an open approach is used, it is important to open the chest through a low intercostal space (sixth or seventh) to gain access to the vascular attachments to the aorta. These attachments may insert into the aorta below the diaphragm; in these cases, division of the vessels as they traverse the thoracic cavity is essential. Prognosis is generally excellent. However, failure to obtain adequate control of these vessels may result in their retraction into the abdomen and result in uncontrollable hemorrhage. It is also possible to perform a combined thoracoscopic and open approach, wherein the vessels are clipped and divided thoracoscopically and then the lesion safely removed through a limited thoracotomy.

**Bronchogenic Cyst.** Bronchogenic cysts are duplication cysts originating from the airway, regardless of the identity of the lining epithelial identity. They can occur anywhere along the respiratory tract and can present at any age, although typically they present after accumulation of intraluminal contents and not within the newborn period. Histologically, they are hamartomatous and usually consist of a single cyst lined with an epithelium; the mesenchyme contains cartilage and smooth muscle. They are probably embryonic rests of foregut origin that have been pinched off from the main portion of the developing tracheobronchial tree and are closely associated in causation with other foregut duplication cysts such as those arising from the esophagus. Bronchogenic cysts may be seen on prenatal US but are discovered most often incidentally on postnatal chest X-ray. Although they may be completely asymptomatic, bronchogenic cysts may produce symptoms, usually compressive, depending on the anatomic location and size, which increases over time if there is no egress for building luminal contents. In the para-tracheal region of the neck they can produce airway compression and respiratory distress. In the lung parenchyma, they may become infected and present with fever and cough. In addition, they may cause obstruction of the bronchial lumen with distal atelectasis and infection, or they may cause mediastinal compression. Rarely, rupture of the cyst can occur. Chest X-ray usually shows a dense mass, and CT scan or MRI delineates the precise anatomic location of the lesion. Treatment consists of resection of the cyst, which may need to be undertaken in emergency circumstances for airway or cardiac compression. Resection can be performed either as an open procedure, or more commonly using a thoracoscopic approach. If resection of a common wall will result in injury to the airway, resection of the inner epithelial cyst lining after marsupialization is acceptable.

**Bronchiectasis**

Bronchiectasis is an abnormal and irreversible dilatation of the bronchi and bronchioles associated with chronic suppurative disease of the airways. Usually patients have an underlying congenital pulmonary anomaly, cystic fibrosis, or immunologic deficiency. Bronchiectasis can also result from chronic infection secondary to a neglected bronchial foreign body. The symptoms include a chronic cough, often productive of purulent secretions, recurrent pulmonary infection, and hemoptysis. The diagnosis is suggested by a chest X-ray that shows increased bronchovascular markings in the affected lobe. Chest CT delineates bronchiectasis with excellent resolution. The preferred treatment for bronchiectasis is medical, consisting of antibiotics, postural drainage, and bronchodilator therapy because many children with the disease show signs of airflow obstruction and bronchial hyperresponsiveness. Lobectomy or segmental resection is indicated for localized disease that has not responded appropriately to medical therapy. In severe cases, lung transplantation may be required to replace the terminally damaged, septic lung.

**Foreign Bodies**

The inherent curiosity of children and their innate propensity to place new objects into their mouths to fully explore them place them at great risk for aspiration. Aspirated objects can be found either in the airway or in the esophagus; in both cases the results can be life-threatening.

**Airway Ingestion.** Aspiration of foreign bodies most commonly occurs in the toddler age group. Peanuts are the most common object that is aspirated, although other materials (popcorn, for instance) may also be involved. A solid foreign body often will cause air trapping, with hyperlucency of the affected lobe or lung seen especially on expiration. Oil from the peanut is very irritating and may cause pneumonia. Delay in diagnosis can lead to atelectasis and infection. The most common anatomic location for a foreign body is the right main stem bronchus or the right lower lobe. The child usually will cough or choke while eating but may then become asymptomatic. Total respiratory obstruction with tracheal foreign body may occur; however, respiratory distress is usually mild if present at all. A unilateral wheeze is often heard on auscultation. This wheeze often leads to an inappropriate diagnosis of “asthma” and may delay the correct diagnosis for some time. Chest X-ray will show a radiopaque foreign body, but in the case of nuts, seeds, or plastic toy parts, the only clue may be hyperexpansion of the affected lobe on an expiratory film or fluoroscopy. Bronchoscopy confirms the diagnosis and allows removal of the foreign body. It can be a very simple procedure or it may be extremely difficult, especially with a smooth foreign body that cannot be grasped easily or one that has been retained for some time. The rigid bronchoscope should be used in all cases, and utilization of the optical forcesps facilitates grasping the inhaled object. Epinephrine may be injected into the mucosa when the object has been present for a long period of time, which minimizes bleeding. Bronchietasis may be seen as an extremely late phenomenon after repeated infections of the poorly aerated lung and may require partial or total resection of the affected lobe. The differential diagnosis of a bronchial foreign body includes an intraluminal tumor (i.e., carcinoid, hemangioma, or neurofibroma).

**Foreign Bodies and Esophageal Injury.** The most common foreign body in the esophagus is a coin, followed by small toy parts. Toddlers are most commonly affected. The coin is retained in the esophagus at one of three locations: the cricopharyngeus, the area of the aortic arch, or the gastroesophageal junction, all of which are areas of normal anatomic narrowing. Symptoms are variable depending on the anatomic position of the foreign body and the degree of obstruction. There is often a relatively asymptomatic period after ingestion. The initial symptoms are gastrointestinal, and include dysphagia, drooling, and dehydration. The longer the foreign body remains in the esophagus with oral secretions unable to transit the esophagus, the greater the incidence of respiratory symptoms including cough, stridor, and wheezing. These findings may be interpreted as signs of upper respiratory infections. Objects that are present for a long period of time—particularly in children who have underlying neurological impairment—may manifest as chronic dysphagia. The chest X-ray is diagnostic in the case of a coin. A contrast swallow, or preferably an esophagoscopy, may be required for nonradiopaque foreign bodies. Coins lodged within the upper
esophagus for less than 24 hours may be removed using Magill forceps during direct laryngoscopy. For all other situations, the treatment is by esophagoscopy, rigid or flexible, and removal of the foreign body. In the case of sharp foreign bodies such as open safety pins, extreme care is required on extraction to avoid injury to the esophagus. Rarely, esophagotomy is required for removal, particularly of sharp objects. Diligent follow-up is required after removal of foreign bodies, especially batteries, which can cause strictures, and sharp objects, which can injure the underlying esophagus. In the case of a retained battery, this case should be handled as a surgical emergency, as the negative pole of the battery directly damages the surrounding tissue, and tracheoesophageal fistula, aortic exsanguination, and mediastinitis have all been described after local tissue necrosis at the site where the battery has lodged.

**ESOPHAGUS**

**Esophageal Atresia and Tracheoesophageal Fistula**

The management of esophageal atresia (EA) and tracheoesophageal fistula (TEF) is one of the most gratifying pediatric surgical conditions to treat. In the not so distant past, nearly all infants born with EA and TEF died. In 1939 Ladd and Leven achieved the first success repair by ligating the fistula, placing a gastrostomy, and reconstructing the esophagus at a later time. Subsequently, Dr. Cameron Haight, in Ann Arbor, Michigan, performed the first successful primary anastomosis for esophageal atresia, which remains the current approach for treatment of this condition. Despite the fact that there are several common varieties of this anomaly and the underlying cause remains obscure, a careful approach consisting of meticulous perioperative care and attention to the technical detail of the operation can result in an excellent prognosis in most cases.

**Anatomic Varieties.** The five major varieties of EA and TEF are shown in Fig. 39-8. The most commonly seen variety is esophageal atresia with distal tracheoesophageal fistula (type C), which occurs in approximately 85% of the cases in most series. The next most frequent is pure esophageal atresia (type A), occurring in 8% to 10% of patients, followed by tracheoesophageal fistula without esophageal atresia (type E). This occurs in 8% of cases and is also referred to as an H-type fistula, based upon the anatomic similarity to that letter (Fig. 39-9). Esophageal atresia with fistula between both proximal and distal ends of the esophagus and trachea (type D) is seen in approximately 2% of cases, and type B, esophageal atresia with tracheoesophageal fistula between distal esophagus and trachea, is seen in approximately 1% of all cases.

**Etiology and Pathologic Presentation.** The esophagus and trachea share a common embryologic origin. At approximately 4 weeks’ gestation, a diverticulum forms off the anterior aspect of the proximal foregut in the region of the primitive pharynx. This diverticulum extends caudally with progressive formation of the laryngo-tracheal groove, thus, creating a separate trachea and esophagus. Successful development of these structures is the consequence of extremely intricate interplay of growth and transcription factors necessary for rostral-caudal and anterior-posterior specification. The variations in clinically observed EA and TEF that must result in failure of successful formation of these structures are depicted in Fig. 39-8. While definitive genetic mutations have been difficult to identify in isolated EA-TEF, mutations in N-myc, Sox2, and CHD7 have been characterized in syndromic EA-TEF with associated anomalies. Other congenital anomalies commonly occur in association with EA-TEF. For instance, VACTERL syndrome is associated with vertebral anomalies (absent vertebrae or hemi-vertebrae) and anorectal anomalies (imperforate anus), cardiac

defects, tracheoesophageal fistula, renal anomalies (renal agenesis, renal anomalies), and radial limb hyperplasia. In nearly 20% of the infants born with esophageal atresia, some variant of congenital heart disease occurs.

Clinical Presentation of Infants With Esophageal Atresia and Tracheoesophageal Fistula. The anatomic variant of infants with EA-TEF predicts the clinical presentation. When the esophagus ends either as a blind pouch or as a fistula into the trachea (as in types A, B, C, or D), infants present with excessive drooling, followed by choking or coughing immediately after feeding is initiated as a result of aspiration through the fistula tract. As the neonate coughs and cries, air is transmitted through the fistula into the stomach, resulting in abdominal distention. As the abdomen distends, it becomes increasingly more difficult for the infant to breathe. This leads to further atelectasis, which compounds the pulmonary dysfunction. In patients with type C and D varieties, the regurgitated gastric juice passes through the fistula where it collects in the trachea and lungs and leads to a chemical pneumonitis, which further exacerbates the pulmonary status. In many instances, the diagnosis is actually made by the nursing staff who attempt to feed the baby and notice the accumulation of oral secretions.

The diagnosis of esophageal atresia is confirmed by the inability to pass an orogastric tube into the stomach (Fig. 39-10). The dilated upper pouch may be occasionally seen on a plain chest radiograph. If a soft feeding tube is used, the tube will coil in the upper pouch, which provides further diagnostic certainty. An important alternative diagnosis that must be considered when an orogastric tube does not enter the stomach is that of an esophageal perforation. This problem can occur in infants after traumatic insertion of a nasogastric or orogastric tube. In this instance, the perforation classically occurs at the level of the piriform sinus, and a false passage is created, which prevents the tube from entering the stomach. Whenever there is any diagnostic uncertainty, a contrast study will confirm the diagnosis of EA and occasionally document the TEF. The presence of a tracheoesophageal fistula can be demonstrated clinically by finding air in the gastrointestinal tract. This can be proven at the bedside by percussion of the abdomen and confirmed by obtaining a plain abdominal radiograph. Occasionally, a diagnosis of EA-TEF can be suspected prenatally on US evaluation. Typical features include failure to visualize the stomach and the presence of polyhydramnios. These findings reflect the absence of efficient swallowing by the fetus.

In a child with esophageal atresia, it is important to identify whether coexisting anomalies are present. These include cardiac defects in 38%, skeletal defects in 19%, neurologic defects in 15%, renal defects in 15%, anorectal defects in 8%, and other abnormalities in 13%. Examination of the heart and great vessels with echocardiography is important to exclude cardiac defects, as these are often the most important predictors of survival in these infants. The echocardiogram also demonstrates whether the aortic arch is left sided or right sided, which may influence the approach to surgical repair. Vertebral anomalies are assessed by plain radiography, and a spinal US is obtained if any are detected. A patent anus should be confirmed clinically. The kidneys in a newborn may be assessed clinically by palpation. A US of the abdomen will demonstrate the presence of renal anomalies, which should be suspected in the child who fails to make urine. The presence of extremity anomalies is suspected when there are missing digits and confirmed by plain radiographs of the hands, feet, forearms, and legs. Rib anomalies may also be present. These may include the presence of a 13th rib.

Initial Management. The initial treatment of infants with EA-TEF includes attention to the respiratory status, decompression of the upper pouch, and appropriate timing of surgery. Because the major determinant of poor survival is the presence of other severe anomalies, a search for other defects including congenital cardiac disease is undertaken in a timely fashion. The initial strategy after the diagnosis is confirmed is to place the neonate in an infant warmer with the head elevated at least 30°. A sump catheter is placed in the upper pouch on continuous suction. Both of these strategies are designed to minimize the degree of aspiration from the esophageal pouch. When saliva accumulates in the upper pouch and is aspirated into the lungs, coughing, bronchospasm, and desaturation episodes can occur, which may be minimized by ensuring the patency of the sump catheter. IV antibiotic therapy is initiated, and warmed electrolyte solution is administered. Where possible, the right upper extremity is avoided as a site to start an IV line, as this location may interfere with positioning of the patient during the surgical repair. Some surgeons place a central line in all patients to facilitate the administration of antibiotics and total parenteral nutrition as needed.

The timing of repair is influenced by the stability of the patient. Definitive repair of the EA-TEF is rarely a surgical emergency. If the child is hemodynamically stable and is oxygenating well, definitive repair may be performed within 1 to 2 days after birth. This allows for a careful determination of the presence of coexisting anomalies and for selection of an experienced anesthetic team.

Management of Esophageal Atresia and Tracheoesophageal Fistula in the Preterm Infant. The ventilated, premature neonate with EA-TEF and associated hyaline membrane disease represents a patient who may develop severe, progressive, cardiopulmonary dysfunction. The tracheoesophageal fistula can worsen the fragile pulmonary status as a result of recurrent aspiration through the fistula, and as a result of increased abdominal distention, which impairs lung expansion. Moreover, the elevated airway pressure that is required to ventilate these patients can worsen the clinical course by forcing air through the fistula into the stomach, thereby exacerbating the
degree of abdominal distention and compromising lung expansion. In this situation, the first priority is to minimize the degree of positive pressure needed to adequately ventilate the child. This can be accomplished using high frequency oscillatory ventilation (HFOV). If the gastric distention becomes severe, a gastrostomy tube should be placed. This procedure can be performed at the bedside under local anesthetic, if necessary. The dilated, air-filled stomach can easily be accessed through an incision in the left-upper quadrant of the abdomen. Once the gastrostomy tube is placed and the abdominal pressure is relieved, the pulmonary status can paradoxically worsen. This is because the ventilated gas may pass preferentially through the fistula, which is the path of least resistance, and bypass the lungs thereby worsening the hypoxemia. To correct this problem, the gastrostomy tube may be placed under water seal, elevated, or intermittently clamped. If these maneuvers are to no avail, ligation of the fistula may be required. This procedure can be performed in the neonatal intensive care unit if the infant is too unstable to be transported to the operating room. These interventions allow for the infant’s underlying hyaline membrane disease to improve, for the pulmonary secretions to clear, and for the infant to reach a period of stability so that definitive repair can be performed.

**Primary Surgical Correction.** In a stable infant, definitive repair is achieved through performance of a primary esophagegosphagostomy. There are two approaches to this operation: open thoracotomy or thoracoscopy. In the open approach, the infant is brought to the operating room, intubated, and placed in the lateral decubitus position with the right side up in preparation for right posterolateral thoracotomy. If a right-sided arch was determined previously by echocardiography, consideration is given to performing the repair through the left chest, although most surgeons believe that the repair can be performed safely from the right side as well. Bronchoscopy may be performed to exclude the presence of additional, upper-pouch fistulae in cases of esophageal atresia (i.e., differentiation of types B, C, and D variants) and identification of a laryngeo-tracheoesophageal cleft.

The operative technique for primary repair is as follows (Fig. 39-11). A retropleural approach is generally used as this technique prevents widespread contamination of the thorax if a postoperative anastomotic leak occurs. The sequence of steps is as follows: (a) mobilization of the pleura to expose the structures in the posterior mediastinum; (b) division of the fistula and closure of the tracheal opening; (c) mobilization of the upper esophagus sufficiently to permit an anastomosis without tension and to determine whether a fistula is present between the upper esophagus and the trachea (forward pressure by the anesthesia staff on the sump drain in the pouch can greatly facilitate dissection at this stage of the operation; care must be taken when dissecting posteriorly to avoid violation of either the lumen of trachea and esophagus); (d) mobilization of the distal esophagus (this needs to be performed judiciously to avoid

---

**Figure 39-11.** Primary repair of type C tracheosophageal fistula. A. Right thoracotomy incision. B. Azygos vein transected, proximal and distal esophagus demonstrated, and fistula identified. C. Tracheoesophageal fistula transected and defect in trachea closed. D. End-to-end anastomosis between proximal and distal esophagus (posterior row). E. Completed anastomosis.
devascularization since the blood supply to the distal esophagus is segmental from the aorta; most of the esophageal length is obtained from mobilizing the upper pouch since the blood supply travels via the submucosa from above; (e) performing a primary esophagosophageal anastomosis (most surgeons perform this procedure in a single layer using 5-0 sutures; if there is excess tension, the muscle of the upper pouch can be circumferentially incised without compromising blood supply to increase its length; many surgeons place a transanastomotic feeding tube in order to institute feeds in the early postoperative period); and (f) placement of a retropleural drain and closure of the incision in layers.

When a minimally invasive approach is selected, the patient is prepared for right-sided, transthoracic thorascoscopic repair. The same steps as described earlier for the open repair are undertaken, and the magnification and superb optics that are provided by the thorascoscopic approach provide for superb visualization. Identification of the fistula is performed as a first step; this can be readily ligated and divided between thorascopically placed sutures. The anastomosis is performed in a single layer. The thorascopically performed TEF repair requires clear and ongoing communication between the operating surgeons and the anesthesiologist; visualization can be significantly reduced with sudden changes in lung inflation, potentially leading to the need to convert to open repair. Although clear guidelines for patient selection for a thorascoscopic repair as opposed to an open repair remain lacking, reasonable selection criteria include patients over 2.5 kg who are hemodynamically stable and without comorbidities.

Postoperative Course. The postoperative management strategy of patients with EA-TEF is influenced to a great degree by the preference of the individual surgeon and the institutional culture. Many surgeons prefer not to leave the infants intubated postoperatively to avoid the effects of positive pressure on the site of tracheal closure. However, early extubation may not be possible in babies with preoperative lung disease either from prematurity or pneumonia or when there is any vocal cord edema. When a transanastomotic tube is placed, feeds are begun slowly in the postoperative period. Some surgeons institute parenteral nutrition for several days, using a central line. The retropleural drain is assessed daily for the presence of saliva, indicating an anastomotic leak. Many surgeons obtain a contrast swallow 1 week after repair to assess the caliber of the anastomosis and to determine whether a leak is present. If there is no leak, feedings are started. The principal benefit of the thorascoscopic approach is that postoperative pain is significantly reduced, as is the requirement for postoperative narcotic analgesia.

Complications of Surgery. Anastomotic leak occurs in 10% to 15% of patients and may be seen either in the immediate postoperative period or after several days. Early leakage (i.e., within the first 24 to 48 hours) is manifested by a new pleural effusion, pneumothorax, and sepsis and requires immediate exploration. In these circumstances, the anastomosis may be completely disrupted, possibly due to excessive tension. Revision of the anastomosis may be possible. If not, cervical esophagostomy and gastrostomy placement is required, with a subsequent procedure to reestablish esophageal continuity. Anastomotic leakage that is detected after several days usually heals without intervention, particularly if a retropleural approach is used. Under these circumstances, broad spectrum antibiotics, pulmonary toilet, and optimization of nutrition are important. After approximately a week or so, a repeat esophagram should be performed, at which time the leakage may have resolved.

Strictures at the anastomosis are not infrequent (10–20%), particularly if a leak has occurred. A stricture may become apparent at any time, from the early postoperative period to months or years later. It may present as choking, gagging, or failure to thrive, but it often becomes clinically apparent with the transition to eating solid food. A contrast swallow or esophagoscopy is confirmatory, and simple dilatation is usually corrective. Occasionally, repeated dilatations are required. These may be performed in a retrograde fashion, during which a silk suture is placed into the oropharynx and delivered from the esophagus through a gastrostomy tube. Tucker dilators are then tied to the suture and passed in a retrograde fashion from the gastrostomy tube and delivered out of the oropharynx. Increasing sizes are used, and the silk is replaced at the end of the procedure where it is taped to the side of the face at one end, and to the gastrostomy tube at the other. Alternatively, image-guided balloon dilation over a guide wire may be performed, using intraoperative contrast radiography to determine the precise location of the stricture and to assess the immediate response to the dilation.

"Recurrent" tracheosophageal fistula may represent a missed upper pouch fistula or a true recurrence. This may occur after an anastomotic disruption, during which the recurrent fistula may heal spontaneously. Otherwise, reoperation may be required. Recently, the use of fibrin glue has been successful in treating recurrent fistulas, although long-term follow-up is lacking.

Gastroesophageal reflux commonly occurs after repair of EA-TEF, potentially due to alterations in esophageal motility and the anatomy of the gastroesophageal junction. The clinical manifestations of such reflux are similar to those seen in other infants with primary gastroesophageal reflux disease (GERD). A loose antireflux procedure, such as a Nissen fundoplication, is used to prevent further reflux, but the child may have feeding problems after antireflux surgery as a result of the intrinsic dysmotility of the distal esophagus. The fundoplication may be safely performed laparoscopically in experienced hands, although care should be taken to ensure that the wrap is not excessively tight.

Special Circumstances. Patients with type E tracheosophageal fistulas (also called H-type) most commonly present beyond the newborn period. Presenting symptoms include recurrent chest infections, bronchospasm, and failure to thrive. The diagnosis is suspected using barium esophagography and confirmed by endoscopic visualization of the fistula. Surgical correction is generally possible through a cervical approach with concurrent placement of a balloon catheter across the fistula and requires mobilization and division of the fistula. Outcome is usually excellent.

Patients with duodenal atresia and EA-TEF may require urgent treatment due to the presence of a closed obstruction of the stomach and proximal duodenum. In stable patients, treatment consists of repair of the esophageal anomaly and correction of the duodenal atresia if the infant is stable during surgery. If not, a staged approach should be utilized consisting of ligation of the fistula and placement of a gastrostomy tube. Definitive repair can then be performed at a later point in time.

Primary esophageal atresia (type A) represents a challenging problem, particularly if the upper and lower ends are too far apart for an anastomosis to be created. Under these
circumstances, treatment strategies include placement of a gastrostomy tube and performing serial bougienage to increase the length of the upper pouch. This occasionally allows for primary anastomosis to be performed. Occasionally, when the two ends cannot be brought safely together, esophageal replacement is required using either a gastric pull-up or colon interposition (see the following section).

**Outcome.** Various classification systems have been utilized to predict survival in patients with EA-TEF and to stratify treatment. A system devised by Waterston in 1962 was used to stratify neonates based on birth weight, the presence of pneumonia, and the identification of other congenital anomalies. In response to advances in neonatal care, the surgeons from the Montreal Children’s Hospital proposed a new classification system in 1993. In the Montreal experience only two characteristics independently affected survival: preoperative ventilator dependence and associated major anomalies. Pulmonary disease as defined by ventilator dependence appeared to be more accurate than pneumonia. When the two systems were compared, the Montreal system more accurately identified children at highest risk. Spitz and colleagues analyzed risk factors in infants who died with EA-TEF. Two criteria were found to be important predictors of outcome: birth weight less than 1500 g and the presence of major congenital cardiac disease. A new classification for predicting outcome in esophageal atresia was therefore proposed: group I: birth weight ≥1500 g, without major cardiac disease, survival 97% (283 of 293); group II: birth weight <1500 g, or major cardiac disease, survival 59% (41 of 70); and group III: birth weight <1500 g, and major cardiac disease, survival 22% (2 of 9).

In general, surgical correction of EA-TEF leads to a satisfactory outcome with nearly normal esophageal function in most patients. Overall survival rates of greater than 90% have been achieved in patients classified as stable, in all the various staging systems. Unstable infants have an increased mortality (40–60% survival) because of potentially fatal associated cardiac and chromosomal anomalies or prematurity. However, the use of a staged procedure also has increased survival in even these high-risk infants.

**Corrosive Injury of the Esophagus**

Injury to the esophagus after ingestion of corrosive substances most commonly occurs in the toddler age group. Both strong alkali and strong acids produce injury by liquefaction or coagulation necrosis, and since all corrosive agents are extremely hygroscopic, the caustic substance will cling to the esophageal epithelium. Subsequent strictures occur at the anatomic narrowed areas of the esophagus, cricopharyngeus, midesophagus, and gastroesophageal junction. A child who has swallowed an injurious substance may be symptom-free but usually will be drooling and unable to swallow saliva. The injury may be restricted to the oropharynx and esophagus, or it may extend to include the stomach. There is no effective immediate antidote. Diagnosis is by careful physical examination of the mouth and endoscopy with a flexible or rigid esophagoscope. It is important to endoscope only to the first level of the burn in order to avoid perforation. Early barium swallow may delineate the extent of the mucosal injury. It is important to realize that the esophagus may be burned without evidence of injury to the mouth. Although previously used routinely, steroids have not been shown to alter stricture development or modify the extent of injury and are no longer part of the management of caustic injuries. Antibiotics are administered during the acute period.

The extent of injury is graded endoscopically as either mild, moderate, or severe (grade I, II, or III). Circumferential esophageal injuries with necrosis have an extremely high likelihood of stricture formation. These patients should undergo placement of a gastrostomy tube once clinically stable. A string should be inserted through the esophagus either immediately or during repeat esophagoscopy several weeks later. When established strictures are present (usually 3 to 4 weeks), dilatation is performed. Fluoroscopically guided balloon dilatation of the stricture is effective, which should be performed in association with esophagoscopy, and allows for a precise evaluation of the nature and extent of the stenosis. The procedure should be performed under general anesthesia, and care must be taken to ensure there is no airway injury. Dislodgment of the endotracheal tube can occur during this procedure, and careful communication with the anesthesiologist is critical during the procedure.

In certain circumstances, especially if a gastrostomy tube has been placed, retrograde dilatation may be performed, using graduated dilators brought through the gastrostomy and advanced into the esophagus via the transesophageal string. Management of esophageal perforation during dilatation should include antibiotics, irrigation, and closed drainage of the thoracic cavity to prevent systemic sepsis. When recognition is delayed or if the patient is systemically ill, esophageal diversion may be required with staged reconstruction at a later time.

Although the native esophagus can be preserved in most cases, severe stricture formation that does not respond to dilatation is best managed by esophageal replacement. The most commonly used options for esophageal substitution are the colon (right colon or transverse/left colon) and the stomach (gastric tubes or gastric pull-up). Pedicled or free grafts of the jejunum are rarely used. The right colon is based on a pedicle of the middle colic artery, and the left colon is based on a pedicle of the middle colic or left colic artery. Gastric tubes are fashioned from the greater curvature of the stomach based on the pedicle of the left gastropiploic artery. When the entire stomach is used, as in gastric pull-up, the blood supply is provided by the right gastric artery. The neoesophagus may traverse (a) submucosally; (b) through a transthoracic route; or (c) through the posterior mediastinum to reach the neck. A feeding jejunostomy is placed at the time of surgery and tube feedings are instituted once the postoperative ileus has resolved. Long-term follow-up has shown that all methods of esophageal substitution can support normal growth and development, and the children enjoy reasonably normal eating habits. Because of the potential for late complications such as ulceration and stricture, follow-up into adulthood is mandatory, but complications appear to diminish with time.

**Gastroesophageal Reflux**

Gastroesophageal reflux (GER) occurs to some degree in all children and refers to the passage of gastric contents into the esophagus. By contrast, gastroesophageal reflux disease (GERD) describes the situation where reflux is symptomatic. Typical symptoms include failure to thrive, bleeding, stricture formation, reactive airway disease, aspiration pneumonia, or apnea. Failure to thrive and pulmonary problems are particularly common in infants with GERD, whereas strictures and esophagitis are more common in older children and adolescents. GERD is particularly problematic in neurologically impaired children.

**Clinical Manifestations.** Because all infants experience occasional episodes of GER to some degree, care must be taken
before a child is labeled as having pathologic reflux. A history of repeated episodes of vomiting that interferes with growth and development, or the presence of apparent life-threatening events, are required for the diagnosis of GERD. In older children, esophageal bleeding, stricture formation, severe heartburn, or the development of Barrett’s esophagus unequivocally connotes pathologic reflux or GERD. In neurologically impaired children, vomiting due to GER must be distinguished from chronic retching.

The workup of patients suspected of having GERD includes documentation of the episodes of reflux and evaluation of the anatomy. A barium swallow should be performed as an initial test. This will determine whether there is obstruction of the stomach or duodenum (due to duodenal webs or pyloric stenosis) and will determine whether malrotation is present. The frequency and severity of reflux should be assessed using a 24-hour pH probe study. Although this test is poorly tolerated, it provides the most accurate determination that GERD is present. Esophageal endoscopy with biopsies may identify the presence of esophagitis, and it is useful to determine the length of intrabdominal esophagus and the presence of Barrett’s esophagus. Some surgeons obtain a radioisotope “milk scan” to evaluate gastric emptying, although there is little evidence to show that this test changes management when a diagnosis of GERD has been confirmed using the aforementioned modalities.

**Treatment.** Most patients with GERD are treated initially by conservative means. In the infant, propping and thickening the formula with rice cereal are generally recommended. Some authors prefer a prone, head-up position. In the infant unresponsive to position and formula changes and the older child with severe GERD, medical therapy is based on gastric acid reduction with an H₂-blocking agent and/or a proton pump inhibitor. Medical therapy is successful in most neurologically normal infants and younger children, many of whom will outgrow their need for medications. In certain patients, however, medical treatment does not provide symptomatic relief and surgery is therefore indicated. The least invasive surgical option includes the placement of a nasojejunal or gastrojejunal feeding tube. The tubes often become dislodged, acid reflux still occurs, and bolus feeding is generally not possible. Fundoplication provides definitive treatment for gastroesophageal reflux and is highly effective in most circumstances. The fundus may be wrapped around the distal esophagus either 360° (i.e., Nissen) or to lesser degrees (i.e., Thal or Toupet). At present, the standard approach in most children is to perform these procedures laparoscopically whenever possible. In children with feeding difficulties and in infants under 1 year of age, a gastrostomy tube should be placed at the time of surgery. Early postoperative complications include pneumonia and atelectasis, often due to inadequate pulmonary toilet and pain control with abdominal splinting. Late postoperative complications include wrap breakdown with recurrent reflux, which may require repeat fundoplication, and dysphagia due to a wrap performed too tightly, which generally responds to dilation. These complications are more common in children with neurologic impairment. The keys to successful surgical management of patients with GERD include careful patient selection and meticulous operative technique. There are emerging concerns regarding the long-term use of acid reducing agents, which may increase the frequency with which antireflux procedures are performed in children, especially those with neurological impairment.

**GASTROINTESTINAL TRACT**

**An Approach to the Vomiting Infant**

All infants vomit. Because infant vomiting is so common, it is important to differentiate between normal and abnormal vomiting, which may be indicative of a potentially serious underlying disorder. In order to determine the seriousness of a particular infant’s bouts of emesis, one needs to characterize what the vomit looks like and how sick the baby is. Vomit that looks like feeds and comes up immediately after a feeding is almost always gastroesophageal reflux. This may or may not be of concern, as described earlier. Vomiting that occurs a short while after feeding, or vomiting that projects out of the baby’s mouth may be indicative of pyloric stenosis. By contrast, vomit that has any green color in it is always worrisome. This may be reflective of intestinal volvulus, an underlying infection, or some other cause of intestinal obstruction. A more detailed description of the management of these conditions is provided in the following sections.

**Hypertrophic Pyloric Stenosis**

**Clinical Presentation.** Infants with hypertrophic pyloric stenosis (HPS) typically present with nonbilious vomiting that becomes increasingly projectile, over the course of several days to weeks due to progressive thickening of the pylorus muscle. HPS occurs in approximately 1 in 300 live births and commonly in infants between 3 and 6 weeks of age. Male-to-female ratio is nearly 5:1.

Eventually as the pyloric muscle thickening progresses, the infant develops a complete gastric outlet obstruction and is no longer able to tolerate any feeds. Over time, the infant becomes increasingly hungry, unsuccessfully feeds repeatedly, and becomes increasingly dehydrated. Wet diapers become less frequent, and there may even be a perception of less passage of flatus. HPS may be associated with jaundice due to an indirect hyperbilirubinemia, although the nature of this relation is unclear.

The cause of HPS has not been determined. Studies have shown that HPS is found in several generations of the same family, suggesting a familial link. Recently, a genome-wide significant locus for pyloric stenosis at chromosome 11q23.3 was identified, and the single-nucleotide polymorphism (SNP) with the greatest significance was associated with part of the genome that regulates cholesterol. It is not clear how this links to the development of pyloric stenosis, but it does suggest a potential dietary link.

Infants with HPS develop a hypochloremic, hypokalemic metabolic alkalosis. The urine pH level is high initially, but eventually drops because hydrogen ions are preferentially exchanged for sodium ions in the distal tubule of the kidney as the hypochloremia becomes severe (paradoxical aciduria). While in the past the diagnosis of pyloric stenosis was most often made on physical examination by palpation of the typical “olive” in the right upper quadrant and the presence of visible gastric waves on the abdomen, current standard of care is to perform an US, which can diagnose the condition accurately in 95% of patients. Criteria for US diagnosis include a channel length of over 16 mm and pyloric thickness over 4 mm. It is important to note that younger babies may have lower values...
for pyloric thickness and still be abnormal, and a close clinical correlation with the US result is mandatory. In cases in which the diagnosis remains unclear, upper gastrointestinal evaluation by contrast radiography will reveal delayed passage of contents from the stomach through the pyloric channel and a typical thickened appearance to the pylorus.

**Treatment.** Given frequent fluid and electrolyte abnormalities at time of presentation, pyloric stenosis is never a surgical emergency. Fluid resuscitation with correction of electrolyte abnormalities and metabolic alkalosis is essential prior to induction of general anesthesia for operation. For most infants, fluid containing 5% dextrose and 0.45% saline with added potassium of 2 to 4 mEq/kg over 24 hours at a rate of approximately 150 to 175 mL/kg for 24 hours will correct the underlying deficit. It is important to ensure that the child has an adequate urine output (>2 cc/kg per hour) as further evidence that rehydration has occurred.

After resuscitation, a Fredet-Ramstedt pyloromyotomy is performed (Fig. 39-12). It may be performed using an open or laparoscopic approach. The open pyloromyotomy is performed through either an umbilical or a right upper quadrant transverse abdominal incision. The former route is cosmetically more appealing, although the transverse incision provides easier access to the antrum and pylorus. In recent years, the laparoscopic approach has gained great popularity. Two randomized trials have demonstrated that both the open and laparoscopic approaches may be performed safely with equal incidence of postoperative complications, although the cosmetic result is clearly superior with the laparoscopic approach. Whether done through an open or laparoscopic approach, surgical treatment of pyloric stenosis involves splitting the pyloric muscle while leaving the underlying submucosa intact. The incision extends from just proximal to the pyloric vein of Mayo to the gastric antrum; it typically measures between 1 and 2 cm in length. Postoperatively, IV fluids are continued for several hours, after which Pedialyte is offered, followed by formula or breast milk, which is gradually increased to 24 cc every 3 hours. Most infants can be discharged home within 24 to 48 hours following surgery. Recently, several authors have shown that ad lib feeds are safely tolerated by the neonate and result in a shorter hospital stay.

The complications of pyloromyotomy include perforation of the mucosa (1–3%), bleeding, wound infection, and recurrent symptoms due to inadequate myotomy. When perforation occurs, the mucosa is repaired with a stitch that is placed to tack the mucosa down and reapproximate the serosa in the region of the tear. A nasogastric tube is left in place for 24 hours. The outcome is generally very good.

### Intestinal Obstruction in the Newborn

The cardinal symptom of intestinal obstruction in the newborn is bilious emesis. Prompt recognition and treatment of neonatal intestinal obstruction can truly be lifesaving.

The incidence of neonatal intestinal obstruction is 1 in 2000 live births. The approach to intestinal obstruction in the newborn infant is critical for timely and appropriate intervention. When a neonate develops bilious vomiting, one must consider a surgical etiology. Indeed, the majority of newborns with bilious emesis have a surgical condition. In evaluating a potential intestinal obstruction, it is helpful to determine whether the intestinal obstruction is either proximal or distal to the ligament of Treitz. One must conduct a detailed prenatal and immediate postnatal history and a thorough physical examination. In all cases of intestinal obstruction, it is vital to obtain abdominal films in the supine and upright (or lateral decubitus) views to assess the presence of air-fluid levels or free air as well as how far downstream air has managed to travel. Importantly, one should recognize that it is difficult to determine whether a loop of bowel is part of either the small or large intestine, as neonatal bowel lacks clear features, such as haustra or plica circulares, normally present in older children or adults. As such, contrast imaging may be necessary for diagnosis in some instances.

Proximal intestinal obstructions typically present with bilious emesis and minimal abdominal distention. The normal neonate should have a rounded, soft abdomen; in contrast, a neonate with a proximal intestinal obstruction typically exhibits a flat or scaphoid abdomen. On a series of upright and supine abdominal radiographs, one may see a paucity or absence of bowel gas, which normally should be present throughout the gastrointestinal tract within 24 hours. Of utmost importance is the exclusion of a malrotation with midgut volvulus from all other intestinal obstructions as this is a surgical emergency.

Distal obstructions typically present with bilious emesis and abdominal distention. Passage of black-green meconium should have occurred within the first 24 to 38 hours. Of great

Figure 39-13. Abdominal X-ray showing “double bubble” sign in a newborn infant with duodenal atresia. The two “bubbles” are numbered.
when there is diagnostic uncertainty, or when distal intestinal obstruction is apparent, a barium enema is useful to establish whether a microcolon is present and to diagnose the presence of meconium plugs, small left colon syndrome, Hirschsprung’s disease, or meconium ileus. Judicious use of barium enema is therefore required in order to safely manage neonatal intestinal obstruction, based on an understanding of the expected level of obstruction.

Surgical correction of the small intestinal atresia should be performed relatively urgently, especially when there is a possibility of volvulus. At laparotomy, one of several types of atresia will be encountered. In type 1 there is a mucosal atresia with intact muscularis. In type 2, the atretic ends are connected by a fibrous band. In type 3A, the two ends of the atresia are separated by a V-shaped defect in the mesentery. Type 3B is an “apple-peel” deformity or “Christmas tree” deformity in which the bowel distal to the atresia receives its blood supply in a retrograde fashion from the ileocolic or right colic artery (Fig. 39-15). In type 4 atresia, there are multiple atresias with a “string of sausage” or “string of beads” appearance. Disparity in lumen size between the proximal distended bowel and the small diameter of collapsed bowel distal to the atresia has led to a number of innovative techniques of anastomosis. However, under most circumstances, an anastomosis can be performed using the end-to-back technique in which the distal, compressed loop is “fish-mouthed” along its antimesenteric border. The proximal distended loop can be tapered as previously described. Because the distended proximal bowel rarely has normal motility, the extremely dilated portion should be resected prior to performing the anastomosis.

Occasionally the infant with intestinal atresia will develop ischemia or necrosis of the proximal segment secondary to volvulus of the dilated, bulbous, blind-ending proximal bowel. Under these conditions, primary anastomosis may be performed as described earlier. Alternatively, an end ileostomy and mucus fistula should be created, and the anastomosis should be deferred to another time after the infant stabilizes.

Malrotation and Midgut Volvulus
Embryology. During the sixth week of fetal development, the midgut grows too rapidly to be accommodated in the abdominal cavity and therefore herniates into the umbilical cord. Between the 10th and 12th week, the midgut returns to the abdominal cavity, undergoing a 270° counterclockwise rotation around the superior mesenteric artery. Because the duodenum also rotates caudal to the artery, it acquires a C-loop, which traces this path. The cecum rotates cephalad to the artery, which determines the location of the transverse and ascending colon. Subsequently, the duodenum becomes fixed retroperitoneally in its third portion and at the ligament of Treitz, while the cecum becomes fixed to the lateral abdominal wall by peritoneal bands. The takeoff of the branches of the superior mesenteric artery elongates and becomes fixed along a line extending from its emergence from the aorta to the cecum in the right lower quadrant. Genetic mutations likely disrupt the signaling critical for normal intestinal rotation. For instance, mutations in the gene BCL6 resulting in absence of left-sided expression of its transcript lead to reversed cardiac orientation, defective ocular development, and malrotation. The essential role of the dorsal gut mesentery in mediating normal intestinal rotation and the role of the forkhead box transcription factor FOXF1 in formation of the dorsal mesentery in mice are consistent with the noted association of intestinal malrotation with alveolar capillary dysplasia, caused by mutations in FOXF1. If rotation is incomplete, the cecum remains in the epigastrium, but the bands fixing the duodenum to the retroperitoneum and cecum continue to form. This results in (Ladd’s) bands extending from the cecum to the lateral abdominal wall and crossing the duodenum, which creates the potential for obstruction. The mesenteric takeoff remains confined to the epigastrium, resulting in a narrow pedicle suspending all the branches of the superior mesenteric artery and the entire midgut. A volvulus may therefore occur around the mesentery. This twist not only obstructs the proximal jejunum but also cuts off the blood supply to the midgut. Intestinal obstruction and complete infarction of the midgut occur unless the problem is promptly corrected surgically.

Presentation and Management. Midgut volvulus can occur at any age, though it is seen most often in the first few weeks of life. Bilious vomiting is usually the first sign of volvulus and all infants with bilious vomiting must be evaluated rapidly to ensure that they do not have intestinal malrotation with volvulus. The child with irritability and bilious emesis should raise particular suspicions for this diagnosis. If left untreated, vascular...
compromise of the midgut initially causes bloody stools, but it eventually results in circulatory collapse. Additional clues to the presence of advanced ischemia of the intestine include erythema and edema of the abdominal wall, which progresses to shock and death. It must be reemphasized that the index of suspicion for this condition must be high, since abdominal signs are minimal in the early stages. Abdominal films show a paucity of gas throughout the intestine with a few scattered air-fluid levels (Fig. 39-16). When these findings are present, the patient should undergo immediate fluid resuscitation to ensure adequate perfusion and urine output followed by prompt exploratory laparotomy. In cases where the child is stable, laparoscopy may be considered.

Often the patient will not appear ill, and the plain films may suggest partial duodenal obstruction. Under these conditions, the patient may have malrotation without volvulus. This is best diagnosed by an upper gastrointestinal series that shows incomplete rotation with the duodenojejunal junction displaced to the right. The duodenum may show a corkscrew effect diagnosing volvulus, or complete duodenal obstruction, with the small bowel loops entirely in the right side of the abdomen. Barium enema may show a displaced cecum, but this sign is unreliable, especially in the small infant in whom the cecum is normally in a somewhat higher position than in the older child.

When volvulus is suspected, early surgical intervention is mandatory if the ischemic process is to be avoided or reversed. Volvulus occurs clockwise, and it is therefore untwisted counterclockwise. This can be remembered using the memory aid "turn back the hands of time." Subsequently, a Ladd’s procedure is performed. This operation does not correct the malrotation, but it does broaden the narrow mesenteric pedicle to prevent volvulus from recurring. This procedure is performed as follows (Fig. 39-17). The bands between the cecum and the abdominal wall and between the duodenum and terminal ileum are divided sharply to splay out the superior mesenteric artery and its branches. This maneuver brings the straightened duodenum into the right lower quadrant and the cecum into the left lower quadrant. The appendix is usually removed to avoid diagnostic errors in later life. No attempt is made to suture the cecum or duodenum in place. With advanced ischemia, reduction of the volvulus without the Ladd’s procedure is accomplished, and a “second look” 24 to 36 hours later often may show some vascular recovery. A plastic transparent silo may be placed to facilitate constant evaluation of the intestine and to plan for the timing of reexploration. Clearly necrotic bowel can then be resected conservatively. With early diagnosis and correction, the prognosis is excellent. However, diagnostic delay can lead to mortality or to short-gut syndrome requiring intestinal transplantation.

A subset of patients with malrotation will demonstrate chronic obstructive symptoms. These symptoms may result from Ladd’s bands across the duodenum, or occasionally, from intermittent volvulus. Symptoms include intermittent abdominal pain and intermittent vomiting that may occasionally be bilious. Infants with malrotation may demonstrate failure to thrive, and they may be diagnosed initially as having gastroesophageal reflux disease. Surgical correction using Ladd’s procedure as described earlier can prevent volvulus from occurring and improve symptoms in many instances. In these cases, a laparoscopic approach may be taken, where diagnosis of Ladd’s bands and direct visualization of the relevant anatomy may be achieved.

**Meconium Ileus**

**Pathogenesis and Clinical Presentation.** Infants with cystic fibrosis have characteristic pancreatic enzyme deficiencies and abnormal chloride secretion in the intestine that result in the production of viscous, water-poor meconium. This phenotype is explained by the presence of mutations in the CFTR gene. Meconium ileus occurs when this thick, highly viscous meconium becomes impacted in the ileum and leads to high-grade intestinal obstruction. Recently, additional mutations were identified in genes encoding multiple apical plasma membrane proteins of infants with meconium ileus. Meconium ileus can be either uncomplicated, in which there is no intestinal perforation, or complicated, in which prenatal perforation of the intestine has occurred or vascular compromise of the distended ileum develops. Antenatal US may reveal the presence of intra-abdominal or scrotal calcifications, or distended bowel loops. These infants present shortly after birth with progressive abdominal distention and failure to pass meconium with intermittent bilious emesis. Abdominal radiographs show dilated loops of intestine. Because the enteric contents are so viscous, air-fluid levels do not form, even when obstruction is complete. Small bubbles of gas become entrapped in the inspissated meconium in the distal ileum, where they produce a characteristic “ground glass” appearance.

The diagnosis of meconium ileus is confirmed by a contrast enema that typically demonstrates a microcolon. In patients with uncomplicated meconium ileus, the terminal ileum is filled with pellets of meconium. In patients with complicated meconium ileus, intraperitoneal calcifications form, producing an eggshell pattern on plain abdominal X-ray.

**Management.** The treatment strategy depends on whether the patient has complicated or uncomplicated meconium ileus. Patients with uncomplicated meconium ileus can be
treated nonoperatively. Either dilute water-soluble contrast or N-acetylcysteine (Mucomyst) is infused transanally via catheter under fluoroscopic control into the dilated portion of the ileum. Because these agents act by absorbing fluid from the bowel wall into the intestinal lumen, infants undergoing treatment are at risk of fluid and electrolyte abnormalities so that appropriate resuscitation of the infant during this maneuver is extremely important. The enema may be repeated at 12-hour intervals over several days until all the meconium is evacuated. Inability to reflux the contrast into the dilated portion of the ileum signifies the presence of an associated atresia or complicated meconium ilus, and thus warrants exploratory laparotomy. If surgical intervention is required because of failure of contrast enemas to relieve obstruction, operative irrigation with dilute contrast agent, N-acetylcysteine, or saline through a purse-string suture may be successful. Alternatively, resection of the distended terminal ileum is performed, and the meconium pellets are flushed from the distal small bowel. At this point, an end ileostomy may be created. The distal bowel may be brought up as a mucus fistula or sewn to the side of the ileum as a classic Bishop-Koop anastomosis. An end-to-end anastomosis may also be considered in the appropriate setting (Fig. 39-18).

**Necrotizing Enterocolitis**

**Clinical Features.** Necrotizing enterocolitis (NEC) is the most frequent and lethal gastrointestinal disorder affecting the intestine of the stressed, preterm neonate. The overall mortality ranges between 10% and 50%. Advances in neonatal care such as surfactant therapy as well as improved methods of mechanical ventilation have resulted in increasing numbers of
low-birth-weight infants surviving neonatal hyaline membrane disease. An increasing proportion of survivors of neonatal respiratory distress syndrome will therefore be at risk for developing NEC. Consequently, it is estimated that NEC may eventually surpass respiratory distress syndrome as the principal cause of death in the preterm infant. This is especially relevant, as NEC is a significant risk factor for more severe respiratory distress in premature infants.

Multiple risk factors have been associated with the development of NEC. These include prematurity, initiation of enteral feeding, bacterial infection, intestinal ischemia resulting from birth asphyxia, umbilical artery cannulation, persistence of a patent ductus arteriosus, cyanotic heart disease, and maternal cocaine abuse. Nonetheless, the mechanisms by which these complex interacting etiologies lead to the development of the disease remain undefined. The only consistent epidemiologic precursors for NEC are prematurity and enteral alimentation, representing the commonly encountered clinical situation of a stressed infant who is fed enterally. Of note, there is some debate regarding the type and strategy of enteral alimentation in the pathogenesis of NEC. A prospective randomized study showed no increase in the incidence of NEC despite an aggressive feeding strategy.

The indigenous intestinal microbial flora has been shown to play a central role in the pathogenesis of NEC. The importance of bacteria in the pathogenesis of NEC is further supported by the finding that NEC occurs in epistemic waves that can be abrogated by infection control measures, and the fact that NEC usually develops at least 10 days postnatally, when the GI tract is colonized by coliforms. More recently, outbreaks of NEC have been reported in infants fed formula contaminated with *Enterobacter sakazakii*. Common bacterial isolates from the blood, peritoneal fluid, and stool of infants with advanced NEC include *Escherichia coli*, *Enterobacter*, Klebsiella, and occasionally, coagulase-negative *Staphylococcus* species.

NEC may involve single or multiple segments of the intestine, most commonly the terminal ileum, followed by the colon. The gross findings in NEC include bowel distention with patchy areas of thinning, pneumatosis, gangrene, or frank perforation. The microscopic features include the appearance of a “bland infarct” characterized by full thickness necrosis.
Clinical Manifestations. Infants with NEC present with a spectrum of disease. In general, the infants are premature and may have sustained one or more episodes of stress, such as birth asphyxia, or they may have congenital cardiac disease. The clinical picture of NEC has been characterized as progressing from a period of mild illness to that of severe, life-threatening sepsis by Bell and colleagues. Although not all infants progress through the various “Bell stages,” this classification scheme provides a useful format to describe the clinical picture associated with the development of NEC. In the earliest stage (Bell stage I), infants present with feeding intolerance. This is suggested by vomiting or by the presence of a large residual volume from a previous feeding in the stomach at the time of the next feeding. Following appropriate treatment, which consists of bowel rest and IV antibiotics, many of these infants will not progress to more advanced stages of NEC. These infants are colloquially described as suffering from an “NEC scare” and represent a population of neonates who are at risk of developing more severe NEC if a more prolonged period of stress supervenes.

Infants with Bell stage II have established NEC that is not immediately life-threatening. Clinical findings include abdominal distention and tenderness, bilious nasogastric aspirate, and bloody stools. These findings indicate the development of intestinal ileus and mucosal ischemia, respectively. Abdominal examination may reveal a palpable mass indicating the presence of an inflamed loop of bowel, diffuse abdominal tenderness, cellulitis, and edema of the anterior abdominal wall. The infant may appear systemically ill, with decreased urine output, hypotension, tachycardia, and noncardiac pulmonary edema. Hematologic evaluation reveals either leukocytosis or leukopenia, an increase in the number of bands, and thrombocytopenia. An increase in the blood urea nitrogen and plasma creatinine level may be found, which signify the development of renal dysfunction. The diagnosis of NEC may be confirmed by abdominal radiography. The pathognomonic radiographic finding in NEC is pneumatosis intestinalis, which represents invasion of the ischemic mucosa by gas producing microbes (Fig. 39-19). Other findings include the presence of ileus or portal venous gas. The latter is a transient finding that indicates the presence of severe NEC with intestinal necrosis. A fixed loop of bowel may be seen on serial abdominal radiographs, which suggests the possibility that a diseased loop of bowel, potentially with a localized perforation, is present. Although these infants are at risk of progressing to more severe disease, with timely and appropriate treatment, they often recover.

Infants with Bell stage III have the most advanced form of NEC. Abdominal radiographs often demonstrate the presence of pneumoperitoneum, indicating that intestinal perforation has occurred. These patients may develop a fulminant course with progressive peritonitis, acidosis, sepsis, disseminated intravascular coagulopathy, and death.

Pathogenesis of Necrotizing Enterocolitis. Several theories have been proposed to explain the development of NEC. In general terms, the development of diffuse pneumatosis intestinalis—which is associated with the development of stage II NEC—is thought to be due to the presence of gas within the wall of the intestine from enteric bacteria, suggesting the causative role of bacteria in the pathogenesis of NEC. Furthermore, the development of pneumoperitoneum indicates disease progression with severe disruption of the intestinal barrier (intestinal perforation).

Finally, systemic sepsis with diffuse multisystem organ dysfunction suggests the role for circulating proinflammatory cytokines in the pathogenesis of NEC. It has also been demonstrated that the premature intestine responds in an exaggerated fashion to bacterial products, rendering the host susceptible to barrier dysfunction and the development of NEC. Various groups have shown that NEC pathogenesis requires activation of the bacterial receptor—Toll-like receptor 4 (TLR4)—in the intestinal epithelium. The expression of TLR4 is significantly elevated in the premature infant intestine as compared with the full-term infant intestine, a consequence of the role that TLR4 plays in normal intestinal development. When the infant is born prematurely and TLR4 expression levels are elevated, subsequent activation of TLR4 by colonizing bacteria in the neonatal intensive care unit leads to the induction of a severe proinflammatory response and the development of NEC. It is noteworthy that breast milk—long known to be protective against NEC—is able to suppress TLR4 signaling and that synthetic TLR4 antagonists are known to prevent NEC in preclinical models, suggesting the possibility of preventive approaches for this disease.

Treatment. In all infants suspected of having NEC, feedings are discontinued, a nasogastric tube is placed, and broad-spectrum parenteral antibiotics are given. The infant is resuscitated, and inotropes are administered to maintain perfusion as needed. Intubation and mechanical ventilation may be required to maintain oxygenation. Total parenteral nutrition is started. Subsequent treatment may be influenced by the particular stage of NEC that is present. Patients with Bell stage I are closely monitored and generally remain NPO and on IV antibiotics for 7 to 10 days, prior to reintroducing enteral nutrition. If the infant fully recovers, feedings may be reinitiated.

Patients with Bell stage II disease merit close observation. Serial physical examinations are performed looking for the development of diffuse peritonitis, a fixed mass, progressive abdominal wall cellulitis or systemic sepsis. If infants fail to improve after several days of treatment, consideration should be given to exploratory laparotomy. Paracentesis may be performed, and if the Gram stain demonstrates multiple organisms and leukocytes, perforation of the bowel should be suspected, and patients should undergo laparotomy.

Figure 39-19. Abdominal radiograph of infant with necrotizing enterocolitis. Arrows point to area of pneumatosis intestinalis.
In the most severe form of NEC (Bell stage III), patients have definite intestinal perforation or have not responded to nonoperative therapy. Two schools of thought direct further management. One group favors exploratory laparotomy. At laparotomy, frankly gangrenous or perforated bowel is resected, and the intestinal ends are brought out as stomas. When there is massive intestinal involvement, marginally viable bowel is retained and a “second-look” procedure is carried out after the infant stabilizes (24–48 hours). Patients with extensive necrosis at the second look may be managed by placing a proximal diverting stoma, resecting bowel that is definitely not viable, and leaving questionably viable bowel behind, distal to the diverted segment. When the intestine is viable except for a localized perforation without diffuse peritonitis and if the infant’s clinical condition permits, intestinal anastomosis may be performed. In cases where the diseased, perforated segment cannot be safely resected, drainage catheters may be left in the region of the diseased bowel, and the infant is allowed to stabilize.

An alternative approach to the management of infants with perforated NEC involves drainage of the peritoneal cavity. This may be performed under local anesthesia at the bedside, and it can be an effective means of stabilizing the desperately ill infant by relieving increased intra-abdominal pressure and allowing ventilation. When successful, this method also allows for drainage of perforated bowel by establishing a controlled fistula. Approximately one-third of infants treated with drainage alone survive without requiring additional operations. Infants that do not respond to peritoneal drainage alone after 48 to 72 hours should undergo laparotomy. This procedure allows for the resection of frankly necrotic bowel diversion of the fecal stream and facilitates more effective drainage. It is noteworthy that a recent randomized controlled trial demonstrated that outcomes were similar in infants with NEC that were treated either with primary peritoneal drainage or laparotomy, although this study was criticized for the large number of patients who were excluded from randomization. There was also concern that a number of patients who were thought to have NEC may actually have had spontaneous intestinal perforation, given their lack of pneumatosis and relatively early onset of presentation; these patients would be anticipated to improve after peritoneal drainage due to the more local nature of their disease process.

Necrotizing Enterocolitis in Older Infants. Although NEC is typically a disease that affects preterm infants, several independent groups have reported a tendency for early onset of NEC in term and near-term infants. In these patients, the pattern of disease was found to be different from that found in premature infants. Specifically, NEC in older infants typically is localized to the end of the small intestine and beginning of the colon, suggestive of an ischemic pathophysiologic. There are four pertinent associations that are observed in term infants that develop NEC: congenital heart disease, in utero growth restriction, polycythemia, and perinatal hypoxic-ischemic events. As with NEC in preterm infants, NEC in older patients is also associated with formula consumption and is very rare in exclusively breastfed infants. Patients with NEC at full term typically present with bloody stools and may be characterized by rapid onset of symptoms and a fulminant course. Thus, although it is true that NEC is typically a disease of premature babies, in the appropriate setting, NEC can develop at any age.

Spontaneous Intestinal Perforation Versus Necrotizing Enterocolitis. In addition to NEC, preterm infants with intestinal pathology may develop spontaneous intestinal perforation (SIP). SIP is a distinct clinical entity from NEC, and it is essentially a perforation in the terminal ileum. The histopathology of SIP is different from NEC. Specifically, the mucosa is intact and not necrotic, there is no sign of ischemia, and the submucosa is thinned at the site of perforation. In contrast to NEC, pneumatosis intestinalis is absent in SIP. Moreover, the demographics of NEC and SIP are slightly different, in that patients with SIP tend to be slightly more premature, smaller, and more likely to have been on inotropic support. SIP occurs in two separate time points, both within a few days after birth and approximately 10 days later, and in all cases, free air will be present, but pneumatosis will be absent. Because patients with SIP have isolated disease without necrosis or systemic inflammation, they tend to have a better outcome and are likely to respond better to peritoneal drainage. In short, the diagnosis of SIP versus NEC has important prognostic significance. Treatment for SIP should primarily be surgical, with intestinal resection and stoma creation, followed by stoma reversal once the child is stable.

In both SIP and NEC, the timing of stoma closure is a matter of ongoing debate. Whereas in the past, pediatric surgeons typically waited until the child reached 5 kg or so, experience indicates that there is no benefit in waiting this long, and children tolerate stoma closure very well when they are at much lower weights. One approach is to close the stoma when the calculated gestational age is approximately 38 to 40 weeks, which will, on average, be at approximately 6 weeks after the initial surgery. This time point is selected based on the observation that proinflammatory gene expression has normalized by then, and NEC recurrence is very unlikely.

Outcome. Survival in patients with NEC is dependent on the stage of disease, the extent of prematurity, and the presence of associated comorbidities. Survival by stage has recently been shown to be approximately 85%, 65%, and 35% for stages I, II, and III, respectively. Strictures develop in 20% of medically or surgically treated patients, and a contrast enema is mandatory before reestablishing intestinal continuity. If all other factors are favorable, the ileostomy is closed when the child is between 2 and 2.5 kg. At the time of stoma closure, the entire intestine should be examined to search for areas of NEC. Patients who develop massive intestinal necrosis are at risk of developing short bowel syndrome, particularly when the total length of the viable intestinal segment is less than 40 cm. These patients require TPN to provide adequate calories for growth and development, and may develop parenteral nutrition–associated cholestasis and hepatic fibrosis. In a significant number of these patients, transplantation of the liver and small bowel may be required.

Short Bowel Syndrome

Short bowel syndrome (SBS) is an extremely morbid condition with an increasing incidence. Various congenital and perinatal acquired conditions such as gastrochisis, malrotation, atresia, and NEC may lead to SBS. Medical and surgical treatment options carry high dollar and human costs and morbidities including multiple infections and hospitalizations for vascular access, liver failure in conjunction with parenteral nutrition–associated cholestasis, and death. Medical centers that have developed multidisciplinary clinics focused on treating children with short bowel syndrome have achieved significant success in
Intussusception

Intussusception is the leading cause of intestinal obstruction in the young child. It refers to the condition whereby a segment of intestine becomes drawn into the lumen of the more proximal bowel. The process usually begins in the region of the terminal ileum, and extends distally into the ascending, transverse, or descending colon. Rarely, an intussusception may prolapse through the rectum.

The cause of intussusception is not clear, although one hypothesis suggests that hypertrophy of the Peyer’s patches in the terminal ileum from an antecedent viral infection acts as a lead point. Peristaltic action of the intestine then causes the bowel distal to the lead point to invaginate into itself. Idiopathic intussusception occurs in children between the ages of approximately 6 and 24 months of age. Beyond this age group, one should consider the possibility that a pathologic lead point maybe present. These include polyps, malignant tumors such as lymphoma, enteric duplication cysts or Meckel’s diverticulum. Such intussusceptions are rarely reduced by air or contrast enema, and thus the lead point is identified when operative reduction of the intussusception is performed.

Clinical Manifestations. Since intussusception is frequently preceded by a gastrointestinal viral illness, the onset may not be easily determined. Typically, the infant develops paroxysms of crampy abdominal pain and intermittent vomiting. Between attacks, the infant may act normally, but as symptoms progress, increasing lethargy develops. Bloody mucus ("currant-jelly" stool) may be passed per rectum. Ultimately, if reduction is not accomplished, gangrene of the intussusceptum occurs, and perforation may ensue. On physical examination, an elongated mass is detected in the right upper quadrant or epigastrium with an absence of bowel in the right lower quadrant (Dance’s sign). The mass may be seen on plain abdominal X-ray but is more easily demonstrated on air or contrast enema.

Treatment. Patients with intussusception should be assessed for the presence of peritonitis and for the severity of systemic illness. Following resuscitation and administration of IV antibiotics, the child is assessed for suitability to proceed with radiographic versus surgical reduction. In the absence of peritonitis, the child should undergo radiographic reduction. If peritonitis is present, or if the child appears systemically ill, urgent laparotomy is indicated.

In the stable patient, the air enema is both diagnostic and may be curative, and it is the preferred method of diagnosis and treatment of intussusception. Air is introduced with a manometer, and the pressure that is administered is carefully monitored. Under most instances, this should not exceed 120 mmHg. Successful reduction is marked by free reflux of air into multiple loops of small bowel and symptomatic improvement as the infant suddenly becomes pain free. Unless both of these signs are observed, it cannot be assumed that the intussusception is reduced. If reduction is unsuccessful, and the infant remains stable, the infant should be brought back to the radiology suite for a repeat attempt at reduction after a few hours. This strategy has improved the success rate of nonoperative reduction in many centers. In addition, hydrostatic reduction with barium may be useful if pneumatic reduction is unsuccessful. The overall success rate of radiographic reduction varies based on the experience of the center, and it is typically between 60% and 90%.

If nonoperative reduction is successful, the infant may be given oral fluids after a period of observation. Failure to reduce the intussusception mandates surgery. which can be approached through an open or laparoscopic technique. In an open procedure, exploration is carried out through a right lower quadrant incision, delivering the intussuscepted mass into the wound. Reduction usually can be accomplished by gentle distal pressure, where the intussusceptum is gently milked out of the intussuscipiens (Fig. 39-20). Care should be taken not to pull the bowel out, as this can cause damage to the bowel wall. The blood supply to the appendix is often compromised, and appendectomy is therefore often performed. If the bowel is frankly gangrenous, resection and primary anastomosis is performed. In experienced hands, laparoscopic reduction may be performed, even in very young infants. This is performed using a 5-mm laparoscope placed in the umbilicus, and two additional 5 mm ports in the left and right lower quadrants. The bowel is inspected, and if it appears to be viable, reduction is performed by milking the bowel or using gentle traction, although this approach is normally discouraged during manual reduction. Atraumatic bowel graspers allow the bowel to be handled without injuring it.

IV fluids are continued until the postoperative ileus subsides. Patients are started on clear liquids, and their diet is advanced as tolerated. Of note, recurrent intussusception occurs in 5% to 10% of patients, independent of whether the bowel is reduced radiographically or surgically. Patients present with recurrent symptoms in the immediate postoperative period. Treatment involves repeat air enema, which is successful in most cases. In patients who experience three or more episodes of intussusception, the presence of a pathologic lead point should be suspected and carefully evaluated using contrast studies. After the third episode of intussusception, many pediatric surgeons will perform an exploratory laparotomy to reduce the bowel and to resect a pathologic lead point if identified.

Appendicitis

Presentation. Correct diagnosis of appendicitis in children can be one of the most humbling and challenging tasks facing the pediatric surgeon. The classical presentation is known to all students and practitioners of surgery: generalized abdominal pain that localizes to the right lower quadrant followed by nausea, vomiting, fever, and localized peritoneal irritation in the region of McBurney’s point. When children present in this
manner, there should be little diagnostic delay. The child should be made NPO, administered IV fluids and broad-spectrum antibiotics, and brought to the operating room for an appendectomy. However, children often do not present in this manner. The coexistence of nonspecific viral syndromes and the inability of young children to describe the location and quality of their pain often result in diagnostic delay. As a result, children with appendicitis often present with perforation, particularly those who are under 5 years of age. Perforation increases the length of hospital stay and makes the overall course of the illness significantly more complex.

**Diagnosis of Appendicitis in Children.** There have been significant improvements in the role of radiographic studies in the diagnosis of acute appendicitis. While CT is quite reliable in making the diagnosis, US is very useful when performed in experienced centers and good visualization of the appendix is achieved. MRI may be performed where available with high specificity and sensitivity—and avoidance of radiation. US is very useful for excluding ovarian causes of abdominal pain. Despite these radiographic measures, the diagnosis of appendicitis remains largely clinical, and each clinician should develop his or her own threshold to operate or to observe the patient. A reasonable practice guideline is as follows. When the diagnosis is clinically apparent, appendectomy should obviously be performed with minimal delay. Localized right lower quadrant tenderness associated with low-grade fever and leukocytosis in boys should prompt surgical exploration. In girls, ovarian or uterine pathology must also be considered. When there is diagnostic uncertainty, the child may be observed, rehydrated, and reassessed. In girls of menstruating age, an US may be obtained to exclude ovarian pathology (cysts, torsion, or tumor). If all studies are negative, yet the pain persists, and the abdominal findings remain equivocal, diagnostic laparoscopy may be employed to determine the etiology of the abdominal pain. The appendix should be removed even if it appears to be normal, unless another pathologic cause of the abdominal pain is definitively identified and the appendectomy would substantially increase morbidity.

**Surgical Treatment of Appendicitis.** The definitive treatment for acute appendicitis is appendectomy. Prior to surgery, it is important that patients receive adequate IV fluids in order to correct dehydration that commonly develops as a result of fever and vomiting in patients with appendicitis. Patients should also be started on antibiotics (such as a second-generation cephalosporin). Most surgeons will perform a laparoscopic appendectomy, which may have some advantage over removing the appendix through a single, larger incision. During the laparoscopic appendectomy, a small incision is made at the umbilicus, and two additional incisions are made in the lower abdomen. The appendix is typically delivered through the umbilicus, and all incisions are then closed, with dissolvable sutures. If the appendix is not ruptured, the patient may start drinking liquids shortly after waking up from the operation, and may be advanced to a solid diet the next day. In general, the same steps are taken when appendectomy is performed through an open approach. The most common complication after appendectomy is a surgical site infection. Other risks—including bleeding or damage to other structures inside the abdomen—are extremely rare. Recovery from surgery is dependent upon the individual patient. Most children are back to school approximately 1 week from surgery and usually are allowed to return to full physical activity after 2 to 3 weeks. During the recovery period, over-the-counter pain medication may be required. Older patients tend to require a longer time for full recovery.

**Management of the Child With Perforated Appendicitis.** The signs and symptoms of perforated appendicitis can closely mimic those of gastroenteritis and include abdominal pain, vomiting, and diarrhea. Alternatively, the child may present with symptoms of intestinal obstruction. An abdominal mass may be present in the lower abdomen. When the symptoms have been present for more than 4 or 5 days, and an abscess is suspected, it is reasonable to obtain a computerized tomogram of the abdomen and pelvis with IV, oral, and rectal contrast in order to visualize the appendix and the presence of an associated abscess, phlegmon, or fecalith (Fig. 39-21).

An individualized approach is necessary for the child who presents with perforated appendicitis. When there is evidence of generalized peritonitis, intestinal obstruction or evidence of systemic toxicity, the child should undergo appendectomy. This should be delayed only for as long as is required to ensure adequate fluid resuscitation and administration of broad-spectrum antibiotics. The operation can be performed through an open or through a laparoscopic approach. One distinct advantage of the laparoscopic approach is that it provides excellent visualization of the pelvis and all four quadrants of the abdomen. At the time of surgery, adhesions are gently lysed, abscess cavities are drained and the appendix is removed. Drains are seldom used, and the skin incisions can be closed primarily. If a fecalith is identified outside the appendix on computerized tomography, every effort should be made to retrieve it and to remove it along with the appendix, if at all possible. Often, the child in whom symptoms have been present for more than 4 or 5 days will present with an abscess without evidence of generalized peritonitis. Under these circumstances, it is appropriate to perform image-guided percutaneous drainage of the abscess followed by broad-spectrum antibiotic therapy. The inflammation will generally subside within several days, and the appendix can be safely removed as an outpatient 6 to 8 weeks later. If the child’s symptoms do not improve, or if the abscess is not amenable to percutaneous drainage, then laparoscopic or open appendectomy and abscess drainage is required. Patients who present with a phlegmon in the region of a perforated appendix may be managed in a similar manner. In general, children who are younger...
than 4 or 5 years of age do not respond as well to an initial nonoperative approach because their bodies do not localize or isolate the inflammatory process. Thus, these patients are more likely to require early surgical intervention. Patients who have had symptoms of appendicitis for no more than 4 days should probably undergo “early” appendectomy because the inflammatory response is not as excessive during that initial period and the procedure can be performed safely.

**Nonoperative Management of Acute Appendicitis.** Despite the fact that surgical removal of the acutely inflamed appendix is effective in all cases, there has been a growing recognition that certain children will respond to antibiotics alone and thus avoid surgery. Several trials have shown that acute appendicitis may be treated with antibiotics alone effectively in nearly 80% of patients. However, the failure rate is considered unacceptably high for many patients, who effectively will have suffered a delay from definitive care. Furthermore, the heterogeneity of disease presentation, and varying degree of illness severity, make it quite difficult to predict who will respond to antibiotics alone. This question is currently being answered in the United States in the form of a randomized controlled trial that is recruiting over 1500 patients in eight states, which will be divided into antibiotic therapy versus surgery (ClinicalTrials.gov, identifier NCT02800785).

**Other Causes of Abdominal Pain That Mimic Appendicitis in Children.** As mentioned earlier, appendicitis can be one of the most difficult diagnoses to establish in children with abdominal pain, in part because of the large number of diseases that present in a similar fashion. Patients with urinary tract infection can present very similarly to those with appendicitis. However, patients with urinary tract infection are less likely to present with vomiting and are likely to also experience difficulty with urination, characterized by pressure, burning, and frequency. Constipation may be commonly confused with appendicitis in its earliest stages. However, patients with constipation rarely have fever and will not have abnormalities in their blood work. Ovarian torsion can mimic appendicitis, given the severe abdominal pain that accompanies this condition. However, patients with ovarian torsion are generally asymptomatic until the acute onset of severe pain. By contrast, patients with appendicitis generally experience gradual onset of pain associated with nausea and vomiting. Finally, children and young adults are always at risk for the development of gastroenteritis. However, unlike appendicitis, patients with gastroenteritis generally present with persistent vomiting and occasionally diarrhea, which precedes the onset of the abdominal pain.

**Intestinal Duplications**

Duplications represent mucosa-lined structures that are in continuity with the gastrointestinal tract. Although they can occur at any level in the gastrointestinal tract, duplications are found most commonly in the ileum within the leaves of the mesentery. Duplications may be long and tubular but usually are cystic masses. In all cases, they share a common wall with the intestine. Symptoms associated with enteric duplication cysts include recurrent abdominal pain, emesis from intestinal obstruction, or hematochezia. Such bleeding typically results from ulceration in the duplication or in the adjacent intestine if the duplication contains ectopic gastric mucosa. On examination, a palpable mass is often identified. Children may also develop intestinal obstruction. Torsion may produce gangrene and perforation.

The ability to make a preoperative diagnosis of enteric duplication cyst usually depends on the presentation. CT, US, and technetium pertechnetate scanning can be very helpful. Occasionally, a duplication can be seen on small bowel follow-through or technetium imaging. In the case of short duplications, resection of the cyst and adjacent intestine with end-to-end anastomosis can be performed. If resection of long duplications would compromise intestinal length, multiple enterotomies and mucosal stripping in the duplicated segment will allow the walls to collapse and become adherent. An alternative method is to divide the common wall using the GIA stapler, forming a common lumen. Patients with duplications who undergo complete excision without compromise of the length of remaining intestine have an excellent prognosis.

**Meckel’s Diverticulum**

A Meckel’s diverticulum is a remnant of the embryonic omphalomesenteric (vitelline) duct. It is located on the antimesenteric border of the ileum, usually within 2 ft of the ileocecal valve (Fig. 39-22). It may be found incidentally at surgery or may present with inflammation masquerading as appendicitis. Perforation of a Meckel’s diverticulum may occur if the outpouching becomes impacted with food, leading to distention and necrosis. Occasionally, bands of tissue extend from the Meckel’s diverticulum to the anterior abdominal wall, and these may represent lead points around which internal hernias may develop. This is an important cause of intestinal obstruction in the older child who has a scarless abdomen. Similar to duplications, ectopic gastric mucosa may produce ileal ulcerations that bleed and lead to the passage of maroon-colored stools. Pancreatic mucosa may also be present. Diagnosis may be made by technetium pertechnetate scans when the patient presents with bleeding. Treatment is surgical. If the base is narrow and there is no mass present in the lumen of the diverticulum, a wedge resection of the diverticulum with transverse closure of the ileum can be performed. A linear stapler is especially useful in this circumstance. When a mass of ectopic tissue is palpable, if the base is wide, or when there is inflammation, it is preferable to perform a resection of the involved bowel and end-to-end ileoileostomy.

**Mesenteric Cysts**

Mesenteric cysts are similar to duplications in their location within the mesentry. However, they do not contain any mucosa or muscular wall. Chylous cysts may result from congenital

![Figure 39-22. Operative photograph showing the presence of a Meckel’s diverticulum (arrow).](image)
lymphatic obstruction. Mesenteric cysts can cause intestinal obstruction or may present as an abdominal mass. The diagnosis may be made by abdominal US or CT. Treatment involves surgical excision. This may require resection of the adjacent intestine, particularly for extensive, multicystic lesions. In cases where complete excision is not possible due to the close proximity to vital structures, partial excision or marsupialization should be performed.

**Hirschsprung’s Disease**

**Pathogenesis.** In his classic textbook entitled *Pediatric Surgery*, Dr. Orvar Swenson, who is eponymously associated with one of the classic surgical treatments for Hirschsprung’s disease, described this condition as follows: “Congenital megacolon is caused by a malformation in the pelvic parasympathetic system which results in the absence of ganglion cells in Auerbach’s plexus of a segment of distal colon. Not only is there an absence of ganglion cells, but the nerve fibers are large and excessive in number, indicating that the anomaly may be more extensive than the absence of ganglion cells.” This narrative of Hirschsprung’s disease is as accurate today as it was more than 50 years ago and summarizes the essential pathologic features of this disease: absence of ganglion cells in Auerbach’s plexus and hypertrophy of associated nerve trunks. The cause of Hirschsprung’s disease remains incompletely understood, although current thinking suggests that the disease results from a defect in the migration of neural crest cells, which are the embryonic precursors of the intestinal ganglion cell. Under normal conditions, the neural crest cells migrate into the intestine from cephalad to caudal. The process is completed by the 12th week of gestation, but the migration from midtransverse colon to anus takes 4 weeks. During this latter period, the fetus is most vulnerable to defects in migration of neural crest cells. This may explain why most cases of aganglionosis involve the rectum and rectosigmoid. The length of the aganglionic segment of bowel is therefore determined by the most distal region that the migrating neural crest cells reach. In rare instances, total colonic aganglionosis may occur.

Recent studies have shed light on the molecular basis for Hirschsprung’s disease. Patients with Hirschsprung’s disease have an increased frequency of mutations in several genes, including *GDNF*, its receptor *Ret*, or its coreceptor *Gfra-1*. Moreover, mutations in these genes also lead to aganglionic megacolon in mice, which provides the opportunity to study the function of the encoded proteins. Initial investigations indicate that *GDNF* promotes the survival, proliferation, and migration of mixed populations of neural crest cells in culture. Other studies have revealed that *GDNF* is expressed in the gut in advance of migrating neural crest cells and is chemotactic for neural crest cells in culture. These findings raise the possibility that mutations in the *GDNF* or *Ret* genes could lead to impaired neural crest migration in utero and the development of Hirschsprung’s disease.

**Clinical Presentation.** The incidence of sporadic Hirschsprung’s disease is 1 in 5000 live births. There are reports of increased frequency of Hirschsprung’s disease in multiple generations of the same family. Occasionally, such families have mutations in the genes described earlier, including the *Ret* gene. Because the aganglionic colon does not permit normal peristalsis to occur, the presentation of children with Hirschsprung’s disease is characterized by a functional distal intestinal obstruction. In the newborn period, the most common symptoms are abdominal distention, failure to pass meconium, and bilious emesis. Any infant who does not pass meconium beyond 48 hours of life must be investigated for the presence of Hirschsprung’s disease. Occasionally, infants present with a dramatic complication of Hirschsprung’s disease called *enterocolitis*. This pattern of presentation is characterized by abdominal distention and tenderness, and it is associated with manifestations of systemic toxicity that include fever, failure to thrive, and lethargy. Infants are often dehydrated and demonstrate a leukocytosis or increase in circulating band forms on hematologic evaluation. On rectal examination, forceful expulsion of foul-smelling liquid feces is typically observed and represents the accumulation of stool under pressure in an obstructed distal colon. Treatment includes rehydration, systemic antibiotics, nasogastric decompression, and rectal irrigations while the diagnosis of Hirschsprung’s disease is being confirmed. In children that do not respond to nonoperative management, a decompressive stoma is required. It is important to ensure that this stoma is placed in ganglion-containing bowel, which must be confirmed by frozen section at the time of stoma creation.

In approximately 20% of cases, the diagnosis of Hirschsprung’s disease is made beyond the newborn period. These children have severe constipation, which has usually been treated with laxatives and enemas. Abdominal distention and failure to thrive may also be present at diagnosis.

**Diagnosis.** The definitive diagnosis of Hirschsprung’s disease is made by rectal biopsy. Samples of mucosa and submucosa are obtained at 1 cm, 2 cm, and 3 cm from the dentate line. This can be performed at the bedside in the neonatal period without anesthesia, as samples are taken in bowel that does not have somatic innervation and is thus not painful to the child. In older children, the procedure should be performed using IV sedation. The histopathology of Hirschsprung’s disease is the absence of ganglion cells in the myenteric plexuses, increased acetylcholinesterase staining, and the presence of hypertrophied nerve bundles.

It is important to obtain a barium enema in children in whom the diagnosis of Hirschsprung’s disease is suspected. This test may demonstrate the location of the transition zone between the dilated ganglionic colon and the distal constricted aganglionic rectal segment. Our practice is to obtain this test before instituting rectal irrigations if possible so that the difference in size between the proximal and distal bowel is preserved. Although the barium enema can only suggest, but not reliably establish, the diagnosis of Hirschsprung’s disease, it is very useful in excluding other causes of distal intestinal obstruction. These include small left colon syndrome (as occurs in infants of diabetic mothers), colonic atresia, meconium plug syndrome, or the unused colon observed in infants after the administration of magnesium or tocolytic agents. The barium enema in total colonic aganglionosis may show a markedly shortened colon. Some surgeons have found the use of rectal manometry helpful, particularly in older children, although it is relatively inaccurate.

**Treatment.** The diagnosis of Hirschsprung’s disease requires surgery in all cases. The classic surgical approach consisted of a multiple stage procedure. This included a colostomy in the newborn period, followed by a definitive pull-through operation after the child was over 10 kg. There are three viable options for the definitive pull-through procedure that are currently used. Although individual surgeons may advocate one procedure over another, studies have demonstrated that the outcome after each type of operation is similar. For each of
the operations that is performed, the principles of treatment include confirming the location in the bowel where the transition zone between ganglionic and aganglionic bowel exists, resecting the aganglionic segment of bowel, and performing an anastomosis of ganglionicated bowel to either the anus or a cuff of rectal mucosa (Fig. 39-23).

It is now well established that a primary pull-through procedure can be performed safely, even in the newborn period. This approach follows the same treatment principles as a staged procedure and saves the patient from an additional surgical procedure. Many surgeons perform the intra-abdominal dissection using the laparoscope. This approach is especially useful in the newborn period as this provides excellent visualization of the pelvis. In children with significant colonic distention, it is important to allow for a period of decompression using a rectal tube if a single-staged pull-through is to be performed. In older children with very distended, hypertrophied colon, it may be prudent to perform a colostomy to allow the bowel to decompress prior to performing a pull-through procedure. However, it should be emphasized that there is no upper age limit for performing a primary pull-through.

Of the three pull-through procedures performed for Hirschsprung’s disease, the first is the original Swenson procedure. In this operation, the aganglionic rectum is dissected in the pelvis and removed down to the anus. The ganglionic colon is then anastomosed to the anus via a perineal approach. In the Duhamel procedure, dissection outside the rectum is confined to the retrorectal space, and the ganglionic colon is anastomosed posteriorly just above the anus. The anterior wall of the ganglionic colon and the posterior wall of the aganglionic rectum are anastomosed, using a stapler. Although both of these procedures are extremely effective, they are limited by the possibility of damage to the parasympathetic nerves that are adjacent to the rectum. To circumvent this potential problem, Soave’s procedure involves dissection entirely within the rectum. The rectal mucosa is stripped from the muscular sleeve, and the ganglionic colon is brought through this sleeve and anastomosed to the anus. This operation may be performed completely from below. In all cases, it is critical that the level at which ganglionicated bowel exists be determined. Most surgeons believe that the anastomosis should be performed at least 5 cm from the point at which ganglion cells are found. This avoids performing a pull-through in the transition zone, which is associated with a high incidence of complications due to inadequate emptying of the pull-through segment. Up to one-third of patients who undergo a transition zone pull-through will require a reoperation.

The main complications of all procedures include postoperative enterocolitis, constipation, and anastomotic stricture. There is also a reported incidence of recurrent Hirschsprung’s disease, which may reflect either residual aganglionic bowel left behind after the pull-through, or the presence of ischemia in the pulled-through segment leading to ganglion cell loss. Long-term results with the three procedures are comparable and generally excellent in experienced hands. These three procedures also can be adapted for total colonic aganglionosis in which the ileum is used for the pull-through segment.

Anorectal Malformations

Anatomic Description. Anorectal malformations describe a spectrum of congenital anomalies that include imperforate anus and persistent cloaca. Anorectal malformations occur in approximately 1 in 5000 live births and affect males and females almost equally. The embryologic basis includes failure of descent of the urorectal septum. The level to which this septum descends determines the type of anomaly that is present, which subsequently influences the surgical approach.

In patients with imperforate anus, the rectum fails to descend through the external sphincter complex. Instead, the rectal pouch ends “blindly” in the pelvis, above or below the levator ani muscle. In most cases, the blind rectal pouch communicates more distally with the genitourinary system or with the perineum through a fistulous tract. Traditionally, anatomic
SPECIFIC CONSIDERATIONS

PART II

Figure 39-24. Low imperforate anus in a male. Note the well-developed buttocks. The perineal fistula was found at the midline raphe.

Imperforate anus in a female. A catheter has been placed into the fistula, which is in the vestibule of the vagina.

Description of imperforate anus has been characterized as either “high” or “low” depending on whether the rectum ends above the levator ani muscle complex or partially descends through this muscle (Fig. 39-24). Based upon this classification system, in male patients with high imperforate anus the rectum usually ends as a fistula into the membranous urethra. In females, high imperforate anus often occurs in the context of a persistent cloaca. In both males and females, low lesions are associated with a fistula to the perineum. In males, the fistula connects with the median raphe of the scrotum or penis. In females, the fistula may end within the vestibule of the vagina, which is located immediately outside the hymen or at the perineum.

Because this classification system is somewhat arbitrary, Peña proposed a classification system that specifically and unambiguously describes the location of the fistulous opening. In men, the fistula may communicate with: (a) the perineum (cutaneous perineal fistula); (b) the lowest portion of the posterior urethra (rectourethral bulbar fistula); (c) the upper portion of the posterior urethra (rectourethral prostatic fistula); or (d) the bladder neck (rectovesical fistula). In females, the urethra may open to the perineum between the female genitalia and the center of the sphincter (cutaneous perineal fistula) or into the vestibule of the vagina (vestibular fistula) (Fig. 39-25).

In both sexes, the rectum may end in a completely blind fashion (imperforate anus without fistula). In rare cases, patients may have a normal anal canal, yet there may be total atresia or severe stenosis of the rectum.

The most frequent defect in males is imperforate anus with rectourethral fistula, followed by rectoperineal fistula, then rectovesical fistula or rectobladder neck. In females, the most frequent defect is the rectovestibular defect, followed by the cutaneous perineal fistula. The third most common defect in females is the persistent cloaca. This lesion represents a wide spectrum of malformations in which the rectum, vagina, and urinary tract meet and fuse into a single common channel. On physical examination, a single perineal orifice is observed, and it is located at the place where the urethra normally opens. Typically, the external genitalia are hypoplastic.

Associated Malformations. Approximately 60% of patients have an associated malformation. The most common is a urinary tract defect, which occurs in approximately 50% of patients. Skeletal defects are also seen, and the sacrum is most commonly involved. Spinal cord anomalies especially tethered cord are common, particularly in children with high lesions. Gastrointestinal anomalies occur, most commonly esophageal atresia. Cardiac anomalies may be noted, and occasionally patients present with a constellation of defects as part of the VACTERL syndrome (described earlier).

Management of Patients With Imperforate Anus. Patients with imperforate anus are usually stable, and the diagnosis is readily apparent. Despite the obstruction, the abdomen is initially not distended, and there is rarely any urgency to intervene. The principles of management center around diagnosing the type of defect that is present (high vs. low), and evaluating the presence of associated anomalies. It may take up to 24 hours before the presence of a fistula on the skin is noted, and thus it is important to observe the neonate for some period of time before definitive surgery is undertaken. All patients should therefore have an orogastric tube placed and be monitored for the appearance of meconium in or around the perineum or in the urine. Investigation for associated defects should include an US of the abdomen to assess for the presence of urinary tract anomaly. Other tests should include an echocardiogram and spinal radiographs. An US of the spine should be performed to look for the presence of a tethered cord. To further classify the location of the fistula as either “high” versus “low,” a lateral abdominal radiograph can be obtained with a radiopaque marker on the perineum. By placing the infant in the inverted position, the distance between the most distal extent of air in the rectum and the perineal surface can be measured. This study is imprecise, however, and may add little to the overall management of these patients.

The surgical management of infants with imperforate anus is determined by the anatomic defect. In general, when a low lesion is present, only a perineal operation is required without a colostomy. Infants with a high lesion require a colostomy in the newborn period, followed by a pull-through procedure at approximately 2 months of age. When a persistent cloaca is present, the urinary tract needs to be carefully evaluated at the time of colostomy formation to ensure that normal emptying can occur and to determine whether the bladder needs to be drained by means of a vesicostomy. If there is any doubt about the type of lesion, it is safer to perform a colostomy rather than jeopardize the infant’s long-term chances for continence by an injudicious perineal operation.
The type of pull-through procedure favored by most pediatric surgeons today is the posterior sagittal anorectoplasty (PSARP procedure), as described by Peña and DeVries. This involves placing the patient in the prone jack-knife position, dividing the levator ani and external sphincter complex in the midline posteriorly, dividing the communication between the gastrointestinal tract and the urinary tract, and bringing down the rectum after sufficient length is achieved. The muscles are then reconstructed and sutured to the rectum. The outcome of 1192 patients who had undergone this procedure has been reviewed by Peña and Hong. Seventy-five percent of patients were found to have voluntary bowel movements, and nearly 40% were considered totally continent. As a rule, patients with high lesions demonstrate an increase incidence of incontinence, whereas those with low lesions are more likely to be constipated. Management of patients with high imperforate anus can be greatly facilitated using a laparoscopic assisted approach, in which the patient is operated on in the supine position, and the rectum is mobilized down to the fistulous connection to the bladder neck. This fistulous connection is then divided, and the rectum is completely mobilized down to below the peritoneal reflection. The operation then proceeds at the perineum, and the location of the muscle complex is determined using the nerve stimulator. A Veress needle is then advanced through the skin at the indicated site, with the laparoscope providing guidance to the exact intrapelvic orientation. Dilators are then placed over the Veress needle, the rectum is then pulled through this peritoneal opening, and an anoplasty is performed.

JAUNDICE

The Approach to the Jaundiced Infant

Jaundice is present during the first week of life in 60% of term infants and 80% of preterm infants. There is usually accumulation of unconjugated bilirubin, but there may also be deposition of direct bilirubin. During fetal life, the placenta is the principal route of elimination of unconjugated bilirubin. In the newborn infant, bilirubin is conjugated through the activity of \textit{glucoronyl transferase}. In the conjugated form, bilirubin is water soluble, which results in its excretion into the biliary system and then into the gastrointestinal tract. Newborns have a relatively high level of circulating hemoglobin and relative immaturity of the conjugating machinery. This results in a transient accumulation of bilirubin in the tissues, which is manifested as jaundice. Physiologic jaundice is evident by the second or third day of life and usually resolves within approximately 5 to 7 days. By definition, jaundice that persists beyond 2 weeks is considered pathologic.

Pathologic jaundice may be due to biliary obstruction, increased hemoglobin load, or to liver dysfunction. The workup of the jaundiced infant therefore should include a search for the following possibilities: (a) obstructive disorders, including biliary atresia, choledochal cyst, and inissipated bile syndrome; (b) hematologic disorders, including ABO incompatibility, \textit{Rh} incompatibility, \textit{spherocytosis}; (c) metabolic disorders, including \textit{α}-1 antitrypsin deficiency, \textit{galactosemia}; pyruvate kinase deficiency; and (d) congenital infection, including syphilis and rubella.

Biliary Atresia

Pathogenesis. Biliary atresia is a rare disease associated with significant morbidity and mortality. This disease is characterized by a fibroproliferative obliteration of the biliary tree which progresses toward hepatic fibrosis, cirrhosis, and end-stage liver failure. The incidence of this disease is approximately 1 in 8000 to 1 in 18,000. The etiology of biliary atresia is likely multifactorial. In the classic textbook, \textit{Abdominal Surgery of Infancy and Childhood}, Ladd and Gross described the cause of biliary atresia as an “arrest of development during the solid stage of bile duct formation.” Previously proposed theories on the etiology of biliary atresia have focused on defects in hepatogenesis, prenatal vasculogenesis, immune dysregulation, infectious agents, and exposure to toxins. More recently, genetic mutations in the \textit{cfc1} gene, implicated in left-right axis determinations, were identified in patients with biliary atresia-splenic malformation syndrome. Additionally, the detection of higher incidence of maternal microchimerism in the livers of males with biliary atresia has led to the suggestion that consequent expression of maternal antigens may lead to an autoimmune process leading to inflammation and obliteration of the biliary tree. Recent animal studies strongly implicate perinatal exposure to reovirus or rotavirus. Such viral exposure may lead to perportal inflammation mediated by interferon-γ and other cytokines.

Clinical Presentation. Infants with biliary atresia present with jaundice at birth or shortly thereafter. The diagnosis of biliary atresia is frequently not entertained by pediatricians in part because physiologic jaundice of the newborn is so common and biliary atresia is so uncommon. As such, it is not unusual for there to be a delay in diagnosis. However, infants with biliary atresia characteristically have acholic, pale gray appearing stools, secondary to obstructed bile flow. With further passage of time, these infants manifest progressive failure to thrive, and if untreated, develop stigmata of liver failure and portal hypertension, particularly splenomegaly and esophageal varices.

The oblitative process of biliary atresia involves the common duct, cystic duct, one or both hepatic ducts, and the gallbladder, in a variety of combinations. The histopathology of patients with biliary atresia includes inflammatory changes within the parenchyma of the liver, as well as fibrous deposition at the portal plates that is observed on trichrome staining of frozen tissue sections. In certain cases, bile duct proliferation may be seen, a relatively nonspecific marker of liver injury. Approximately 25% of patients with biliary atresia have coincidental malformations, often associated with polysplenia, and may include intestinal malrotation, preduodenal portal vein, and intrahepatic vena cava.

Diagnosis. In general, the diagnosis of biliary atresia is made utilizing a combination of studies, as no single test is sufficiently sensitive or specific. Fractionation of the serum bilirubin is performed to determine if the associated hyperbilirubinemia is conjugated or unconjugated. Workup commonly includes the analysis of TORCH infection titers as well as viral hepatitis. Typically, a US is performed to assess the presence of other causes of biliary tract obstruction, including choledochal cyst. The absence of a gallbladder is highly suggestive of the diagnosis of biliary atresia. However, the presence of a gallbladder does not exclude the diagnosis of biliary atresia because in approximately 10% of biliary atresia patients, the distal biliary tract is patent and a gall bladder may be visualized, even though the proximal ducts are atretic. It is important to note that the intrahepatic bile ducts are never dilated in patients with biliary atresia. In many centers, a nuclear medicine scan using technetium 99m IDA (DISIDA), performed after pretreatment of the patient with phenobarbital, has proven to be an accurate and reliable study.
If radionuclide appears in the intestine, there is patency of the biliary tree, and the diagnosis of biliary atresia is excluded. If radionuclide is concentrated by the liver but not excreted despite treatment with phenobarbital, and the metabolic screen, particularly $\alpha_1$-antitrypsin determination, is normal, the presumptive diagnosis is biliary atresia. A percutaneous liver biopsy might potentially distinguish between biliary atresia and other sources of jaundice such as neonatal hepatitis. When these tests point to or cannot exclude the diagnosis of biliary atresia, surgical exploration is warranted. At surgery, a cholangiogram may be performed if possible, using the gallbladder as a point of access. This may be performed using a laparoscope. The cholangiogram demonstrates the anatomy of the biliary tree, determines whether extrahepatic bile duct atresia is present, and evaluates whether there is distal bile flow into the duodenum. The cholangiogram may demonstrate hypoplasia of the extrahepatic biliary system. This condition is associated with hepatic parenchymal disorders that cause severe intrahepatic cholestasis, including $\alpha_1$-antitrypsin deficiency and biliary hypoplasia (Alagille’s syndrome). Alternatively, a cursory assessment of the extrahepatic biliary tree may clearly delineate the atresia.

**Inspissated Bile Syndrome.** This term is applied to patients with normal biliary tracts who have persistent obstructive jaundice. Increased viscosity of bile and obstruction of the canaliculi are implicated as causes. The condition has been seen in infants receiving parenteral nutrition, but it is also encountered in conditions associated with hemolysis, or in cystic fibrosis. In some instances, no etiologic factors can be defined. Neonatal hepatitis may present in a similar fashion to biliary atresia. This disease is characterized by persistent jaundice due to acquired biliary inflammation without obliteration of the bile ducts. There may be a viral etiology, and the disease is usually self-limited. In this case, cholangiography is both diagnostic and therapeutic.

**Treatment.** If the diagnosis of biliary atresia is confirmed intraoperatively, then surgical treatment is undertaken at the same setting. Currently, first-line therapy consists of creation of a hepatopancreatic duct fistula, as described by Kasai. The purpose of this procedure is to promote bile flow into the intestine. The procedure is based on Kasai’s observation that the fibrous tissue at the porta hepatis invests microscopically patent biliary ductules that, in turn, communicate with the intrahepatic ductal system (Fig. 39-26). Transecting this fibrous tissue at the portal plate, invariably encountered cephalad to the bifurcating portal vein, opens these channels and establishes bile flow into a surgically constructed intestinal conduit, usually a Roux-en-Y limb of jejunum (Fig. 39-27). Some authors believe that an intussuscepted antireflux valve is useful in preventing retrograde bile reflux, although the data suggest that it does not impact outcome. A liver biopsy is performed at the time of surgery to determine the degree of hepatic fibrosis that is present. The diameter of bile ducts at the portal plate is predictive of likelihood of long-term success of biliary drainage through the portoenterostomy. Numerous studies also suggest that the likelihood of surgical success is inversely related to the age at the time of portoenterostomy. Infants treated prior to 60 days of life are more likely to achieve successful and long-term biliary drainage than older infants. Although the outlook is less favorable for patients after the 12th week, it is reasonable to proceed with surgery even beyond this time point, as the alternative is certain liver failure. It is noteworthy that a significant number of patients have had favorable outcomes after undergoing portoenterostomy despite advanced age at time of diagnosis.

Bile drainage is anticipated when the operation is carried out early; however, bile flow does not necessarily imply cure. Approximately one-third of patients remain symptom free after portoenterostomy, the remainder require liver transplantation due to progressive liver failure. Independent risk factors that predict failure of the procedure include bridging liver fibrosis at the time of surgery and postoperative cholangitic episodes. A review of the data of the Japanese Biliary Atresia Registry (JBAR), which

![Figure 39-26. Operative photograph showing Kasai portoenterostomy. Arrows denote the site of the anastomosis. Note the engorged liver.](image)

![Figure 39-27. Schematic illustration of the Kasai portoenterostomy for biliary atresia. An isolated limb of jejunum is brought to the porta hepatitis and anastomosed to the transected ducts at the liver plate.](image)
includes the results of 1381 patients, showed that the 10-year survival rate was 53% without transplantation, and 66.7% with transplantation. A common postoperative complication is cholangitis. There is no effective strategy to completely eliminate this complication, and the effectiveness of long-term prophylactic antibiotics has not been fully resolved. The Childhood Liver Research and Education Network (ChiLDREn, formerly the Biliary Atresia Research Consortium) is an active consortium of 15 children’s hospitals in the United States, funded by the National Institutes of Health (NIH) that studies rare cholestatic liver diseases of infants and children (http://childrennetwork.org). An NIH-funded, randomized, double-blinded, placebo-controlled trial designed to determine if adjuvant steroids improve outcome of infants undergoing Kasai portoenterostomy has been completed. This trial showed that among infants with biliary atresia who have undergone hepatopancreatorenostomy, high-dose steroid therapy following surgery did not result in statistically significant treatment differences in bile drainage at 6 months, although a small clinical benefit could not be excluded. Steroid treatment was associated with earlier onset of serious adverse events in children with biliary atresia.

Previous authors have published merits of revising the portoenterostomy in select patients if drainage of bile stops. Recently, Bondoc et al reported on their experience with revision of portoenterostomies. Specifically, the authors reported on 183 patients who underwent Kasai portoenterostomy for biliary atresia, of which 24 underwent revision for recurrence of nondrainage after successful bypass. Of the patients who underwent revision for nondrainage, 75% ultimately achieved drainage after the second procedure, of which nearly 50% survived long term with their native livers. The authors conclude that in selected patients in which bile flow was established following the Kasai procedure and then lost, revision of the portoenterostomy is a reasonable treatment option with good success.

**Choledochal Cyst**

**Classification.** The term *choledochal cyst* refers to a spectrum of congenital biliary tract disorders that were previously grouped under the name *idiopathic dilation of the common bile duct*. After the classification system proposed by Alonso-Lej, five types of choledochal cyst are described. Type I cyst is characterized by fusiform dilatation of the bile duct. This is the most common type and is found in 80% to 90% of cases. Type II choledochal cysts appear as an isolated diverticulum protruding from the wall of the common bile duct. The cyst may be joined to the common bile duct by a narrow stalk. Type III choledochal cysts arise from the intraduodenal portion of the common bile duct and are also known as choledochoceles. Type IVA cysts consist of multiple dilatations of the intrahepatic and extrahepatic bile ducts. Type IVB choledochal cysts are multiple dilatations involving only the extrahepatic bile ducts. Type V (Carolí’s disease) consists of multiple dilatations limited to the intrahepatic bile ducts.

Choledochal cyst is most appropriately considered the predominant feature in a constellation of pathologic abnormalities that can occur within the pancreato-biliary system. Frequently associated with choledochal cyst is an anomalous junction of the pancreatic and common bile ducts. The etiology of choledochal cyst is controversial. Babbit proposed an abnormal pancreatic and biliary duct junction, with the formation of a “common channel” into which pancreatic enzymes are secreted. This process results in weakening of the bile duct wall by gradual enzymatic destruction, leading to dilatation, inflammation, and finally cyst formation. Not all patients with choledochal cyst demonstrate an anatomic common channel, which raises questions regarding the accuracy of this model.

**Clinical Presentation.** Choledochal cyst is more common in females than in males (4:1). Typically, these present in children beyond the toddler age group. The classic symptom triad consists of abdominal pain, mass, and jaundice. However, this complex is actually encountered in fewer than half of the patients. The more usual presentation is that of episodic abdominal pain, often recurring over the course of months or years, and generally associated with only minimal jaundice that may escape detection. If left undiagnosed, patients may develop cholangitis or pancreatitis. Cholangitis may lead to the development of cirrhosis and portal hypertension. Choledochal cyst can present in the newborn period, where the symptoms are very similar to those of biliary atresia. Often neonates will have an abdominal mass at presentation.

**Diagnosis.** Choledochal cyst is frequently diagnosed in the fetus at a screening prenatal US. In the older child or adolescent, abdominal US may reveal a cystic structure arising from the biliary tree. CT will confirm the diagnosis. These studies will demonstrate the dimensions of the cyst and define its relationship to the vascular structures in the porta hepatis, as well as the intrahepatic ductal configuration. Endoscopic retrograde cholangiopancreatography (ERCP) is reserved for patients in whom confusion remains after evaluation by less invasive imaging modalities. Magnetic resonance cholangiopancreatography may provide a more detailed depiction of the anatomy of the cyst and its relationship to the bifurcation of the hepatic ducts and into the pancreas.

**Treatment.** The cyst wall is composed of fibrous tissue and is devoid of mucosal lining. As a result, the treatment of choledochal cyst is surgical excision followed by biliary-enteric reconstruction. There is no role for internal drainage by cystenterostomy, which leaves the cyst wall intact and leads to the inevitable development of cholangitis. Rarely, choledochal cyst can lead to the development of a biliary tract malignancy. This provides a further rationale for complete cyst excision.

Resection of the cyst may be performed via open or laparoscopic approach, and where possible, requires circumferential dissection. The posterior plane between the cyst and portal vein must be carefully dissected to accomplish removal. The pancreatic duct, which may enter the distal cyst, is vulnerable to injury during distal cyst excision but can be avoided by avoiding entry into the pancreatic parenchyma. In cases were the degree of pericystic inflammation is dense, it may be unsafe to attempt complete cyst removal. In this instance, it is reasonable to dissect within the posterior wall of the cyst, which allows the inner lining of the back wall to be dissected free from the outer layer that directly overlies the portal vascular structures. The lateral and anterior cyst, as well as the internal aspect of the back wall, is removed, yet the outer posterior wall remains behind. Cyst excision is accomplished, and the proximal bile duct is anastomosed to the intestinal tract typically via a Roux-en-Y limb of jejunum. More recently, laparoscopic-assisted resections of choledochal cysts have been described. In these cases, the end-to-side jejunoojejunostomy is performed extracorporeally, but the remainder of the procedure is completed utilizing minimally invasive techniques.

The prognosis for children who have undergone complete excision of choledochal cyst is excellent. Complications include anastomotic stricture, cholangitis, and intrahepatic stone
DEFORMITIES OF THE ABDOMINAL WALL

Embryology of the Abdominal Wall

The abdominal wall is formed by four separate embryologic folds: cephalic, caudal, right, and left lateral folds. Each of these is composed of somatic and splanchnic layers and develops toward the anterior center portion of the coelomic cavity, joining to form a large umbilical ring that surrounds the two umbilical arteries, the vein, and the yolk sac or omphalomesenteric duct. These structures are covered by an outer layer of amnion, and the entire unit composes the umbilical cord. Between the 5th and tenth weeks of fetal development, the intestinal tract undergoes rapid growth outside the abdominal cavity within the proximal portion of the umbilical cord. As development is completed, the intestine gradually returns to the abdominal cavity. Contraction of the umbilical ring completes the process of abdominal wall formation.

Failure of the cephalic fold to close results in sternal deformities such as congenital absence of the sternum. Failure of the caudal fold to close results in exstrophy of the bladder and, in more extreme cases, exstrophy of the cloaca. Interruption of central migration of the lateral folds results in omphalocele. Gastrochisis, originally thought to be a variant of omphalocele, possibly results from a fetal accident in the form of intrauterine rupture of a hernia of the umbilical cord, although other hypotheses have been advanced.

Umbilical Hernia

Failure of the umbilical ring to close results in a central defect in the linea alba. The resulting umbilical hernia is covered by normal umbilical skin and subcutaneous tissue, but the fascial defect allows protrusion of abdominal contents. Hernias less than a centimeter in size at the time of birth usually will close spontaneously by 4 to 5 years of life and in most cases should not undergo early repair. Sometimes the hernia is large enough that the protrusion allows protrusion of abdominal contents. Hernias less than a centimeter in size at the time of birth usually will close spontaneously by 4 to 5 years of life and in most cases should not undergo early repair. Sometimes the hernia is large enough that the protrusion is disfiguring and disturbing to both the child and the family. In such circumstances, early repair may be advisable (Fig. 39-28).

Umbilical hernias are generally asymptomatic protrusions of the abdominal wall. They are generally noted by parents or physicians shortly after birth. All families of patients with umbilical hernia should be counseled about signs of incarceration, which is rare in umbilical hernias and more common in smaller (1 cm or less) rather than larger defects. Incarceration presents with abdominal pain, bilious emesis, and a tender, hard mass protruding from the umbilicus. This constellation of symptoms mandates immediate exploration and repair of the hernia to avoid strangulation. More commonly, the child is asymptomatic and treatment is governed by the size of the defect, the age of the patient, and the concern that the child and family have regarding the cosmetic appearance of the abdomen. When the defect is small and spontaneous closure is likely, most surgeons will delay surgical correction until 5 years of age. If closure does not occur by this time or a younger child has a very large or symptomatic hernia, it is reasonable to proceed to repair.

Repair of uncomplicated umbilical hernia is performed under general anesthesia as an outpatient procedure. A small curving incision that fits into the skin crease of the umbilicus is made, and the sac is dissected free from the overlying skin. The fascial defect is repaired with permanent or long-lasting absorbable, interrupted sutures that are placed in a transverse plane. The skin is closed using subcuticular sutures. The postoperative recovery is typically uneventful and recurrence is rare, but it is more common in children with elevated intraabdominal pressures, such as those with a VP shunt.

Patent Urachus

During the development of the coelomic cavity, there is free communication between the urinary bladder and the abdominal wall through the urachus, which exits adjacent to the omphalomesenteric duct. Persistence of this tract results in a communication between the bladder and the umbilicus. The first sign of a patent urachus is moisture or urine flow from the umbilicus. Recurrent urinary tract infection can result. The urachus may be partially obliterated, with a remnant beneath the umbilicus in the extraperitoneal position as an isolated cyst that may be identified by US. A urachal cyst usually presents as an inflammatory mass inferior to the umbilicus. Initial treatment is drainage of the infected cyst followed by cyst excision as a separate procedure once the inflammation has resolved.

In the child with a persistently draining umbilicus, a diagnosis of patent urachus should be considered. The differential diagnosis includes an umbilical granuloma, which generally responds to local application of silver nitrate. The diagnosis of patent urachus is confirmed by umbilical exploration. The urachal tract is excised and the bladder is closed with an absorbable suture. A patent vitelline duct may also present with umbilical drainage. In this circumstance, there is a communication with the small intestine, often at the site of a Meckel’s diverticulum. Treatment includes umbilical exploration with resection of the duct remnant (Fig. 39-29).

Omphalocele

Presentation. Omphalocele refers to a congenital defect of the abdominal wall in which the bowel and solid viscera are covered by peritoneum and amniotic membrane (Fig. 39-30). The umbilical cord inserts into the sac. Omphalocele can vary from a small defect with intestinal contents to giant omphalocele in which the abdominal wall defect measures 4 cm or more in diameter and contains liver. The overall incidence is approximately 1 in 5000
live births, with 1 in 10,000 that are giant omphaloceles. Omphalocele occurs in association with special syndromes such as extrophy of the cloaca (vesicointestinal fissure), the Beckwith-Wiedemann constellation of anomalies (macroglossia, macrosomia, hypoglycemia, and visceromegaly and omphalocele) and Cantrell’s Pentalogy (lower thoracic wall malformations [cleft sternum], ectopia cordis, epigastric omphalocele, anterior midline diaphragmatic hernia and cardiac anomalies). There is a 60% to 70% incidence of associated anomalies, especially cardiac (20–40% of cases) and chromosomal abnormalities. Chromosomal anomalies are more common in children with smaller defects. Omphalocele is associated with prematurity (10–50% of cases) and intrauterine growth restriction (20% of cases).

**Treatment.** Immediate treatment of an infant with omphalocele consists of attending to the vital signs and maintaining the body temperature. A blood glucose should be evaluated because of the association with Beckwith-Wiedemann. The omphalocele should be covered to reduce fluid loss, but moist dressings may result in heat loss and are not indicated. No pressure should be placed on the omphalocele sac in an effort to reduce its contents because this maneuver may increase the risk of rupture of the sac or may interfere with abdominal venous return. Prophylactic broad-spectrum antibiotics should be administered in case of rupture. The subsequent treatment and outcome is determined by the size of the omphalocele. In general terms, small to medium-sized defects have a significantly better prognosis than extremely large defects in which the liver is present. In these cases, not only is the management of the abdominal wall defect a significant challenge, but these patients often have concomitant pulmonary insufficiency that can lead to significant morbidity and mortality. If possible, and if the pulmonary status will permit it, a primary repair of the omphalocele should be undertaken. This involves resection of the omphalocele membrane and closure of the fascia. A layer of prosthetic material may be required to achieve closure. In infants with a giant omphalocele, the defect cannot be closed primarily because there is not adequate intraperitoneal domain to reduce the viscera (see Fig. 39-30). Some infants may have associated congenital anomalies that complicate surgical repair, and because cardiac anomalies are common, an echocardiogram should be obtained prior to any procedure. If repair is contraindicated, such as with a very large defect, a nonoperative approach can be used. The omphalocele sac can be treated with topical treatments, which serve to harden the sac to allow more protective coverage where muscle and skin cannot be used given the large defect. Various authors describe success with iodine-containing solutions, silver sulfadiazine, or saline, and some surgeons rotate these solutions because of the impact of iodine on the thyroid and the difficulty of cleaning off all of the silver sulfadiazine and its association with leukopenia. It typically takes 2 to 3 months before reepithelialization occurs. In the past, mercury compounds were used, but they have been discontinued because of associated systemic toxicity. After epithelialization has occurred, attempts should be made to achieve closure of the anterior abdominal wall but may be delayed by associated pulmonary insufficiency. Such procedures typically require complex measures to achieve skin closure, including the use of biosynthetic materials or component separation. In cases of giant omphalocele, prolonged hospitalization is typical. If the base is very narrow—which can occur even for babies with very large omphaloceles—it may be wise to open the base in order to allow the abdominal contents and the liver to reenter the abdominal cavity, and thereby achieve abdominal domain. This approach will, by necessity, require sewing in some synthetic material in order to achieve fascial closure, and prolonged hospitalization will be required to allow for skin coverage to occur. These patients require high amounts of caloric support, given the major demands for healing.

**Gastroschisis**

**Presentation.** Gastroschisis represents a congenital anomaly characterized by a defect in the anterior abdominal wall through which the intestinal contents freely protrude. Unlike omphalocele, there is no overlying sac, and the size of the defect is usually <4 cm. The abdominal wall defect is located at the junction of the umbilicus and normal skin, and is almost always to the right of the umbilicus (Fig. 39-31). The umbilicus becomes partly detached, allowing free communication with the...
abdominal cavity. The appearance of the bowel provides some information with respect to the in-utero timing of the defect. The intestine may be normal in appearance, suggesting that the rupture occurred relatively late during the pregnancy. More commonly, however, the intestine is thick, edematous, discolored, and covered with exudate, implying a more longstanding process. Progression to full enteral feeding is usually delayed, with diminished motility that may be related to these changes.

Unlike infants born with omphalocele, associated anomalies are not usually seen with gastroschisis except for a 10% rate of intestinal atresia. This defect can readily be diagnosed on prenatal US (Fig. 39-32). There is no advantage to performing a cesarean section instead of a vaginal delivery. In a decade long retrospective review, early deliver did not affect the thickness of bowel peel, yet patients delivered before 36 weeks had significantly longer length of stay in the hospital and time to enteral feeds. Based upon these findings, it is thought that fetal well-being should be the primary determinant of delivery for gastroschisis.

Treatment. All infants born with gastroschisis require urgent surgical treatment. Of equal importance, these infants require vigorous fluid resuscitation in the range of 160 to 190 cc/kg per day to replace significant evaporative fluid losses. In many instances, the intestine can be returned to the abdominal cavity, and a primary surgical closure of the abdominal wall is performed. Some surgeons believe that they facilitate primary closure with mechanical stretching of the abdominal wall, thorough orogastric suctioning with foregut decompression, rectal irrigation, and evacuation of meconium. Care must be taken to prevent markedly increased abdominal pressure during the reduction, which will lead to compression of the inferior vena cava, respiratory embarrassment, and abdominal compartment syndrome. To avoid this complication, it is helpful to monitor the bladder or airway pressures during reduction. In infants whose intestine has become thickened and edematous, it may be impossible to reduce the bowel into the peritoneal cavity in the immediate postnatal period. Under such circumstances, a plastic spring-loaded silo can be placed onto the bowel and secured beneath the fascia or a sutured silastic silo constructed. The silo covers the bowel and allows for graduated reduction on a daily basis as the edema in the bowel wall decreases (Fig. 39-33). It is important to ensure that the silo-fascia junction does not become a constricting point or “funnel,” in which case the intestine will be injured upon return to the peritoneum. In this case, the fascial opening must be enlarged. Surgical closure can usually be accomplished within approximately 1 to 2 weeks. A prosthetic piece of material may be required to bring the edges of the fascia together. If an atresia is noted at the time of closure, it is prudent to reduce the bowel at the first operation and return after several weeks once the edema has resolved to correct the atresia. Intestinal function does not typically return for several weeks in patients with gastroschisis. This is especially true if the bowel is thickened and edematous. As a result, these patients will require central line placement and institution of total parenteral nutrition in order to grow. Feeding advancement should be slow and typically requires weeks to arrive at full enteral nutrition.
Prune-Belly Syndrome

Clinical Presentation. Prune-belly syndrome refers to a disorder that is characterized by extremely lax lower abdominal musculature, dilated urinary tract including the bladder, and bilateral undescended testes (Fig. 39-34). The term prune-belly syndrome appropriately describes the wrinkled appearance of the anterior abdominal wall that characterizes these patients. Prune-belly syndrome is also known as Eagle-Barrett syndrome as well as the triad syndrome because of the three major manifestations. The incidence is significantly higher in males. Patients manifest a variety of comorbidities. The most significant is pulmonary hypoplasia, which can be unsurvivable in the most severe cases. Skeletal abnormalities include dislocation or dysplasia of the hip and pectus excavatum.

The major genitourinary manifestation in prune-belly syndrome is ureteral dilation. The ureters are typically long and tortuous and become more dilated distally. Ureteric obstruction is rarely present, and the dilation may be caused by decreased smooth muscle and increased collagen in the ureters. Additionally, up to eighty percent of these patients will have some degree of vesicoureteral reflux, which can predispose to urinary tract infection. Despite the marked dilatation of the urinary tract, most children with prune-belly syndrome have adequate renal parenchyma for growth and development. Factors associated with the development of long-term renal failure include the presence of abnormal kidneys on US or renal scan and persistent pyelonephritis.

Treatment. Despite the ureteric dilation, there is currently no role for ureteric surgery unless an area of obstruction develops. The testes are invariably intraabdominal, and bilateral orchidopexy can be performed in conjunction with abdominal wall reconstruction at 6 to 12 months of age. Despite orchidopexy, fertility in a boy with prune-belly syndrome is unlikely as spermatogenesis over time is insufficient. Deficiencies in the production of prostatic fluid and a predisposition to retrograde ejaculation contribute to infertility. Abdominal wall repair is accomplished through an abdominoplasty, which typically requires a transverse incision in the lower abdomen extending into the flanks.

Inguinal Hernia

An understanding of the management of pediatric inguinal hernias is a central component of modern pediatric surgical practice. Inguinal hernia repair represents one of the most common operations performed in children. The presence of an inguinal hernia in a child is an indication for surgical repair. The operation is termed a hernioplasty because it involves closing off the patent processus vaginalis. This is to be contrasted with the hernioplasty that is performed in adults, which requires a reconstruction of the inguinal floor.

Embryology. In order to understand how to diagnose and treat inguinal hernias in children, it is critical to understand their embryologic origin. It is very useful to describe these events to the parents, who often are under the misconception that the hernia was somehow caused by their inability to console their crying child, or the child’s high activity level. Inguinal hernia results from a failure of closure of the processus vaginalis; a finger-like projection of the peritoneum that accompanies the testicle as it descends into the scrotum. Closure of the processus vaginalis normally occurs a few months prior to birth. This explains the high incidence of inguinal hernias in premature infants. When the processes vaginalis remains completely patent, a communication persists between the peritoneal cavity and the groin, resulting in a hernia. Partial closure can result in entrapped fluid, which results in the presence of a hydrocele. A communicating hydrocele refers to a hydrocele that is in communication with the peritoneal cavity and can therefore be thought of as a hernia. Using the classification system that is typically applied to adult hernias, all congenital hernias in children are by definition indirect inguinal hernias. Children also present with direct inguinal and femoral hernias, although these are much less common.

Clinical Manifestation. Inguinal hernias occur more commonly in males than females (10:1) and are more common on the right side than the left. Infants are at high risk for incarceration of an inguinal hernia because of the narrow inguinal ring. Patients most commonly present with a groin bulge that is noticed by the parents as they change the diaper (Fig. 39-35).
Older children may notice the bulge themselves. On examination, the cord on the affected side will be thicker, and pressure on the lower abdomen usually will display the hernia on the affected side. The presence of an incarcerated hernia is manifested by a firm bulge that does not spontaneously resolve and may be associated with fussiness and irritability in the child. The infant that has a strangulated inguinal hernia will manifest an edematous, tender bulge in the groin, occasionally with overlying skin changes. The child will eventually develop intestinal obstruction, peritonitis, and systemic toxicity.

Usually an incarcerated hernia can be reduced. Occasionally this may require light sedation. Gentle pressure is applied on the sac from below in the direction of the internal inguinal ring. Following reduction of the incarcerated hernia, the child may be admitted for observation, and herniorrhaphy is performed within the next 24 hours to prevent recurrent incarceration. Alternatively, the child may be scheduled for surgery at the next available time slot. If the hernia cannot be reduced, or if evidence of strangulation is present, emergency operation is necessary. This may require a laparotomy and bowel resection.

When the diagnosis of inguinal hernia is made in an otherwise normal child, operative repair should be planned. Spontaneous resolution does not occur, and therefore a nonoperative approach cannot ever be justified. An inguinal hernia in a female infant or child frequently contains an ovary rather than intestine. Although the gonad usually can be reduced into the abdomen by gentle pressure, it often prolapses in and out until surgical repair is carried out. In some patients, the ovary and fallopian tube constitute one wall of the hernial sac (sliding hernia), and in these patients, the ovary can be reduced effectively only at the time of operation. If the ovary is irreducible, prompt hernia repair is indicated to prevent ovarian torsion or strangulation.

When a hydrocele is diagnosed in infancy and there is no evidence of a hernia, observation is proper therapy until the child is older than 12 months. If the hydrocele has not disappeared by 12 months, invariably there is a patent processus vaginalis, and operative hydrocelectomy with excision of the processus vaginalis is indicated. When the first signs of a hydrocele are seen after 12 months of age, the patient should undergo elective hydrocelectomy, which in a child is always performed through a groin incision. Aspiration of hydroceles is discouraged because almost all without a patent processus vaginalis will resorb spontaneously and those with a communication to the peritoneum will recur and require operative repair eventually. Transillumination as a method to distinguish between hydrocele and hernia is nonspecific. A noncommunicating hydrocele is better identified by palpation of a nonreducible oval structure that appears to have a blunt end below the external ring, indicating an isolated fluid collection without a patent connection to the peritoneum. Surgical Repair. The repair of a pediatric inguinal hernia can be extremely challenging, particularly in the premature child with incarceration. A small incision is made in a skin crease in the groin directly over the internal inguinal ring. Scarpa’s fascia is seen and divided. The external oblique muscle is dissected free from overlying tissue, and the location of the external ring is confirmed. The external oblique aponeurosis is then opened along the direction of the external oblique fibers over the inguinal canal. The undersurface of the external oblique is then cleared from surrounding tissue. The cremasteric fibers are separated from the cord structures and hernia sac, and these are then elevated into the wound. Care is taken not to grasp the vas deferens. The hernia sac is then dissected up to the internal ring and doubly suture ligated. The distal part of the hernia sac is opened widely to drain any hydrocele fluid. When the hernia is very large and the patient very small, tightening of the internal inguinal ring or even formal repair of the inguinal floor may be necessary, although the vast majority of children do not require any treatment beyond high ligation of the hernia sac.

Controversy exists regarding the role for exploration of an asymptomatic opposite side in a child with an inguinal hernia. Several reports indicate that frequency of a patent processus vaginalis on the side opposite the obvious hernia is approximately 30%, although this figure decreases with increasing age of the child. Management options include never exploring the opposite side, to exploring only under certain conditions such as in premature infants or in patients in whom incarceration is present. The opposite side may readily be explored laparoscopically. To do so, a blunt 3-mm trochar is placed into the hernia sac of the affected side. The abdominal cavity is insufflated, and the 2.7-mm 70° camera is placed through the trochar such that the opposite side is visualized. The status of the processes vaginalis on the opposite side can be visualized. However, the presence of a patent processus vaginalis by laparoscopy does not always imply the presence of a hernia.

There has been quite widespread adoption of laparoscopic approach in the management of inguinal hernias in children, especially those under the age of 2 years. This technique requires insufflation through the umbilicus and the placement of an extraperitoneal suture to ligate the hernia sac. Proponents of this procedure emphasize the fact that no groin incision is used, so there is a decreased chance of injuring cord structures, and that visualization of the contralateral side is achieved immediately. The long-term results of this technique have been quite excellent.

Inguinal hernias in children recur in less than 1% of patients, and recurrences usually result from missed hernia sacs at the first procedure, a direct hernia, or a missed femoral hernia. All children should have local anesthetic administered either by caudal injection or by direct injection into the wound. Spinal anesthesia in preterm infant decreases the risk of postoperative apnea when compared with general anesthesia.

**GENITALIA**

**Undescended testis**

**Embryology.** The term undescended testicle (cryptorchidism) refers to the interruption of the normal descent of the testis into the scrotum. The testicle may reside in the retroperitoneum, in the internal inguinal ring, in the inguinal canal, or even at the external ring. The testicle begins as a thickening on the urogenital ridge in the fifth to sixth week of embryologic life. In the seventh and eighth months, the testicle descends along the inguinal canal into the upper scrotum, and with its progress the processus vaginalis is formed and pulled along with the migrating testicle. At birth, approximately 95% of infants have the testicle normally positioned in the scrotum.

A distinction should be made between an undescended testicle and an ectopic testicle. An ectopic testis, by definition, is one that has passed through the external ring in the normal pathway and then has come to rest in an abnormal location overlying either the rectus abdominis or external oblique muscle, or the soft tissue of the medial thigh, or behind the scrotum in the perineum. A congenitally absent testicle results from failure of normal development or an intrauterine accident leading to loss of blood supply to the developing testicle.
Clinical Presentation. The incidence of undescended testes is approximately 30% in preterm infants, and 1% to 3% at term. For diagnosis, the child should be examined in the supine position, where visual inspection may reveal a hypoplastic or poorly rugated scrotum. Usually a unilateral undescended testicle can be palpated in the inguinal canal or in the upper scrotum. Occasionally, the testicle will be difficult or impossible to palpate, indicating either an abdominal testicle or congenital absence of the gonad. If the testicle is not palpable in the supine position, the child should be examined with his legs crossed while seated. This maneuver diminishes the cremasteric reflex and facilitates identification of the location of the testicle. If there is uncertainty regarding location of a testis, repeated evaluations over time may be helpful.

It is now established that cryptorchid testes demonstrate an increased predisposition to malignant degeneration. In addition, fertility is decreased when the testicle is not in the scrotum. For these reasons, surgical placement of the testicle in the scrotum (orchidopexy) is indicated. It should be emphasized that this procedure does improve the fertility potential, although it is never normal. Similarly, the testicle is still at risk of malignant change, although its location in the scrotum facilitates potentially earlier detection of a testicular malignancy. Other reasons to consider orchidopexy include the risk of trauma to the testicle located at the pubic tubercle and incidence of torsion, as well as the psychological impact of an empty scrotum in a developing male. The reason for malignant degeneration is not established, but the evidence points to an inherent abnormality of the testicle that predisposes it to incomplete descent and malignancy rather than malignancy as a result of an abnormal environment.

Treatment. Males with bilateral undescended testicles are often infertile. When the testicle is not present within the scrotum, it is subjected to a higher temperature, resulting in decreased spermatogenesis. Mengel and coworkers studied 515 undescended testicles by histology and demonstrated reduced spermatogonia after 2 years of age. It is now recommended that the undescended testicle be surgically repositioned by 1 year of age. Despite orchidopexy, the incidence of infertility is approximately two times higher in men with unilateral orchidopexy compared to men with normal testicular descent.

The use of chorionic gonadotropin occasionally may be effective in patients with bilateral undescended testes, suggesting that these patients are more apt to have a hormone insufficiency than children with unilateral undescended testicle. The combination of micro-penis and bilateral undescended testes is an indication for hormonal evaluation and testosterone replacement if indicated. If there is no testicular descent after a month of endocrine therapy, operative correction should be undertaken. A child with unilateral cryptorchidism should have surgical correction of the problem. The operation is typically performed through a combined groin and scrotal incision. The cord vessels are fully mobilized, and the testicle is placed in a dartos pouch within the scrotum. An inguinal hernia often accompanies a cryptorchid testis. This should be repaired at the time of orchidopexy.

Patients with a nonpalpable testicle present a challenge in management. The current approach involves laparoscopy to identify the location of the testicle. If the spermatic cord is found to traverse the internal ring or the testis is found at the ring and can be delivered into the scrotum, a groin incision is made and an orchidopexy is performed. If an abdominal testis is identified that is too far to reach the scrotum, a two-staged Fowler-Stephens approach is used. In the first stage, the testicular vessels are clipped laparoscopically, which promotes the development of new blood vessels along the vas deferens. Several months later, the second stage is performed during which the testis is mobilized laparoscopically along with a swath of peritoneum with collateralized blood supply along the vas. Preservation of the gubernacular attachments with its collaterals to the testicle may confer improved testicular survival following orchidopexy in over 90%. It is, nonetheless, preferable to preserve the testicular vessels whenever possible and complete mobilization of the testicle with its vessels intact.

Vaginal Anomalies
Surgical diseases of the vagina in children are either congenital or acquired. Congenital anomalies include a spectrum of diseases that range from simple defects (imperforate hymen) to more complex forms of vaginal atresia, including distal, proximal, and, most severe, complete. These defects are produced by abnormal development of müllerian ducts and/or urogenital sinus. The diagnosis is made most often by physical examination. Secretions into the obstructed vagina produce hydrocolpos, which may present as a large, painful abdominal mass. The anatomy may be defined using US. Pelvic magnetic resonance imaging provides the most thorough and accurate assessment of the pelvic structures. Treatment is dependent on the extent of the defect. For an imperforate hymen, division of the hymen is curative. More complex forms of vaginal atresia require mobilization of the vaginal remnants and creation of an anastomosis at the perineum. Laparoscopy can be extremely useful, both in mobilizing the vagina, in draining hydrocolpos, and in evaluating the internal genitalia. Complete vaginal atresia requires the construction of skin flaps or the creation of a neovagina using a segment of colon.

The most common acquired disorder of the vagina is the straddle injury. This often occurs as young girls fall on blunt objects which cause a direct injury to the perineum. Typical manifestations include vaginal bleeding and inability to void. Unless the injury is extremely superficial, patients should be examined in the operating room where the lighting is optimal and sedation can be administered. Examination under anesthesia is particularly important in girls who are unable to void, suggesting a possible urethral injury. Vaginal lacerations are repaired using absorbable sutures, and the proximity to the urethra should be carefully assessed. Prior to hospital discharge, it is important that girls are able to void spontaneously. In all cases of vaginal trauma, it is essential that the patient be assessed for the presence of sexual abuse. In these cases, early contact with the sexual abuse service is necessary so that the appropriate microbiologic and photographic evidence can be obtained.

Ovarian Cysts and Tumors
Pathologic Classification. Ovarian cysts and tumors may be classified as nonneoplastic or neoplastic. Nonneoplastic lesions include cysts (simple, follicular, inclusion, paraovarian, or corpus luteum), endometriosis, and inflammatory lesions. Neoplastic lesions are classified based on the three primordia that contribute to the ovary: mesenchymal components of the urogenital ridge, germinal epithelium overlying the urogenital ridge, and germ cells migrating from the yolk sac. The most common variety is germ cell tumors. Germ cell tumors are classified based on the degree of differentiation and the cellular components
involved. The least differentiated tumors are the dysgerminomas, which share features similar to the seminoma in males. Although these are malignant tumors, they are extremely sensitive to radiation and chemotherapy. The most common germ cell tumors are the teratomas, which may be mature, immature, or malignant. The degree of differentiation of the neural elements of the tumor determines the degree of immaturity. The sex cord stromal tumors arise from the mesenchymal components of the urogenital ridge. These include the granulosa-theca cell tumors and the Sertoli-Leydig cell tumors. These tumors often produce hormones that result in precocious puberty or hirsutism, respectively. Although rare, epithelial tumors do occur in children. These include serous and mucinous cystadenomas.

**Clinical Presentation.** Children with ovarian lesions usually present with abdominal pain. Other signs and symptoms include a palpable abdominal mass, evidence of urinary obstruction, symptoms of bowel obstruction, and endocrine imbalance. The surgical approach depends on the appearance of the mass at operation (i.e., whether it is benign-appearing or is suspicious for malignancy). In the case of a simple ovarian cyst, surgery depends on the size of the cyst and the degree of symptoms it causes. In general, large cysts (over 4–5 cm) in size should be resected, as they are unlikely to resolve, may be at risk of torsion, and may mask an underlying malignancy. Resection may be performed laparoscopically, and ovarian tissue should be spared in all cases.

**Surgical Management.** For ovarian lesions that appear malignant, it is important to obtain tumor markers including α-fetoprotein (teratomas), β-hCG (dysgerminoma), β-human chorionic gonadotropin (choriocarcinoma), and CA-125 (epithelial tumors). Although the diagnostic sensitivity of these markers is not always reliable, they provide material for postoperative follow-up and indicate the response to therapy. When malignancy is suspected, the patient should undergo a formal cancer operation. This procedure is performed through either a midline incision or a Pfannenstie approach. Ascites and peritoneal washings should be collected for cytologic study. The liver and diaphragm are inspected carefully for metastatic disease. An omentectomy is performed if there is any evidence of tumor present. Pelvic and para-aortic lymph nodes are biopsied, and the primary tumor is resected completely. Finally, the contralateral ovary is carefully inspected, and if a lesion is seen, it should be biopsied. Dysgerminomas and epithelial tumors may be bilateral in up to 15% of cases. The surgical approach for a benign lesion of the ovary should include preservation of the ipsilateral fallopian tube and preservation of the noninvolved ovary.

**Ovarian Cysts in the Newborn.** Ovarian cysts may be detected by prenatal US. The approach to lesions less than 4 cm should include serial US evaluation every 2 months or so as many of these lesions will resolve spontaneously. Consideration should be given to laparoscopic excision of cysts larger than 4 cm to avoid the risks of ovarian torsion or development of abdominal symptoms. For smaller lesions, resolution occurs by approximately 6 months of age. A laparoscopic approach is preferable in these cases. By contrast, complex cysts of any size require surgical intervention at presentation to exclude the possibility of malignancy.

**Ambiguous Genitalia**

**Embryology.** Normal sexual differentiation occurs in the sixth fetal week. In every fetus, wolffian (male) and müllerian (female) ducts are present until the onset of sexual differentiation. Normal sexual differentiation is directed by the sex determining region of the Y chromosome (SRY). This is located on the distal end of the short arm of the Y chromosome. SRY provides a genetic switch that initiates gonadal differentiation in the mammalian urogenital ridge. Secretion of Müllerian-inhibiting substance (MIS) by the Sertoli cells of the seminiferous tubules results in regression of the müllerian duct, the anlage of the uterus, Fallopian tubes, and the upper vagina. The result of MIS secretion therefore is a phenotypic male. In the absence of SRY in the Y chromosome, MIS is not produced, and the müllerian duct derivatives are preserved. Thus, the female phenotype prevails.

In order for the male phenotype to develop, the embryo must have a Y chromosome, the SRY must be normal without point mutations or deletions, testosterone and MIS must be produced by the differentiated gonad, and the tissues must respond to these hormones. Any disruption of the orderly steps in sexual differentiation may be reflected clinically as variants of the intersex syndromes.

These may be classified as (a) true hermaphroditism (with ovarian and testicular gonadal tissue), (b) male pseudohermaphroditism (testicles only), (c) female pseudohermaphroditism (ovarian tissue only), and (d) mixed gonadal dysgenesis (usually underdeveloped or imperfectly formed gonads).

**True Hermaphroditism** This represents the rarest form of ambiguous genitalia. Patients have both normal male and female gonads, with an ovary on one side and a testis on the other. Occasionally, an ovotestis is present on one or both sides. The majority of these patients have a 46,XX karyotype. Both the testis and the testicular portion of the ovotestis should be removed.

**Male Pseudohermaphroditism** This condition occurs in infants with an XY karyotype but deficient masculinization of the external genitalia. Bilateral testes are present, but the duct structures differentiate partly as phenotypic females. The causes include inadequate testosterone production due to biosynthetic error, inability to convert testosterone to dihydrotestosterone due to 5α-reductase deficiency or deficiencies in androgen receptors. The latter disorder is termed testicular feminization syndrome. Occasionally, the diagnosis in these children is made during routine inguinal herniorrhaphy in a phenotypic female at which time testes are found. The testes should be resected due to the risk of malignant degeneration, although this should be performed only after a full discussion with the family has occurred.

**Female Pseudohermaphroditism** The most common cause of female pseudohermaphroditism is congenital adrenal hyperplasia. These children have a 46,XX karyotype but have been exposed to excessive androgens in utero. Common enzyme deficiencies include 21-hydroxylase, 11-hydroxylase, and 3β-hydroxysteroid dehydrogenase. These deficiencies result in overproduction of intermediary steroid hormones, which results in masculinization of the external genitalia of the XX fetus. These patients are unable to synthesize cortisol. In 90% of cases, deficiency of 21-hydroxylase causes adrenocorticotropic hormone (ACTH) to stimulate the secretion of excessive quantities of adrenal androgen, which masculinizes the developing female (Fig. 39-36). These infants are prone to salt loss, and require cortisol replacement. Those with mineralocorticoid deficiency also require fluorocortisone replacement.

**Mixed Gonadal Dysgenesis** This syndrome is associated with dysgenetic gonads and retained müllerian structures. The typical karyotype is mosaic, usually 45XO,46XY. A high incidence of
malignant tumors occur in the dysgenetic gonads, most commonly gonadoblastoma. Therefore, they should be removed.

Management. In the differential diagnosis of patients with intersex anomalies, the following diagnostic steps are necessary: (a) evaluation of the genetic background and family history; (b) assessment of the anatomic structures by physical examination, US, and/or chromosome studies; (c) determination of biochemical factors in serum and urine to evaluate the presence of an enzyme defect; and (d) laparoscopy for gonadal biopsy. Treatment should include correction of electrolyte and volume losses, in cases of congenital adrenal hyperplasia, and replacement of hormone deficiency. Surgical assignment of gender should never be determined at the first operation. Although historically female gender had been assigned, there is abundant and convincing evidence that raising a genotypic male as a female has devastating consequences, not only anatomically but also psychosocially. This is particularly relevant given the role of pre- and postnatal hormones on gender imprinting and identity. In general terms, surgical reconstruction should be performed after a full genetic workup and with the involvement of pediatric endocrinologists, plastic surgeons, and ethicists with expertise in gender issues. Discussion with the family also plays an important role. This approach will serve to reduce the anxiety associated with these disorders and will help to ensure the normal physical and emotional development of these patients.

PEDIATRIC MALIGNANCY

Cancer is the second leading cause of death in children after trauma and accounts for approximately 11% of all pediatric deaths in the United States. The following description will be restricted to the most commonly encountered tumors in children.

Wilms’ Tumor

Clinical Presentation. Wilms’ tumor is the most common primary malignant tumor of the kidney in children. There are approximately 500 new cases annually in the United States, and most are diagnosed between 1 and 5 years with the peak incidence at age 3. Advances in the care of patients with Wilms’ tumor has resulted in an overall cure rate of roughly 90%, even in the presence of metastatic spread. The tumor usually develops in otherwise healthy children as an asymptomatic mass in the flank or upper abdomen. Frequently, the mass is discovered by a parent while bathing or dressing the child. Other symptoms include hypertension, hematuria, obstipation, and weight loss. Occasionally the mass is discovered following blunt abdominal trauma.

Genetics of Wilms’ Tumor. Wilms’ tumor can arise from both germline and somatic mutations and can occur in the presence or absence of a family history. Nearly 97% of Wilms’ tumors are sporadic in that they occur in the absence of a heritable or congenital cause or risk factor. When a heritable risk factor is identified, the affected children often present at an earlier age, and the tumors are frequently bilateral. Most of these tumors are associated with germline mutations. It is well established that there is a genetic predisposition to Wilms’ tumor in WAGR syndrome, which consists of Wilms’ tumor, aniridia, genitourinary abnormalities, and mental retardation. In addition, there is an increased incidence of Wilms’ tumor in certain overgrowth conditions, particularly Beckwith–Wiedemann syndrome and hemihypertrophy. WAGR syndrome has been shown to result from the deletion of one copy each of the Wilms’ tumor gene, WT1, and the adjacent aniridia gene, PAX6, on chromosome 11p13. Beckwith–Wiedemann syndrome is an overgrowth syndrome that is characterized by visceromegaly, macroglossia, and hyperinsulinemic hypoglycemia. It arises from mutations at the 11p15.5 locus. There is evidence to suggest that analysis of the methylation status of several genes in the 11p15 locus could predict the individual risk to the development of Wilms’ tumor. Importantly, most patients with Wilms’ tumor do not have mutations at these genetic loci.

Surgical Treatment. Before operation, all patients suspected of having Wilms’ tumor should undergo abdominal and chest computerized tomography. These studies characterize the mass, identify the presence of metastases, and provide information on the opposite kidney (Fig. 39-37). CT scanning also indicates the presence of nephrogenic rests, which are precursor lesions to Wilms’ tumor. An abdominal US should be performed to evaluate the presence of renal vein or vena caval extension.

The management of patients with Wilms’ tumor has been carefully analyzed within the context of large studies involving thousands of patients. These studies have been coordinated by the National Wilms’ Tumor Study Group (NWTSG) in North America and the International Society of Paediatric Oncology.
(SIOP), mainly involving European countries. Significant differences in the approach to patients with Wilms’ tumor have been highlighted by these studies. NWTSG supports a strategy of surgery followed by chemotherapy in most instances, whereas the SIOP approach is to shrink the tumor using preoperative chemotherapy. There are instances where preoperative chemotherapy is supported by both groups, including the presence of bilateral involvement or inferior vena cava involvement that extends above the hepatic veins and involvement of a solitary kidney by Wilms’ tumor. The NWTSG proponents argue that preoperative therapy in other instances results in a loss of important staging information, and therefore places patients at higher risk for recurrence; alternatively, it may lead to overly aggressive treatment in some cases and greater morbidity. However, the overall survival rates are not different between the NWTSG and SIOP approaches.

The goal of surgery is complete removal of the tumor. It is crucial to avoid tumor rupture or injury to contiguous organs. A sampling of regional lymph nodes should be included, and all suspicious nodes should be sampled. Typically, a large transverse abdominal incision is made, and a transperitoneal approach is used. The opposite side is carefully inspected to ensure that there is no disease present. Although historically this involved the complete mobilization of the contralateral kidney, current evidence indicates that preoperative, high-resolution CT scanning is of sufficient accuracy for the detection of clinically significant lesions if they are present. Provided only unilateral disease is present, a radical nephroureterectomy is then performed with control of the renal pedicle as an initial step. If there is spread above the hepatic veins, an intrathoracic approach may be required. If bilateral disease is encountered, both lesions are biopsied, and chemotherapy is administered followed by a nephron-sparing procedure.

Chemotherapy. Following nephroureterectomy for Wilms’ tumor, the need for chemotherapy and/or radiation therapy are determined by the histology of the tumor and the clinical stage of the patient (Table 39-3). Essentially, patients who have disease confined to one kidney completely excised surgically receive a short course of chemotherapy and can expect a 97% 4-year survival, with tumor relapse rare after that time. Patients with more advanced disease or with unfavorable histology receive more intensive chemotherapy and radiation. Even in stage IV, high cure rates may be achieved. The survival rates are worse in the small percentage of patients considered to have unfavorable histology.

Neuroblastoma
Clinical Presentation. Neuroblastoma is the third most common pediatric malignancy and accounts for approximately 10% of all childhood cancers. The vast majority of patients have advanced disease at the time of presentation, and unlike Wilms’ tumor, in which cure is expected in the vast majority of patients, the overall survival of patients with neuroblastoma is significantly lower. Over 80% of cases present before the age of 4 years, and the peak incidence is two years of age. Neuroblastomas arise from the neural crest cells and show different levels of differentiation. The tumor originates most frequently in the adrenal glands, posterior mediastinum, neck, or pelvis but can arise in any sympathetic ganglion. The clinical presentation depends on the site of the primary and the presence of metastases.

</table>

*Rupture or spillage confined to the flank, including biopsy of the tumor, is no longer included in stage II and is now included in stage III.*
Two-thirds of these tumors are first noted as an asymptomatic abdominal mass. The tumor may cross the midline, and a majority of patients will already show signs of metastatic disease. Occasionally, children may experience pain from the tumor mass or from bony metastases. Proptosis and periorbital ecchymosis may occur due to the presence of retrobulbar metastasis. Because they originate in paraspinal ganglia, neuroblastosmas may invade through neural foramina and compress the spinal cord, causing muscle weakness or sensory changes. Rarely, children may have severe watery diarrhea due to the secretion of vasoactive intestinal peptide by the tumor, or with paraneoplastic neurologic findings including cerebellar ataxia or opsoclonus/myoclonus. The International Neuroblastoma Staging System and the International Neuroblastoma Risk Group Staging System are provided in Table 39-3.

**Diagnostic Evaluation.** Since these tumors derive from the sympathetic nervous system, catecholamines and their metabolites will be produced at increased levels. These include elevated levels of serum catecholamines (dopamine, norepinephrine) or urine catecholamine metabolites: vanillylmandelic acid (VMA) or homovanillic acid (HVA). Measurement of VMA and HVMA in serum and urine aids in the diagnosis and in monitoring adequacy of future treatment and recurrence. The minimum criterion for a diagnosis of neuroblastoma is based on one of the following: (a) an unequivocal pathologic diagnosis made from tumor tissue by light microscopy (with or without immunohistology, electron microscopy, or increased levels of serum catecholamines or urinary catecholamine metabolites); (b) the combination of bone marrow aspirate or biopsy containing unequivocal tumor cells and increased levels of serum catecholamines or urinary catecholamine metabolites as described earlier.

The patient should be evaluated by abdominal computerized tomography, which may show displacement and occasionally obstruction of the ureter of an intact kidney (Fig. 39-38). Prior to the institution of therapy, a complete staging workup should be performed. This includes radiograph of the chest, bone marrow biopsy, and radionuclide scans to search for metastases. Any abnormality on chest X-ray should be followed up with CT of the chest.

**Prognostic Indicators.** A number of biologic variables have been studied in children with neuroblastoma. An open biopsy is required in order to provide tissue for this analysis. Hyperdiploid tumor DNA is associated with a favorable prognosis, and \( N\text{-}myc \) amplification is associated with a poor prognosis regardless of patient age. The Shimada classification describes tumors as either favorable or unfavorable histology based on the degree of differentiation, the mitosis-karyorrhexis index, and the presence or absence of schwannian stroma. In general, children of any age with localized neuroblastoma and infants younger than 1 year of age with advanced disease and favorable disease characteristics have a high likelihood of disease-free survival. By contrast, older children with advanced-stage disease have a significantly decreased chance for cure despite intensive therapy. For example, aggressive multiagent chemotherapy has resulted in a 2-year survival rate of approximately 20% in older children with stage IV disease. Neuroblastoma in the adolescent has a worse long-term prognosis regardless of stage or site and, in many cases, a more prolonged course.

**Surgery.** The goal of surgery is complete resection. However, this is often not possible at initial presentation due to the extensive locoregional spread of the tumor at the time of presentation. Under these circumstances, a biopsy is performed, and preoperative chemotherapy is provided based upon the stage of the tumor. After neoadjuvant treatment has been administered, surgical resection is performed. The principal goal of surgery is to obtain at least 95% resection without compromising major structures. Abdominal tumors are approached through a transverse incision. Thoracic tumors may be approached through a posterolateral thoracotomy or through a thoracosopic approach. These may have an intraspinal component. In all cases of intrathoracic neuroblastoma, particularly those at the thoracic inlet, it is important to be aware of the possibility of a Horner’s syndrome (anhidrosis, ptosis, meiosis) developing. This typically resolves, although it may take many months to do so.

**Neuroblastoma in Infants.** Spontaneous regression of neuroblastoma has been well described in infants, especially in those with stage 4S disease. Regression generally occurs only in tumors with a near triploid number of chromosomes that also lack \( N\text{-}myc \) amplification and loss of chromosome 1p. Recent studies indicate that infants with asymptomatic, small, low-stage neuroblastoma detected by screening may have tumors that spontaneously regress. These patients may be observed safely without surgical intervention or tissue diagnosis.

**Rhabdomyosarcoma**

Rhabdomyosarcoma is a primitive soft tissue tumor that arises from mesenchymal tissues. The most common sites of origin include the head and neck (36%), extremities (19%), genitourinary tract (2%), and trunk (9%), although the tumor can arise virtually anywhere. The clinical presentation of the tumor depends on the site of origin. The diagnosis is confirmed with incisional or excisional biopsy after evaluation by MRI, CT scans of the affected area and the chest, and bone marrow biopsy. The tumor grows locally into surrounding structures and metastasizes widely to lung, regional lymph nodes, liver, brain, and bone marrow. The staging system for rhabdomyosarcoma is based upon the TNM system, as established by the Soft Tissue Sarcoma Committee of the Children’s Oncology Group. It is shown in Table 39-4. Surgery is an important component of the staging strategy and involves biopsy of the lesion and evaluation of lymphatics. Primary resection should be undertaken when complete excision can be performed without causing disability. If this is not possible, the lesion is biopsied, and intensive chemotherapy is administered. It is important to plan the biopsy so that it does not interfere with subsequent resection. After the
tumor has decreased in size, resection of gross residual disease should be performed. Radiation therapy is effective in achieving local control when microscopic or gross residual disease exists following initial treatment. Patients with completely resected tumors of embryonal histology do well without radiation therapy, but radiation therapy benefits patients with group I tumors with alveolar or undifferentiated histology.

**Prognosis.** The prognosis for rhabdomyosarcoma is related to the site of origin, resectability, presence of metastases, number of metastatic sites, and histopathology. Primary sites with more favorable prognoses include the orbit and nonparameningeal head and neck, paratestis and vagina (nonbladder, nonprostate genitourinary), and the biliary tract. Patients with tumors less than 5 cm in size have improved survival compared to children with larger tumors, while children with metastatic disease at diagnosis have the poorest prognosis. Tumor histology influences prognosis and the embryonal variant is favorable while the alveolar subtype is unfavorable.

**Teratoma**

Teratomas are tumors composed of tissue from all three embryonic germ layers. They may be benign or malignant, they may arise in any part of the body, and they are usually found in midline structures. Thoracic teratomas usually present as an anterior mediastinal mass. Ovarian teratomas present as an abdominal mass often with symptoms of torsion, bleeding, or rupture. Retroperitoneal teratomas may present as a flank or abdominal mass.

Most tumors are identified at birth and are benign. Malignant yolk sac tumor histology occurs in a minority of these tumors. Complete resection of the tumor as early as possible is essential. The rectum and genital structures are often distorted by the tumor but usually can be preserved in the course of resection. Perioperative complications of hypothermia and hemorrhage can occur with massive tumors and may prove lethal. This is of particular concern in small, preterm infants with large tumors. The cure rate is excellent if the tumor is excised completely.

**Sacroccocygeal Teratoma.** Sacroccocygeal teratoma usually presents as a large mass extending from the sacrum in the newborn period. Diagnosis may be established by prenatal US. In fetuses with evidence of hydrops and a large sacroccocygeal teratoma, prognosis is poor; thus, prenatal intervention has been advocated in such patients. The mass may be as small as a few centimeters in diameter or as massive as the size of the infant (Fig. 39-39). The tumor has been classified based upon the location and degree of intrapelvic extension. Lesions that grow predominantly into the presacral space often present later in childhood. The differential diagnosis consists of neural tumors, lipoma, and myelomeningoceles.

Most tumors are identified at birth and are benign. Malignant yolk sac tumor histology occurs in a minority of these tumors. Complete resection of the tumor as early as possible is essential. The rectum and genital structures are often distorted by the tumor but usually can be preserved in the course of resection. Perioperative complications of hypothermia and hemorrhage can occur with massive tumors and may prove lethal. This is of particular concern in small, preterm infants with large tumors. The cure rate is excellent if the tumor is excised completely.

T1 = tumor confined to anatomic site of origin; T2 = tumor extension and/or fixed to surrounding tissues; a = ≤5 cm; b = >5 cm; N0 = regional nodes not clinically involved; N1 = regional nodes clinically involved; NX = regional node status unknown; M0 = no distant metastasis; M1 = metastasis present.

Clinical group:
- Group 1: Localized disease, completely resected, no regional lymph node involvement.
- Group 2: Localized disease, gross total resection but microscopic residual disease; or regional lymph nodes involved.
- Group 3: Localized disease with gross residual disease after incomplete resection or biopsy only.
- Group 4: Metastatic disease at diagnosis.

**Figure 39-39.** Sacroccocygeal teratoma in a 2-day-old boy.
The majority of patients who develop recurrent disease are salvagable with subsequent platinum-based chemotherapy.

**Liver Tumors**

More than two-thirds of all liver tumors in children are malignant. There are two major histologic subgroups: hepatoblastoma and hepatocellular carcinoma. The age of onset of liver cancer in children is related to the histology of the tumor. Hepatoblastoma is the most common malignancy of the liver in children, with most of these tumors diagnosed before 4 years of age. Hepatocellular carcinoma is the next most common, with a peak age incidence between 10 and 15 years. Malignant mesenchymomas and sarcomas are much less common but constitute the remainder of the malignancies. The finding of a liver mass does not necessarily imply that a malignancy is present. Nearly 50% of all masses are benign, and hemangiomas are the most common lesion.

Most children with a liver tumor present with an abdominal mass that is usually painless, which the parents note while changing the child’s clothes or while bathing the child. The patients are rarely jaundiced but may complain of anorexia and weight loss. Most liver function tests are normal. AFP levels are increased in 90% of children with hepatoblastomas but much less commonly in other liver malignancies. Radiographic evaluation of these children should include an abdominal CT scan to identify the lesion and to determine the degree of local invasiveness (Fig. 39-40). For malignant appearing lesions, a biopsy should be performed unless the lesion can be completely resected easily. Hepatoblastoma is most often unifocal, while hepatocellular carcinoma is often extensively invasive or multicentric. If a hepatoblastoma is completely removed, the majority of patients survive, but only a minority of patients have lesions amenable to complete resection at diagnosis.

A staging system based on postsurgical extent of tumor and surgical resectability is shown in Table 39-5. The overall survival rate for children with hepatoblastoma is 70%, but it is only 25% for hepatocellular carcinoma. Children diagnosed with stage I and II hepatoblastoma have a cure rate of greater than 90% compared to 60% for stage III and approximately 20% for stage IV. In children diagnosed with hepatocellular carcinoma, those with stage I have a good outcome, whereas stages III and IV are usually fatal. The fibrolamellar variant of hepatocellular carcinoma may have a better prognosis.

**Surgery.** The abdominal CT scan usually will determine the resectability of the lesion, although occasionally this can only be determined at the time of exploration. Complete surgical resection of the tumor is the primary goal and is essential for cure. For tumors that are unresectable, preoperative chemotherapy should be administered to reduce the size of the tumor and improve the possibility for complete removal. Chemotherapy is more successful for hepatoblastoma than for hepatocellular carcinoma. Areas of locally invasive disease, such as the diaphragm, should be resected at the time of surgery. For unresectable tumors, liver transplantation may be offered in select patients. The fibrolamellar variant of hepatocellular carcinoma may have a better outcome with liver transplantation than other hepatocellular carcinomas.

**TRAUMA IN CHILDREN**

Injury is the leading cause of death among children older than 1 year. In fact, trauma accounts for almost half of all pediatric deaths, more than cancer, congenital anomalies, pneumonia, heart disease, homicide, and meningitis combined. Death from unintentional injuries accounts for 65% of all injury-related deaths in children younger than 19 years. Motor vehicle collisions are the leading cause of death in people age 1 to 19 years, followed by homicide or suicide (predominantly with firearms) and drowning. Each year, approximately 20,000 children and teenagers die as a result of injury in the United States. For every child who dies from an injury, it is calculated that 40 others are hospitalized and 1120 are treated in emergency departments. An estimated 50,000 children acquire permanent disabilities each year, most of which are the result of head injuries. Thus, the problem of pediatric trauma continues to be one of the major threats to the health and well-being of children.

Specific considerations apply to trauma in children that influence management and outcome. These relate to the mechanisms of injury, the anatomic variations in children compared to adults, and the physiologic responses.

**Mechanisms of Injury**

Most pediatric trauma is blunt. Penetrating injuries are seen in the setting of gun violence, falls onto sharp objects, or penetration by glass after falling through windows. Age and gender significantly influence the patterns of injury. Male children between 14 and 18 years of age are exposed to contact sports, gun violence, and in some jurisdictions drive motor vehicles. As a result, they have a different pattern of injury than younger children, characterized by higher injury severity scores. In the infant and toddler age group, falls are a

![Figure 39-40. Computed tomography of the abdomen showing a hepatocellular carcinoma in a 12-year-old boy.](image)
common cause of severe injury. Injuries in the home are extremely common. These include falls, near-drownings, caustic ingestion, and nonaccidental injuries.

**Initial Management**

The goals of managing the pediatric trauma patient are similar to those of adults and follow Advanced Trauma Life Support guidelines as established by the American College of Surgeons Committee on Trauma. Airway control is the first priority. In a child, respiratory arrest can proceed quickly to cardiac arrest. It is important to be aware of the anatomic differences between the airway of the child and the adult. The child has a large head, shorter neck, smaller and anterior larynx, floppy epiglottis, short trachea, and large tongue. The size of the endotracheal tube can be estimated by the formula \((\text{age} + 16)/4\). It is important to use uncuffed endotracheal tubes in children younger than 8 years in order to minimize tracheal trauma. After evaluation of the airway, breathing is assessed. It is important to consider that gastric distention from aerophagia can severely compromise respirations. A nasogastric tube should therefore be placed early during the resuscitation if there is no head injury suspected, or an orogastric tube in cases of head injury. Pneumothorax or hemothorax should be treated promptly. When evaluating the circulation, it is important to recognize that tachycardia is usually the earliest measurable response to hypovolemia. Other signs of impending hypovolemic shock in children include changes in mentation, delayed capillary refill, skin pallor, and hypothermia. IV access should be rapidly obtained once the patient arrives in the trauma bay. The first approach should be to use the antecubital fossae. If this is not possible, a cut-down into the saphenous at the groin can be performed quickly and safely. Intraosseous cannulation can provide temporary access in children and young adults until IV access is established. US-guided central line placement in the groin or neck should be considered in patients in whom large bore peripheral IV access is not obtained. Blood is drawn for cross-match and evaluation of liver enzymes, lipase, amylase, and hematologic profile after the IV lines are placed.

In patients who show signs of volume depletion, a 20 mL/kg bolus of saline or lactated Ringer’s should be promptly given. If the patient does not respond to three boluses, blood should be transfused (10 mL/kg). The source of bleeding should be established. Common sites include the chest, abdomen, pelvis, extremity fractures, or large scalp wounds. These should be carefully sought. Care is taken to avoid hypothermia by infusing warmed fluids and by using external warming devices.

**Evaluation of Injury**

All patients should receive an X-ray of the cervical spine, chest, and abdomen with pelvis. All extremities that are suspicious for fracture should also be evaluated by X-ray. Plain cervical spine films are preferable to performing routine neck CT scans in the child, as X-rays provide sufficient anatomic detail. But if a head CT is obtained, it may be reasonable to obtain images down to C-2 since odontoid views in small children are difficult to obtain. In most children, it is possible to diagnose clinically significant cervical spine injuries using this approach while minimizing the degree of radiation exposure. Screening blood work that includes AST, ALT, and amylase/lipase is useful for the evaluation of liver and pancreatic injuries. Significant elevation in these tests requires further evaluation by CT scanning. The child with significant abdominal tenderness and a mechanism of injury that could cause intra-abdominal injury should undergo abdominal CT scanning using IV and oral contrast in all cases. There is a limited role for diagnostic peritoneal lavage (DPL) in children as a screening test. However, this can be occasionally useful in the child who is brought emergently to the operating room for management of significant intracranial hemorrhage. At the time of craniotomy, a DPL, or alternatively, a diagnostic laparoscopy, can be performed concurrently to identify abdominal bleeding. Although focused abdominal US (FAST exam) is extremely useful in the evaluation of adult abdominal trauma, it is not widely accepted in the management of pediatric blunt abdominal trauma. In part, this relates to the widespread use of nonoperative treatment for most solid-organ injuries. Thus, a positive abdominal US scan would not alter this approach in a hemodynamically stable patient.

**Injuries to the Central Nervous System**

The central nervous system (CNS) is the most commonly injured organ system and is the leading cause of death among injured children. In the toddler age group, nonaccidental trauma is the most common cause of serious head injury. Findings suggestive of abuse include the presence of retinal hemorrhage on fundoscopic evaluation and intracranial hemorrhage without evidence of external trauma (indicative of a shaking injury) and fractures at different stages of healing on skeletal survey. In older children, CNS injury occurs most commonly after falls and bicycle and motor vehicle collisions. The initial head CT can often underestimate the extent of injury in children. Criteria for head CT include any loss of consciousness or amnesia to the trauma, or inability to assess the CNS status as in the intubated patient. Patients with mild, isolated head injury (GCS 14-15) and negative CT scans can be discharged if their neurologic status is normal after 6 hours of observation. Young children and those in whom there is multisystem involvement should be admitted to the hospital for observation. Any change in the neurologic status warrants neurosurgical evaluation and repeat CT scanning. In patients with severe head injury (GCS 8 or less), urgent neurosurgical consultation is required. These patients are evaluated for intracranial pressure monitoring and for the need to undergo craniotomy.

**Thoracic Injuries**

The pediatric thorax is pliable due to incomplete calcification of the ribs and cartilages. As a result, blunt chest injury commonly results in pulmonary contusion, although rib fractures are infrequent. Diagnosis is made by chest radiograph and may be associated with severe hypoxia requiring mechanical ventilation. Pulmonary contusion usually resolves with careful ventilator management and judicious volume resuscitation. Children who have sustained massive blunt thoracic injury may develop traumatic asphyxia. This is characterized by cervical and facial petechial hemorrhages or cyanosis associated with vascular engorgement and subconjunctival hemorrhage. Management includes ventilation and treatment of coexisting CNS or abdominal injuries. Penetrating thoracic injuries may result in damage to the lung or to major disruption of the bronchi or great vessels.

**Abdominal Injuries**

In children, the small rib cage and minimal muscular coverage of the abdomen can result in significant injury after seemingly minor trauma. The liver and spleen in particular are relatively unprotected and are often injured after direct abdominal trauma. Duodenal injuries are usually the result of blunt trauma, which may arise from child abuse or injury from a bicycle handlebar. Duodenal hematomas usually resolve without surgery.
Small intestinal injury usually occurs in the jejunum in the area of fixation by the ligament of Treitz. These injuries are usually caused by rapid deceleration in the setting of a lap belt. There may be a hematoma on the anterior abdominal wall caused by a lap belt, the so-called seat belt sign (Fig. 39-41A). This should alert the caregiver to the possibility of an underlying small bowel injury (Fig. 39-41B), as well as to a potential lumbar spine injury (Chance fracture).

The spleen is injured relatively commonly after blunt abdominal trauma in children. The extent of injury to the spleen is graded (Table 39-6), and the management is governed by the injury grade. Current treatment involves a nonoperative approach in most cases, even for grade 4 injuries, assuming the patient is hemodynamically stable. This approach avoids surgery in most cases. All patients should be placed in a monitored unit, and type-specific blood should be available for transfusion. When nonoperative management is successful, as it is in most cases, an extended period of bed rest is prescribed. This optimizes the chance for healing and minimizes the likelihood of reinjury. A typical guideline is to keep the children on extremely restricted activity for 2 weeks longer than the grade of spleen injury (i.e., a child with a grade 4 spleen injury receives 6 weeks of restricted activity). In children who have an ongoing fluid requirement, or when a blood transfusion is required, exploration should not be delayed. At surgery, the spleen can often be salvaged. If a splenectomy is performed, prophylactic antibiotics and immunizations should be administered to protect against overwhelming post splenectomy sepsis. The liver is also commonly injured after blunt abdominal trauma. A grading system is used to characterize hepatic injuries (Table 39-7), and nonoperative management is usually successful (Fig. 39-42). Recent studies have shown that associated injuries are more significant predictors of outcome in children with liver injuries than the actual injury grade. Criteria for surgery are similar to those for splenic injury and primarily involve hemodynamic instability. The intraoperative considerations in the management of massive hepatic injury are similar in children and adults. Renal contusions may occur after significant blunt abdominal trauma. Nonoperative management is usually successful, unless patients are unstable due to active renal bleeding. It is important to confirm the presence of a normal contralateral kidney at the time of surgery.

**FETAL INTERVENTION**

One to the most exciting developments in the field of pediatric surgery has been the emergence of fetal surgery. In general terms, performance of a fetal intervention may be justified in the setting where a defect is present that would cause devastating consequences to the infant if left uncorrected. For the vast majority of congenital anomalies, postnatal surgery is the preferred modality. However, in specific circumstances, fetal surgery may offer the best possibility for a successful outcome.

Specific Considerations

III

Fetal Surgery for Myelomeningocele

Myelomeningocele refers to a spectrum of anomalies in which portions of the spinal cord are uncovered by the spinal column. This leaves the neural tissue exposed to the injurious effects of the amniotic fluid, as well as to trauma from contact with the uterine wall. Nerve damage ensues, resulting in varying degrees of lower extremity paralysis as well as bowel and bladder dysfunction. Initial observations indicated that the extent of injury progressed throughout the pregnancy, which provided the rationale for fetal intervention. The current in utero approach for the fetus with myelomeningocele has focused on obtaining coverage of the exposed spinal cord. The efficacy of in utero treatment versus postnatal repair was recently compared in a large multicenter trial as described earlier and showed that prenatal surgery for myelomeningocele reduced the need for shunting and improved motor outcomes at 30 months but was associated with maternal and fetal risks. The results of this study have paved the way for the acceptance of in utero repair of myelomeningocele in certain centers with the experience and expertise to perform this procedure safely.

The EXIT Procedure

The EXIT procedure is an abbreviation for ex utero intrapartum treatment. It is utilized in circumstances where airway obstruction is predicted at the time of delivery due to the presence of a large neck mass, such as a cystic hygroma or teratoma (Fig. 39-43), or congenital tracheal stenosis. The success of the procedure is dependent upon the maintenance of utero-placental perfusion for a sufficient duration to secure the airway. To achieve this, deep uterine relaxation is obtained during a caesarian section under general anesthesia. Uterine perfusion with warmed saline also promotes relaxation and blood flow to the placenta. On average, between 20 and 30 minutes of placental perfusion can be achieved. The fetal airway is secured either by placement of an orotracheal tube or performance of a tracheotomy. Once the airway is secured, the cord is cut, and a definitive procedure may be performed to relieve the obstruction in the postnatal period. In general terms, cystic neck masses such as lymphangiomas have a more favorable response to an EXIT procedure as compared to solid tumors, such as teratomas, particularly in premature infants.

Figure 39-42. Abdominal computed tomography in a child demonstrating a grade 3 liver laceration (arrows).

Fetal Surgery for Lower Urinary Tract Obstruction

Lower urinary tract obstruction refers to a group of diseases characterized by obstruction of the distal urinary system. Common causes include the presence of posterior urethral valves and urethral atresia, as well as other anomalies of the urethra and bladder. The pathologic effects of lower urinary tract obstruction lie in the resultant massive bladder distention that occurs, which can lead to reflux hydronephrosis. This may result in oligohydramnios, and cause limb contractures, facial anomalies (Potter sequence), and pulmonary hypoplasia. Carefully selected patients with lower urinary tract obstruction may benefit from vesicoamniotic shunting. By relieving the obstruction and improving renal function, fetal growth and lung development may be preserved.

Figure 39-43. The EXIT procedure (ex utero intrapartum treatment) in a 34-week gestation age baby with a large cervical teratoma. Intubation is being performed while the fetus is on placental support.
BIBLIOGRAPHY

Entries highlighted in bright blue are key references.

PART II
SPECIFIC CONSIDERATIONS

Pritchard-Jones K. Controversies and advances in the management of Wilms’ tumour. *Arch Dis Child.* 2002;87:241-244.

The anatomic structures that generally require urologic management include the kidneys, adrenal glands, ureters, bladder, prostate, seminal vesicles, vas deferens, penis, urethra, scrotum, and testes. These organs are located in retroperitoneal or extraperitoneal spaces. However, a transperitoneal approach may be utilized to access the kidney, ureters, bladder, or retroperitoneal lymph nodes during certain urologic operations.

**Kidney and Adrenal Gland**

The kidneys are paired retroperitoneal organs that are invested in a fibro-fatty layer of tissue known as Gerota’s fascia. This natural barrier helps to tamponade bleeding and thus may provide renal and hemodynamic protection in cases of renal trauma or spontaneous renal hemorrhage. It also may assist in preventing tumor invasion into surrounding structures in the case of large renal masses. These organs are located in retroperitoneal or extraperitoneal spaces. However, a transperitoneal approach may be utilized to access the kidney, ureters, bladder, or retroperitoneal lymph nodes during certain urologic operations.

The kidneys are borderer posterolaterally by the quadratus lumborum muscle and posteromedially by the psoas muscle. Additionally, the diaphragm drapes across the posterior aspect of the superior pole of each kidney.

The left kidney is bordered anterolaterally by the spleen and descending colon. The pancreatic tail borders the anteromedial left kidney. The right kidney is bordered anterolaterally by the liver and the ascending colon. The second portion of the duodenum may be encountered near the right renal vessels and thus sometimes requires anteromedial reflection, known as the Kocher maneuver, to achieve intraoperative vascular control during right renal surgery.

The kidneys are end organs, which are responsible for their vulnerability to infarction. The renal arteries extend from the aorta and then branch into several segmental arteries and arterioles before becoming glomeruli. Each artery runs posterior to their respective renal vein. Occasionally, an accessory renal artery will arise, but in general, each kidney receives a single main renal artery. Each renal vein drains directly into the IVC and is located anteriorly to its respective renal artery when entering the kidney. The right renal vein is much shorter than the left and does not receive collateral venous drainage. The left renal vein passes anteriorly to the aorta and receives drainage from the left gonadal vein, the left inferior adrenal vein, and a lumbar vein.

The collecting system of the kidney begins as minor calyces near the renal papillae and then coalesces into major calyces. Major calyces join to form the renal pelvis, which then tapers down to the ureteropelvic junction (UPJ), from which the ureter emanates. The pelvis is located posterior to its respective renal artery.

The adrenal gland is superomedial to its respective kidney within Gerota’s fascia. Adrenal arterial supply arises from multiple sources: the inferior phrenic artery, aortic branches, and renal arterial branches. Venous drainage mirrors arterial supply. On the right side, the adrenal gland drains directly into the IVC. The right adrenal vein can be quite short (<1 cm) and can be
Key Points

1. Most small ureteral calculi will pass spontaneously or with the use of medical expulsive therapy, but larger stones (>6 mm) are better treated with ureteral stenting or lithotripsy.

2. Benign prostatic hyperplasia can be managed effectively with medical therapy or minimally invasive endoscopic and robotic surgical techniques depending on the urinary symptoms, patient bother, prostate size, and patient’s therapeutic choice.

3. Patients with recurrent urethral stricture after endoscopic treatment are unlikely to derive sustained benefit from future endoscopic therapies and should be referred for urethral reconstruction.

4. The vast majority of renal trauma can be treated conservatively, with early surgical intervention reserved for persistent bleeding, renal vascular, or ureteral injuries.

5. Extraperitoneal bladder ruptures can be treated conservatively, but intraperitoneal ruptures typically require surgical repair.

6. Testicular torsion is an emergency where successful testicular salvage is inversely related to the delay in repair, so cases with a high degree of clinical suspicion should not wait for a radiologic diagnosis.

7. Fournier’s gangrene is a rapidly progressive and potentially lethal condition that requires aggressive débridement and close follow-up due to the frequent need for repeat débridement.

8. The management of early stage prostate cancer has changed significantly, with a much greater emphasis on risk stratification. Low risk patients are largely treated with active surveillance.

9. Treatments for urinary incontinence and voiding dysfunction are varied depending on the etiology, severity, and bother of the symptom. Behavior modification, bladder retraining, and medical therapies can all be effective in improving symptoms without the need for surgery.

The bladder is located extraperitoneally in the pelvis and posterior to the aorta and renal artery, and the distal blood supply inserts laterally and arises from the surrounding iliac vessels and their branches. The arterial supply enters via a fatty layer of tissue around the ureter, and thus surgical preservation of the periureteral tissue is essential to maintain vascularization and achieve successful ureteral reconstruction.

The ureters initially course along the psoas muscle and then run distally along the pelvic sidewall. They generally pass posterior to the uterine arteries, making them susceptible to injury during hysterectomy. The ureters enter the bladder laterally and pass through the bladder wall at an oblique angle, which helps prevent reflux of urine during bladder filling. The ureters propel urine into the bladder via the ureteral orifices.

Bladder and Prostate

The bladder is located extraperitoneally in the pelvis and posterior to the pubis. A portion of the bladder dome is draped by peritoneum, and rupture or injury at this location can result in intraperitoneal urine leakage and subsequent chemical peritonitis. The average adult bladder holds approximately 500 mL of urine; however, in rare cases, capacity can reach up to or greater than 1000 mL, in which case the bladder extends towards the umbilicus. The sigmoid colon lies adjacent to the bladder and can fistulize to the lateral wall or dome of the bladder in cases of diverticulitis or colon cancer. The rectum lies posteriorly to the bladder in men, and the uterus and vagina lie posteriorly to the bladder in women.

The prostate is a walnut-shaped gland that encircles the urethra and is located in males immediately beneath the bladder neck. Smooth muscle fibers distribute throughout the gland, which can contract and facilitate bladder outlet obstruction. The average prostate measures approximately 30 mL in volume. Puboprostatic ligaments suspend the prostate to the pubis, and in the instance of pelvic trauma, shearing forces can cause disruption of the posterior urethra (known as pelvic fracture urethral injury). The external urethral sphincter houses the membranous urethra and sits just below the apex of the prostate. Vasculature to the bladder and prostate arises from the superior and inferior vesical arteries, which branch from the internal iliac arteries.

Penis

The penis is comprised of three bodies: two corpora cavernosa, which are responsible for erection, and the corpus spongiosum, which surrounds the urethra and gives rise to the glans penis. These three structures are all encased by skin and dartos fascia, as well as an inner investing layer of fascia called Buck’s fascia. The corpora cavernosa are spongy sinusoidal bodies that expand with parasympathetic neural stimulation to create an erection. Thick fascia, called tunica albuginea, assists in producing rigidity during erection. Each corpus cavernosum features a centrally located cavernosal artery, which arises from the penile artery. A porous septum separates the two corpora and allows for transcorporal blood exchange. The corpus spongiosum is located on the ventrum of the penis. The corpus spongiosum lacks a tough fascia similar to tunica albuginea and thus does not exhibit the same rigidity during erection.

Scrotum and Testes

The scrotum is a potential space that surrounds the testes, epididymis, and spermatic cords. The scrotum is comprised of many layers aside from skin and dartos fascia, and each derives from a particular layer of the anterior abdominal wall. The external spermatic fascia arises from the external oblique fascia, the cremasteric fascia arises from the internal oblique fascia, and the internal spermatic fascia arises from the transversus abdominis fascia. The testes are separated from the scrotal layers by the visceral and parietal layers of the tunica vaginalis, between which hydroceles form. The spermatic cord contains...
the vas deferens, the venous pampiniform plexus, and arterial blood supply to the superior pole of the testis via three separate sources. The testicular artery arises directly from the aorta; the deferential artery, which supplies the vas deferens, arises from the internal iliac artery; and the cremasteric artery, which supplies the cremaster muscle, arises from the external iliac artery. The presence of multiple arterial sources provides collateral flow and prevents ischemia in the event of injury to a particular vascular branch. The venous pampiniform plexus can dilate to form a palpable or visible varicocele, which can serve as an etiology of chronic testicular pain or infertility.

**INFECTION**

**Cystitis**
Uncomplicated cystitis usually presents as new onset urinary frequency, urgency, and dysuria. Patients may also report lower back pain, suprapubic pain, foul-smelling urine, or gross hematuria. Urinalysis with microscopy assists with diagnosis by confirming the presence of pyuria, hematuria, and bacteriuria. Office dipstick may be helpful, as the presence of nitrates reflects bacterial colonization and the presence of leukocyte esterase reflects pyuria. Risk factors for the development of uncomplicated cystitis include female gender, sexual activity, and use of spermicides.\(^1\) Three days of antibiotics are generally sufficient for treatment of uncomplicated cystitis. Fluoroquinolones and trimethoprim-sulfamethoxazole are well tolerated and are easily available. Nitrofurantoin, which is also commonly used for uncomplicated cystitis, requires 5 days of treatment. Men with uncomplicated cystitis should undergo 7 days of treatment.

Complicated cystitis may arise in the setting of structural or functional urinary tract abnormalities, recent urinary tract instrumentation, recent antimicrobial use, immunosuppressed states, pregnancy, or hospital-acquired infection. Symptoms may be similar to uncomplicated cystitis but can progress to pyelonephritis if left untreated. Elderly or very young patients tend to exhibit lethargy, change in mental status, or anorexia, which may confound the diagnosis of a urinary tract infection. Patients may require hospitalization if febrile or if symptoms are severe. Treatment consists of 10 to 14 days of antibiotics. Fluoroquinolones or trimethoprim-sulfamethoxazole are usually effective and should be administered based on culture results and/or regional bacteriograms. Asymptomatic bacteriuria does not require treatment unless detected during pregnancy or if urinary tract instrumentation is planned.\(^1\)

**Pyelonephritis**
Pyelonephritis arises when a bladder infection ascends proximally along the ureters to the renal parenchyma. It may also result from hematogenous spread, such as in the case of intravenous drug abuse or in patients with bacteremia from other sources. Patients with pyelonephritis may present with fevers, flank pain, nausea, vomiting, and lower urinary tract symptoms. Physical exam may reveal tenderness of the costovertebral angle. Patients may appear toxic, with poor oral intake. Laboratory evaluation may reveal leukocytosis with elevated neutrophils. Urinalysis usually demonstrates the presence of pyuria and bacteriuria, and urine culture should be sent prior to starting broad-spectrum antibiotics. Imaging should be considered to rule out obstruction, which could prolong the recovery period despite appropriate antimicrobial treatment.

Acute pyelonephritis requires 7 to 14 days of antibiotic therapy. Mild or moderate cases, even if febrile, can safely be treated as an outpatient with oral antibiotics. Fluoroquinolones and trimethoprim-sulfamethoxazole are ideal for treating pyelonephritis. Nitrofurantoin should not be used as it does not penetrate renal parenchyma. Patients with concern for sepsis or inability to tolerate oral intake may require hospitalization with IV antibiotics while awaiting culture results. Fevers may persist for up to 72 hours despite appropriate treatment. The presence of persistent fevers or symptoms after this time period warrants cross-sectional imaging to rule out renal or perinephric abscess. Treatment for renal or perinephric abscess usually consists of percutaneous drainage and broad-spectrum IV antibiotics.

**Prostatitis**
Acute prostatitis is marked by fever, suprapubic or perineal pain, and new onset lower urinary tract symptoms, namely dysuria, frequency, urgency, changes in stream caliber, or difficulty emptying the bladder. It is most often caused by urinary pathogens. Digital rectal exam may reveal a tender and soft prostate. Bladder drainage with a Foley or suprapubic tube may be required if urinary retention is present. Treatment consists of a long-term course (4–6 weeks) of antibiotics. If not treated in a timely fashion, acute prostatitis can develop into severe sepsis or a prostatic abscess. Prostatic abscesses may require drainage via a transurethral approach or transrectal needle aspiration.

Chronic prostatitis may be bacterial or abacterial. Symptoms in both cases include perineal, suprapubic, or penile pain, along with urinary frequency, urgency, or change in stream caliber. Men may also report pain in the groin, lower back, or testes. Fever is not observed in chronic prostatitis, and onset may occur over many months. Patients with chronic bacterial prostatitis may also report recurrent UTIs, with cultures consistently exhibiting the same bacteria. Differentiation between the two etiologies requires culture of expressed prostatic secretion to confirm the presence or absence of bacteria. Treatment of chronic bacterial prostatitis includes long-term antibiotics and \(\alpha\)-blockers.

Chronic abacterial prostatitis is also known as chronic pelvic pain syndrome (CPPS). Symptoms are similar to chronic bacterial prostatitis, but generally do not respond well to long-term antibiotics for treatment. It is generally somewhat more difficult to achieve symptomatic relief when treating CPPS, and options include \(\alpha\)-blockers, NSAIDs, neuromodulators, and/or pelvic floor physical therapy.\(^2\)

**Epididymo–Orchitis**
Epididymitis refers to inflammation of the epididymis. In most cases of bacterial infection, the testis is also affected, thus is encompassed by the term “epididymo–orchitis.” Common etiologies include sexually transmitted infection, especially in younger males, or urinary tract infection, which is more commonly seen in older males. Other possible etiologies include underlying congenital urologic abnormality or incomplete bladder emptying. Symptoms include pain and swelling of the epididymis and testis. Some men may report nausea or vomiting, which arises as a result of irritation of the spermatic cord. Urinary symptoms may be present, but absence of symptoms does not rule out bacterial epididymo–orchitis. Physical exam generally reveals a tender, swollen epididymis and testis. Scrotal skin erythema or reactive hydrocele may be present as well. A complete blood count should be performed to rule out leukocytosis, and urinalysis with urine culture should be collected prior to initiation of antibiotics. Urethral swab should be performed if sexually transmitted infection is a possible etiology. The clinical presentation of testicular torsion can be quite similar to that of...
epididymo-orchitis. It may be quite difficult to clinically differentiate the two entities, but one should keep in mind that the onset of torsion tends to be slightly more acute (within 4–8 hours) than that of epididymo-orchitis (which generally arises over the course of 24–48 hours). Scrotal ultrasound can assist in diagnosis; however, in cases of severe orchitis, testicular flow can be compromised, which may raise concern for torsion. Scrotal exploration should be considered in any equivocal case: a missed torsion can result in testicular loss secondary to necrosis.

Treatment of epididymo-orchitis consists of single dose of ceftriaxone and azithromycin if there is concern for sexually transmitted infection, as well as 14 days of oral antibiotic therapy, NSAIDs, and scrotal support. If the patient exhibits fevers or toxic presentation, hospitalization with IV antibiotics may be required.

**Balanitis and Balanoposthitis**

Balanitis refers to inflammation of the glans penis. Balanoposthitis arises when the foreskin is also involved. Common etiologies include fungal infection, bacterial infection, contact dermatitis, or local trauma. Exam reveals a diffusely erythematous and warm glans penis, with inner preputial erythema as well if balanoposthitis is present. Treatment includes appropriate hygiene, topical antibiotics or antifungals, and occasionally topical steroids. If there is an inappropriate response to treatment, the differential diagnosis should include malignancy, psoriasis, or infectious agents such as HPV.3

**URINARY TRACT OBSTRUCTION**

**Urolithiasis**

Renal stone disease is a common problem that is a major health care burden to society today. The prevalence of stone disease in the United States has increased over the past several decades as reported by the National Health and Nutrition Examination Survey (NHANES), and was estimated at 8.8% for the period between 2007 and 2010.4 This prevalence has increased with factors such as global warming, poor diet choices, and the obesity trend. Overall, the total estimated annual expenditure for individuals with claims for a diagnosis of urolithiasis was almost $2.1 billion in 2000, representing a 50% increase since 1994.5 Risk factors for stone formation include dietary habits, family history, white race, geographical location or occupational exposure to heat/dehydration, intestinal disease, and male gender, although the gender gap is decreasing.6 More recently, stone formation has also been associated with obesity, metabolic syndrome, and diabetes mellitus.7,8

Stones are most commonly composed of calcium oxalate. Other stone compositions include calcium phosphate, uric acid, cystine, medication-related, and infectious stones (struvite or carbonate apatite) or a mix thereof. Stone composition can vary based on a number of underlying pathophysiological processes. For example, hyperoxaluria may be seen in patients who have undergone small bowel resection, particularly the terminal ileum. This can result in an increase in unabsorbed fatty acids and bile salts which undergo saponification by binding with calcium in the bowel. The increase in unbound oxalate is absorbed by the large intestine and subsequently excreted in the urine, favoring the formation of calcium oxalate stones. Uric acid stones will form in a context of acidic urinary pH, low urinary volume, and high oral intake of purines. Countering these factors by alkalizing the urine and increasing urine output may lead to dissolution of uric acid stones and reduced further formation.9 Proteus species, Klebsiella species, and other urease-producing bacteria metabolize urea into ammonium and bicarbonate. The alkaline milieu (pH >7) predisposes to infectious (struvite) stones with the precipitation of magnesium, ammonium, and phosphate (Fig. 40-1).

Evaluation for first-time stone formers should include a complete medical history and physical exam, basic metabolic panel, calcium, uric acid, urinalysis and culture, and radiographic imaging. A noncontrast computed tomography (CT) scan is the most sensitive (98%) and specific (97%) exam to detect urolithiasis10 and can provide additional anatomical information useful for surgical planning, although its use in recurrent stone formers should be balanced by cost and radiation exposure. Low-dose CT is currently the preferred imaging study for patients with a body mass index (BMI) <30. This imaging study uses less than one-third of the estimated effective ionizing radiation dose (3 mSv) compared to standard dose noncontrast CT (10 mSv),10 while maintaining excellent sensitivity (95%) and specificity (97%).11 Plain abdominal X-ray can be used to follow radiopaque stones such as calcium-containing stones or struvite stones, although at times struvite can be difficult to see on plain X-ray, especially when the fragments are small. Uric acid and triamterene stones are radiolucent on plain abdominal X-ray but will be visible on noncontrast CT. A full metabolic evaluation with a 24-hour urine collection is indicated in recurrent stone formers, high-risk stone formers, or interested first-time stone formers.12

The natural history of stones is variable and depends primarily on their size and location. Smaller and more distal stones are much more likely to pass spontaneously without the need for surgical intervention.13,14 Patients with ureteral stones ≤10 mm can be offered a period of observation if their pain is well controlled without signs of infection or renal insufficiency. α-Blockers, which inhibit ureteral peristalsis, have been shown in meta-analyses to be particularly useful in patients with distal ureter stones ≤10 mm, improving the rate of stone passage from 54% to 77%,15,16 with shortened time to expulsion and fewer colic episodes.17
Patients who have not passed their stone after a 4- to 6-week observation period, those with larger stones, or those who desire immediate intervention, may be offered one of three definitive surgical interventions: shockwave lithotripsy (SWL), ureteroscopy (URS), or percutaneous nephrolithotomy (PCNL). Open surgical management of stones has been relegated to historic interest for the most part with less than 1% of stone surgery needing to be done open with access to modern endourologic equipment. The choice of the procedure will depend primarily on stone-related factors (e.g., stone size, location, and composition/density), and patient-related factors (e.g., comorbidities, coagulopathy, obesity, renal anatomy, and surrounding structures).

Shockwave lithotripsy is the procedure associated with the least morbidity and the lowest complication rate but is also associated with a lower success rate at treating stones as a single procedure and requires the patient to pass the stone fragments afterwards.15,16 The modality can be used for stones in the proximal ureter (particularly if <10 mm) or non–lower-pole renal stones <2 cm.15,16 The stone is located under fluoroscopic guidance, which is coupled to an extracorporeal lithotripter aimed at the stone. The stone is fragmented in a completely noninvasive manner. Complications associated with this procedure include subcapsular or perinephric renal hematoma and ureteral obstruction by stone fragments (“Steinstrasse”; Fig. 40-2). Ureteroscopy is the procedure of choice for patients with middle or distal ureteral stones. It also has a higher success rate than SWL in treating >10-mm proximal ureteral stones and renal stones.15,16 This procedure involves advancing a semi-rigid or flexible ureteroscope to the level of the stone and fragmenting it under direct visualization, often using a holmium:YAG laser. The surgeon is able to visualize the stone during fragmentation and thereby has some control over how small the fragments are. In addition, stone fragments may also be actively removed with a small nitinol stone basket. This is where the procedure may have an advantage over SWL. However, many patients have a ureteral stent placed after ureteroscopy, and, although temporary, this remains a major source of morbidity for the patient. Specific complications of URS include ureteral injury or stricture. PCNL is reserved for patients with larger or more complex stone burden, and requires a percutaneous tract into the kidney. Most stones larger than 2 cm are treated with PCNL although there is a role for PCNL for smaller stones located in the lower pole of the collecting system.18,19 More powerful lithotripters (pneumatic, ultrasound) and larger instruments (stone graspers) can be used to fragment and remove these larger stones through the percutaneous tract. Complications include injury to adjacent organs, acute and delayed renal bleeding due to pseudoaneurysm or arteriovenous fistula formation, sepsis, or renal pelvis perforation.

General preventative measures include correcting dietary habits, particularly increasing fluid intake to produce ≥2.5 liters of urine per day, limiting sodium, reducing animal protein intake, and monitoring foods high in oxalate. Medical therapy such as thiazide diuretics (helpful for hypercalciuria), urinary alkalization with potassium citrate, or allopurinol may also be indicated depending on the clinical situation.12

**Benign Prostatic Hyperplasia**

Benign prostatic hyperplasia (BPH) refers to the histological findings of smooth muscle and fibroblast/epithelial cell proliferation in the transition zone of the prostate. Lower urinary tract symptoms (LUTS) may be secondary to benign prostatic enlargement (BPE) causing progressive bladder outlet obstruction but may also be due to numerous other conditions (e.g., urethral stricture, infection, overactive or neurogenic bladder, malignancy). Although some male patients with LUTS may have BPE, not all patients with an enlarged prostate have LUTS. The prevalence of LUTS attributed to BPH in men over the age of 50 is estimated at 50% to 75% and increases with age with a prevalence of 80% in men over the age of 70.20 The treatment modalities have dramatically evolved over the past decades, with medical management typically used for first-line therapy. Endoscopic and minimally invasive techniques are used for those failing or intolerant of medical therapy.

Men with BPH/LUTS are evaluated with a complete history and physical exam including digital rectal exam. LUTS should be clearly defined, in addition to their severity and degree of bother. Validated questionnaires to quantify the patient’s symptoms and degree of bother include the American Urological Association Symptom Index (AUA-SI) and the International Prostate Symptom Score (IPSS).21,22 Complications of BPH such as urinary retention, incontinence, renal failure, hematuria, or recurrent infections should also be considered. Basic workup includes a urinalysis and culture to rule out infection. After an informative discussion about the risks and benefits of prostate cancer screening, a serum PSA is measured when life expectancy is >10 years and if the diagnosis of prostate cancer will alter management.23 Other diagnostic testing such as cystoscopy, cytology, postvoid residual (PVR), urodynamics, and radiologic imaging of the prostate, although not done routinely, may be required in patients with a definite indication (e.g., hematuria), uncertain diagnosis, poor response to therapy, or for surgical planning.24

The first line of treatment is most commonly pharmacotherapy for those men with bothersome symptoms. 2α-Blockers work by relaxing the smooth muscle of the prostate and bladder neck. All α-blocker agents are equally effective,25 and their side effects may include orthostatic hypotension, dizziness, asthenia, headache, nasal congestion, and retrograde ejaculation. Their effect is usually seen within days. Five-α reductase inhibitors (5-ARIs) block the conversion of...
testosterone to dihydrotestosterone (DHT), the hormone primarily responsible for BPH progression. These reduce prostatic size by 20% to 25%,\(^\text{26}\) but their effects are seen only after 4 to 6 months. Side effects include erectile dysfunction, decreased libido, and, rarely, gynecomastia. 5-ARIs, but not \(\alpha\)-blockers, can alter disease progression as demonstrated by two landmark trials, the MTOPS\(^\text{27}\) and CombAT\(^\text{28}\) trials. These trials evaluated combination therapy using \(\alpha\)-blockers and 5-ARIs. Patients on 5-ARIs, particularly those with larger prostates, had a reduced risk of both developing acute urinary retention and requiring surgical intervention. More recently, daily phosphodiesterase-5 inhibitors, which are most often used for erectile dysfunction (ED), have now been approved for treating patients with BPH. These can be particularly valuable in patients with concomitant ED.\(^\text{29,30}\)

Surgical modalities for BPH continue to evolve towards less invasive endoscopic procedures. Transurethral resection of the prostate (TURP) remains the mainstay of endoscopic procedures, with low treatment failure and complication rates.\(^\text{31}\) TURP syndrome is associated with prolonged use of hypotonic irrigation fluid, resulting in fluid overload and dilutional hyponatremia. Symptoms include nausea/vomiting, bradycardia and hypertension, pulmonary edema, mental status changes, and rarely death. Other endoscopic modalities used today include bipolar TURP and various laser procedures (e.g., Ho:YAG laser enucleation of the prostate, Ho:YAG laser ablation of the prostate, and photoselective vaporization of the prostate) with the goal of enucleating or vaporizing prostatic tissue. Normal saline is used for irrigation with these modalities, which greatly reduces the risk of TURP syndrome. Generally, laser procedures have been associated with shorter catheterization time and length of stay with comparable improvements in LUTS to open prostatectomy or TURP.\(^\text{32-34}\) Open, and more recently laparoscopic and robotic simple prostatectomy can also be performed for patients with moderate-severe, bothersome LUTS due to BPH. These are usually reserved for patients with larger prostatic volumes (>100 cc), or patients requiring concomitant bladder surgery (e.g., bladder diverticulectomy or stones).\(^\text{23}\)

**Urethral Stricture**

A urethral stricture is an area of scarring or fibrosis that causes concentric narrowing of the urethra, impeding the flow of urine as it drains from the bladder. Strictures occur at a prevalence of 0.9% of the population in the United States.\(^\text{35}\) Causes of urethral stricture disease include trauma (19%), iatrogenic causes (33%), inflammatory causes (15%), and idiopathic causes (33%).\(^\text{36}\) Symptoms of urethral stricture disease include incomplete emptying, weak urinary stream, urinary urgency/frequency, and pain.\(^\text{37,38}\)

The anatomy of the urethra in men can be divided into the following segments proceeding from cephalad to caudal: prostatic, membranous, bulbous (the area between the pelvic floor and the penoscoral junction), and penile. A stricture can occur in any segment of the urethra, but it is most common in the bulbar urethra.

Options to treat urethral stricture disease can be divided into two general categories: endoscopic and surgical reconstruction. Endoscopic treatments include a urethral dilation or stricture incision with a cystoscope. The latter is referred to as a direct vision internal urethrotomy. The success rate of one endoscopic attempt to treat a urethral stricture is around 30%.\(^\text{39}\)

The success of repeat endoscopic treatments of a urethral stricture drops to 13%, and recurrent dilations have been associated with the need for more complex reconstructive surgeries for definitive management.\(^\text{39,40}\) For that reason, common practice is to attempt one endoscopic intervention prior to referral for reconstructive surgery.

Surgical reconstruction of the urethra, referred to as a urethroplasty, can be divided into two general categories: excisional and tissue substitution. An excisional repair involves resection of the stricturetured segment of the urethra, and direct anastomosis of the two healthy urethral ends. This repair technique is generally reserved for membranous strictures and short bulbar strictures. Tissue substitution involves augmenting a narrowed urethral lumen with free tissue grafts. The most common tissue substitute is buccal (oral) mucosal graft.

**Other Causes of Obstruction**

Retroperitoneal fibrosis (RPF) is a rare cause of ureteric obstruction secondary to an inflammatory and fibrotic process of the retroperitoneal structures. Most cases (>70%) are idiopathic. Identifiable causes in the remaining cases include periarterial inflammation due to aneurysms, medications (e.g., methysergide, ergot derivatives, \(\beta\)-blockers, phenacetin), infections (e.g., tuberculosis, schistosomiasis), and malignancy (e.g., lymphoma, multiple myeloma, sarcoma). Symptoms are nonspecific and may include general abdominal discomfort or back pain, flank pain due to ureteral obstruction, or lower extremity edema due to vena caval compression. Laboratory abnormalities such as normocytic anemia, an elevated C-reactive protein, or ESR are identified in about two-thirds of cases.\(^\text{41}\) The classic radiological findings consist of a well-defined retroperitoneal soft tissue mass encasing the great vessels with medialization of the ureters. Contrast enhancement on CT scan, magnetic resonance imaging (MRI), and positron emission tomography (PET) scan can also be used to monitor disease activity and assess response to treatment.\(^\text{42}\)

Patients with symptomatic renal obstruction, renal insufficiency, or signs of infection should be decompressed with either ureteral stents or nephrostomy and monitored for postobstructive diuresis. Biopsy of the retroperitoneal mass to exclude malignancy should be considered prior to commencing treatment. Steroid therapy remains the mainstay of medical treatment, although other immunosuppressive agents have been described.\(^\text{43}\) If medical treatment fails, open or minimally invasive bilateral ureterolysis with intraperitonealization or omental wrapping of the ureters is indicated.

Ureteral obstruction secondary to tumor (benign or malignant) is commonly encountered. Ureteral stenting can be tried initially, but it fails in approximately one-half of cases.\(^\text{44}\) Other strategies such as percutaneous nephrostomy, ureteral stenting in tandem, metallic, and metal-mesh stents have been described. Metallic stents may be more cost-effective due to less frequent stent exchanges,\(^\text{45,47}\) although cost savings may be offset by the limited life expectancy in this patient population.\(^\text{44}\)

**GENITOURINARY TRAUMA**

Genitourinary (GU) trauma is rare. Approximately 10% of victims of abdominal trauma will have a urologic injury.\(^\text{48}\) Any portion of the GU tract can be injured including the following: kidneys, ureters, bladder, urethra, and the external genitalia including the testicles. Mechanisms of trauma parallel other injury mechanisms, the majority of which include blunt and penetrating injuries. This section will be divided into the management of each organ involved in the GU system.
The American Association for the Surgery of Trauma (AAST) renal trauma grading system

CT = computed tomography.

Kidneys

The prime goal of renal trauma management is preservation of renal function. Renal trauma has become largely nonoperative in modern times, especially in the setting of low- to intermediate-grade renal injuries from a blunt mechanism of action. The role of angioembolization through vascular and interventional radiology has further increased this nonoperative management.59,60

The first goal of renal trauma is to accurately grade the renal injury. The gold standard test to diagnose and stage a renal injury includes a CT scan with IV contrast, with delayed images. In most centers, this is referred to as a “CT urogram,” in which delayed contrast imaging delineates the upper urinary tract collecting system. Criteria that would mandate renal imaging include the presence of gross hematuria, microscopic hematuria with hypotension, and mechanisms increasing the prevalence of renal injury (sudden deceleration injuries, flank contusion, etc). The American Association for the Surgery of Trauma (AAST) renal trauma grading system is described in Table 40-1.51,52

The management of renal injuries depends not only on the grade but also on the injury mechanism and clinical symptoms. Absolute indications for surgical or radiological intervention on renal trauma include life-threatening hemorrhage, renal pedicle avulsion, or pulsatile/expanding retroperitoneal hematoma. Moreover, those suffering penetrating renal trauma with a retropertioneal hematoma should undergo exploration when hemodynamic instability exists.

In a hemodynamically stable patient with a renal injury, renal trauma should be initially observed. Data suggests that this approach may even be feasible in the setting of isolated, penetrating renal injuries.53 Conservative management entails bed rest and hemodynamic monitoring. Patients with a grade 4 renal injury (Fig. 40-3A to D) should be treated in the same manner, and a repeat CT scan should be done to make certain that the urinary extravasation has resolved.54 Otherwise, urinoma and subsequent abscess formation may occur. If urinary extravasation is persistent, placement of a ureteral stent or nephrostomy tube should be considered.

Across the board, the most common surgery for renal surgery in modern times is unfortunately a nephrectomy.55 Early renal vascular control may minimize nephrectomy rates.56 This is accomplished by isolating the renal vascular medially prior to opening the perinephric hematoma. If uncontrolled bleeding is encountered once the hematoma is opened, occlusion of the renal vasculature can be performed. At that time, a renorrhaphy can be safely done as can a nephrectomy in the setting of a grade 5 renal injury.

Ureters

There is no association between the magnitude of ureteral injury and the degree of hematuria that is present.57 A high index of suspicion is required. Diagnosis requires either a CT urogram, IVP, or a cystoscopy with a retrograde pyelogram. Unlike renal injury, the ureters more commonly are injured through iatrogenic mechanisms. Common surgical procedures in which the ureters are injured include gynecological, colorectal, and urological surgeries. The repair of ureteric injuries depends on the time of identification from initial injury, location, and length of the injured ureteral segment involved.

Iatrogenic ureteral injuries should be initially managed with ureteral stent placement when possible. When stenting is not feasible, open repair may be attempted when the patient presents shortly after injury. When stent placement is not feasible or when presentation is delayed, nephrostomy tube placement should be considered until formal repair can be safely done.

Ureteral injuries of traumatic origin (penetrating injuries, multiple intra-abdominal traumas) should be repaired during the index admission when possible. Hemodynamically stable patients undergoing laparotomy for other reasons in which a high index of suspicion of a ureteral injury is present should have ureteral exploration. Stable patients in this same situation that are identified to have a ureteral injury should have primary repair at the time of exploration. If a patient is hemodynamically unstable, the ureter can be ligated with subsequent nephrostomy tube placement. Ureteral repair can then be delayed until the patient is stable for surgery.
The definitive operative management of a ureteral injury depends on the location and the extent of devitalization. It is important to debride devitalized ends of the ureter, whether it is from a contusion via a gunshot wound or an iatrogenic thermal injury. Upper ureteral injuries that are short can generally be resected and anastomosed primarily. Ureteral mobilization with preservation of ureteral adventitia to maintain vascular supply can aid in bridging short defects. In modern times, more aggressive maneuvers to directly anastomose more proximal ureteral injuries to the bladder are possible. Maneuvers used to bridge the defect of ureteral length for direct anastomosis to the bladder include the following: bladder mobilization with ligation of the contralateral bladder pedicles, psoas hitch (tacking the bladder down to the ipsilateral psoas tendon), and the Boari flap with downward nephropexy. Creation of a Boari flap utilizes a tubularized flap of anterior bladder wall to bridge long defects. Bridging defects as high as the proximal ureter have been reported in association with this technique. When bladder-to-ureter anastomosis is not possible with these maneuvers, the remaining options include trans-ureteroureterostomy (anastomosing the injured ureter to the contralateral ureter), creation of an ileal ureter, or renal auto transplantation to the pelvis.

**Bladder**

The bladder can be injured through iatrogenic and classic traumatic mechanisms. Indications for bladder imaging include gross hematuria in the setting of injuries with a correlation for bladder injury. The most common clinical scenario is gross hematuria associated with a pelvic fracture, which is associated with a 29% chance of bladder laceration. Diagnosis of bladder injuries requires either a CT cystogram or a fluoroscopic cystogram. The sensitivities and specificities of these two modalities are similar. The bladder should be filled with approximately 300 cc of contrast for either of these imaging modalities.

Contrast may be visible at the site of injury, within the peritoneal space (Fig. 40-4A), or in the perivesical space (Fig. 40-4B). Simply capping the Foley catheter alone on a delayed excretory phase of abdominal CT imaging is insufficient to diagnose a bladder injury.

Two general categories of bladder injuries are extraperitoneal and intraperitoneal injuries. An intraperitoneal injury requires repair during the index admission after the patient has been resuscitated. Delayed repairs are associated with abdominal sepsis. Conversely, extra peritoneal injuries can generally be managed with Foley catheter drainage alone. Situations in which extraperitoneal bladder injuries should be treated with operative repair include complex injuries involving bone spicules from a pelvic fracture within the laceration and concurrent rectal or bladder lacerations, which increase the possibility of fistula formation. Bladder neck injuries should also be treated operatively during the index admission as these injuries occasionally do no heal with Foley catheter drainage alone. Repeat cystography should be done 7 to 14 days later prior to Foley removal to ensure that the laceration, or operative repair, has healed.

**Urethral Injuries**

Common mechanisms of trauma of the urethra include pelvic fracture associated injuries and straddle injuries. Pelvic fracture associated injuries occur at the level of the membranous urethra, whereas straddle injuries occur at the level of the bulb urethra. The clinical hallmark of a urethral injury is blood at the meatus. A retrograde urethrogram should be done when this clinical sign is present to diagnose an injury, prior to attempted Foley catheter placement (Fig. 40-5A).

The initial step in management of a urethral injury is bladder drainage to prevent urinoma formation and subsequent abscess formation. In general, this is accomplished through
placement of an SP tube. After stabilization, some centers perform “primary urethral alignment.” This is a dual antegrade and retrograde endoscopic procedure utilizing fluoroscopy to bridge the urethral defect and to place a Foley catheter across the injury. Subsequent restructure rates are high, but the severity of stricture formation may be less when primary alignment is performed. If patients are managed with an SP tube alone, the site of disruption leaves the patient with a urethral stricture and subsequent restructure. This requires a treatment with a urethroplasty after the patient’s period of convalescence has resolved (Fig. 40-5B).

Penetrating injuries to the anterior urethra are rare. In a hemodynamically stable patient with an uncomplicated injury, it is expert opinion to perform exploration with primary repair during index admission. Complicated injuries with extensive tissue devitalization should be managed with SP tube urinary diversion and delayed reconstruction.

External Genital Injuries
Penile fractures classically occur with excessive torqueing of the erect penis. This excessive torqueing results in rupture of the tunica albuginea, the fascial coating of the erectile bodies. Common symptoms include immediate detumescence with subsequent development of a hematoma. Clinical history and examination alone are sufficient to warrant surgical exploration with primary suture repair of the corporal body laceration. For equivocal cases, ultrasonography or an MRI may be done. Up to 10% of penile fractures are associated with urethral injuries. Blood at the meatus signifies the possibility of a coexisting urethral injury. This should be evaluated with either a retrograde urethrogram or cystoscopy at the time of repair.

Scrotal trauma generally occurs from a blunt mechanism. Injuries to the testis, epididymis, and spermatic cord may occur. Hematomas with subsequent ecchymosis are common with such injuries. Testicular rupture occurs with fracture of the fascial coating of the testicle, called the tunica albuginea. This may occur with blunt or penetrating mechanisms. The most specific findings on ultrasonography are loss of testicular contour and heterogeneous echotexture of parenchyma. The highest reported sensitivity for testicular rupture on ultrasound is 93%. With diagnosis of a testicular rupture or when a high index of

Figure 40-4. Intraperitoneal and extraperitoneal bladder injuries. A. During a computed tomography (CT) cystogram, intraperitoneal contrast is seen within the peritoneal space at the red arrow. B. During a CT cystogram, extravesical contrast is seen contained within the extraperitoneal space at the red arrow.

Figure 40-5. A. Retrograde urethrogram showing an area of narrowing at the double white arrow. This indicates a bulbar urethral stricture. B. After urethroplasty, a retrograde urethrogram demonstrates a normal-appearing and patent bulbar urethra at the arrow.
Acute Urinary Retention

Acute urinary retention (AUR) can happen in men or women and results from a variety of causes, although it most commonly occurs in men with benign prostatic hyperplasia (BPH). Other chronic causes of poor bladder emptying, such as diabetic neuropathy, urethral stricture, multiple sclerosis, or Parkinson’s disease, can result in episodes of complete urinary retention, often when the bladder becomes overdistended. This frequently occurs in the hospital setting when patients have limited mobility and are receiving medications that decrease bladder contractility, including opiates or anticholinergics. Constipation, a common side effect of those medications, can itself worsen urinary retention. Significant hematuria can result in the formation of blood clots, which may block the urethra and cause retention.

Although some patients receiving large doses of narcotics or those with chronically decompensated bladders may not experience discomfort, most patients with AUR have significant pain. Untreated severe urinary retention (often accompanied by overflow incontinence) may result in acute renal failure. Treatment should include placement of a urethral catheter as quickly as possible. However, BPH or urethral strictures often make the placement of a catheter difficult. For men with BPH, a coudé (French for curved) catheter is helpful in negotiating past the angulation in the prostatic urethra (Fig. 40-6A). The curved portion (which is angled in line with the balloon port) is maintained at the 12 o’clock position as it is passed through the urethra (Fig. 40-6B). A common mistake is to use a smaller catheter to bypass the enlarged prostate. However, a larger (18F to 20F) catheter is less flexible and is more likely to push into the bladder rather than curl in the prostatic urethra.

Smaller catheters, however, are quite useful for bypassing a urethral stricture. A urethral stricture should be suspected when the catheter meets resistance closer to the meatus, as many strictures occur in the distal urethra, which is narrower than the proximal portion. Using a 12F or 14F catheter often will allow the passage of the catheter into the bladder. If catheter placement is not successful, a urologic consultation should be requested. The urologist can either choose to (a) use a cystoscope, guidewire, and urethral dilators to dilate the stricture and place a Council-tip catheter via Seldinger technique; or (b) place a suprapubic tube approximately two fingerbreadths above the pubic symphysis. With regard to the suprapubic tube, ultrasound-guidance or aspiration with a fender needle should be used first to localize the bladder and avoid intra-abdominal contents, although bowel injury is unlikely with a distended bladder filling the pelvis. If hematuria is the cause of retention, continuous bladder irrigation often is necessary to prevent clot formation. This is done through a large three-way catheter that has an additional port for fluid inflow. Fluid is infused by gravity only because the use of higher pressure may result in bladder rupture if outflow is occluded.

Once the bladder is adequately drained, the cause of AUR should be addressed. For men with suspected BPH, an α-blocker such as tamsulosin should be started, and these have been shown to increase the likelihood of a successful trial without a catheter. Although finasteride and dutasteride (5α-reductase inhibitors) have been shown to reduce the incidence of urinary retention by 50%, they require several months to take effect and are most beneficial in large prostates; therefore, they will not provide significant benefit in the short term. Narcotics should be tapered as tolerated, and constipation should be treated.

Acute spinal cord compression, which is accompanied by saddle paresthesias, is a neurologic emergency that requires neurosurgical or orthopedic consultation. In most cases, except severe neurologic injuries, patients will be able to resume voiding, and the catheter can be removed after 1 to 2 days. Postvoid residuals should be checked with a portable ultrasound device (bladder scanner) or by “straight” catheterization to determine the residual amount of urine left after the patient tries to empty his or her bladder. In patients with severe liver dysfunction, the bladder scanner may inadvertently misinterpret ascites for urine. The inability to void or the presence of a postvoid residual over 200 mL is concerning for development of another episode of AUR. Patients may be given the option of an indwelling catheter for another few days with a subsequent voiding trial or to perform clean intermittent catheterization (CIC), whereby, after
predetermined intervals (4–6 hours) or after voiding attempts, the patient passes a catheter into the bladder and empties it. This is the preferred method because it reduces the likelihood of infections from indwelling catheters and may improve bladder functionality. However, most patients are resistant to this approach.

**Testicular Torsion**
The differential diagnosis of acute scrotal pain includes testicular torsion.74 This usually occurs in neonates or adolescent boys but may be observed in other age groups. The blood supply to the testicle is compromised due to twisting of the spermatic cord within the tunica vaginalis, resulting in ischemia to the epididymis and the testis. In newborns, an extravaginal torsion also can occur with twisting of the tunica vaginalis and spermatic cord together. Risk factors for torsion include undescended testis, testicular tumor, and a “bell-clapper” deformity—poor gubernacular fixation of the testicles to the scrotal wall.

Clinical history is vital for diagnosis.75 Patients describe a sudden onset of pain at a distinct point in time, with subsequent swelling. Physical examination may demonstrate a swollen, asymmetric scrotum with a tender, high-riding testicle. Children normally have a brisk cremasteric reflex that usually is lost in the setting of torsion. The diagnosis is made by clinical history and examination but can be supported by a Doppler ultrasound, which typically shows decreased intratesticular blood flow relative to the contralateral testis. If an ultrasound is not promptly available, timely surgical exploration should be performed.

Immediate surgical exploration can salvage an ischemic testis.76 At the time of surgery, the contralateral testes also must be explored and fixed to the dartos fascia due to the possibility that the same anatomic defect allowing torsion exists on the contralateral side. Midline (along the median raphe) or bilateral transverse scrotal incisions are made. Once the testis is detorsed, it should be assessed for viability after being given time for normal blood flow to resume. One can assess the blood flow using intraoperative Doppler or by incising the tunica vaginalis and observing tissue viability. The testes are fixed to the dartos fascia with a small, nonabsorbable suture on their medial, lateral, and dependent aspects, taking care to ensure that the spermatic cord is not twisted before doing so. An orchietomy should be performed to avoid later risk of abscess formation only if the testis is clearly necrotic.

**Fournier’s Gangrene**
Fournier’s gangrene is a necrotizing fasciitis of the male genitalia and perineum that can be rapidly progressive and fatal if not treated promptly (Fig. 40-7). The mortality rate has been reported to be as high as 67%.77 Risk factors for Fournier’s gangrene include perirectal abscesses, diabetes, obesity, and chronic alcoholism.78 The often polymicrobial infection spreads along dartos, Scarpa’s, and Colles’ fascia. Clinical signs include perineal and scrotal pain, inflammation, necrosis, and crepitus.78 The diagnosis is largely made on clinical suspicion; however, radiographic findings on CT imaging often assist with the diagnosis, including soft tissue air associated with fluid collections within the deep fascia.79

Prompt and aggressive surgical debridement of nonviable tissue and broad spectrum antibiotics are necessary to prevent further spread (Fig. 40-7A). Fecal diversion with endorectal tubes serve as an option for conservative fecal diversion.80 If there is damage to the external anal sphincter, patients may require a colostomy. Patients frequently require return trips to the operating room for further debridement.

Negative pressure wound therapy systems have been shown to reduce hospitalization time by aiding in wound healing.81 Reconstructive strategies involving skin grafting are needed when large tissue defects result from extensive tissue damage.

**Priapism**
Priapism is a persistent erection for greater than 4 hours unrelated to sexual stimulation.82 Priapism is divided into two types, based on the underlying pathophysiology. The most common type—low-flow/ischemic priapism—is a medical emergency. On examination, the penis is very tender, and both cavernosal bodies will be rigid while the glans will be flaccid. Decreased venous outflow with persistent inflow results in increased intracorporal pressure and tumescence, which is the normal process of erection. Diminished arterial inflow due to elevated
intrapenile pressure usually is brief under normal circumstances. Priapism is essentially a compartment syndrome. With prolonged erection (priapism), the sustained decrease in arterial inflow ultimately causes tissue hypoxia, acidosis, and edema and results in long-term fibrosis and impotence, and sometimes frank necrosis. Risk factors include sickle cell disease or trait, malignancy, medications, cocaine abuse, certain antidepressants, and total parenteral nutrition.82-84 If a cause is not identified, a hematologic workup is necessary to rule out malignancy or blood dyscrasias.

The management of priapism is rapid detumescence with the goal of preservation of future erectile function. The ability to achieve normal erections is directly related to the length of the episode of priapism. Ischemic priapism can be confirmed with a penile blood gas from the cavernosal bodies demonstrating hypoxic, acidic blood. Initial management can include systemic treatment of the underlying disorder (fluid and oxygen for sickle cell patients) but this should be done concurrently with an active treatment to reduce the priapism.82 The initial intervention may be therapeutic aspiration or injection of sympathomimetics (phenylephrine). Insertion of a large-gauge needle (16–21 gauge) into the lateral aspect of one corporal body allows thorough aspiration and irrigation of both corporal bodies because of widely communicating intercavernosal channels. Injection of phenylephrine (diluted 100–500 mcg/mL and given in 1 mL increments every 3–5 minutes for up to 1 hour before determining failure) into the corporal bodies works to cause vasoconstriction, but the patient should be monitored for acute hypertension and reflex bradycardia especially in patients with high cardiovascular risk.

A surgical shunt is sometimes necessary to resolve the episode if phenylephrine fails. Distal (corporoglanular) shunts should be performed first because they are the easiest to perform and the lowest amount of complications. A Winter shunt uses a large biopsy needle to create holes between the glans and corpora; however, if this fails, an operative procedure can be performed to remove the distal tips from each corpora (Al-Ghorab). Proximal shunts such as Grayhack (corporal-saphenous vein) or Quackel (proximal cavernosumspongiosum) shunts may be required in refractory cases.

The other form of priapism (high-flow/traumatic priapism) is rare and is related to penile or perineal trauma resulting in a cavernous artery–corporal body fistula. This form is not painful because it is not related to ischemia and can be managed conservatively with observation. Many cases will resolve with time; those that do not can undergo selective arterial embolization.82

Paraphimosis

Paraphimosis is a common problem that represents a true medical emergency for uncircumcised men. When the foreskin is retracted for prolonged periods, constriction of the glans penis may ensue. This is particularly likely in hospitalized patients who are confined to bed or who have altered mental status and are unable to respond to pain. Delay can be catastrophic as penile necrosis may occur due to ischemia. Penile blocks, pain medication, and sedation are sometimes necessary before manual reduction. It is useful to apply firm pressure to the edematous distal penis for several minutes.85 Although painful, this reduction in penile edema can be the key to success. With the fingers pulling the constricting band distally, the thumbs can push the glans penis back into normal location. Compression wraps have shown some benefit without the need for the physician to use hand compression.86 If the foreskin cannot be manually reduced, surgical intervention is required.

Emphysematous Pyelonephritis

Emphysematous pyelonephritis is a life-threatening infection that results from complicated pyelonephritis by gas-producing organisms. It is an acute necrotizing infection of the kidney that occurs predominantly in diabetic patients.87 Patients frequently present with sepsis and ketoacidosis. *Escherichia coli* appears to be the most frequent organism responsible for this infection. Patients require supportive care, IV antibiotics, and relief of any urinary tract obstruction. Third-generation cephalosporins have been suggested as the initial antibiotic of choice and fluoroquinolones avoided due to high rates of resistance.88 Emphysematous pyelonephritis can be subdivided based on the extent of infection. Cases where gas is isolated to the kidney frequently can be managed conservatively with the placement of a nephrostomy tube to allow drainage of purulent material. When there is extensive involvement of the perirenal tissue, conservative management may not be successful and strong consideration should be given to nephrectomy, particularly if the patient is displaying signs of sepsis.89,90

**Bladder Cancer**

**Epidemiology and Presentation.** In 2018, 81,190 men and women will be diagnosed with bladder cancer, and 17,240 will die from their disease.91 The disease is highly prevalent, with over 700,000 patients living with the disease in the United States as of 2016. Men have nearly three times the incidence of women. Tobacco use is the most frequent risk factor, followed by occupational exposure to various carcinogenic materials such as industrial solvents (e.g., aromatic amines). Other risk factors include arsenic, radiation, cyclophosphamide, and chronic exposure to foreign bodies (stones and catheters) and specific urinary parasites. The most common bladder cancer histology in the United States is urothelial carcinoma (UC), accounting for 90% of tumors, which tends towards a better prognosis as compared to the rarer forms, including squamous cell carcinoma (<10%), adenocarcinoma (1–2%), and small cell cancer (<1%). Unfortunately, there is no reliable screening test for bladder cancer, although patients felt to be at high risk may undergo urine sampling for microhematuria or abnormal cytology. Smoking cessation should be advised in all tobacco users as a preventive measure. The most common symptoms at presentation are hematuria (gross or microscopic) and/or irritable voiding (urgency, frequency, and dysuria). Office cystoscopy is an effective means to diagnose bladder cancer.

**Staging.** Clinical staging is completed with CT or MRI to assess intraabdominal nodal and visceral sites of metastasis. The upper tracts should be evaluated with CT urography or retrograde pyelography. Chest radiograph provides initial evaluation of the thorax and mediastinum. A bone scan should be obtained if the patient complains of bone pain, has known locally advanced or metastatic disease, or an unexplained elevation in the serum alkaline phosphatase level. Pathologic staging has been outlined by the American Joint Committee on Cancer.92

Transurethral resection of bladder tumor (TURBT) should include an examination under anesthesia (EUA) and sampling of the bladder muscular wall to fully assess depth of invasion. The presence of induration or a mass on EUA denotes extravesical
tumor extension and may alter the patient’s treatment plan. It may also be appropriate to biopsy multiple areas of mucosa to identify multifocal carcinoma in situ (CIS). Restaging TURBT within 2 to 6 weeks is recommended in the patient with incomplete, under-sampled, or uncertain resection. This is especially important in the patient with Tis, Ta, or T1 disease, as well as the patient with suspected T2 disease who is being considered for a bladder preservation treatment strategy. Invasion into the lamina propria and certainly the muscular wall demonstrates increased potential for distant metastases; muscle invasion is rarely treated completely with TURBT and requires additional therapy for adequate local control.

Recurrence rates of non–muscle-invasive bladder cancers are high, ranging from 50% to 70%.93 Adjuvant treatment strategies have thus been adopted after TURBT to reduce these rates. Intravesical chemotherapy used in conjunction with TURBT can reduce the risk of recurrence by 44% to 73% in patients with primary Ta and T1 tumors and by 38% to 65% in patients with recurrent Ta, T1, and Tis tumors when compared to TURBT alone.94 Intravesical immunotherapy using bacillus Calmette-Guérin (BCG) also provides a significant reduction in recurrence that is greater than 50% in this population. Despite improved rates of disease-free survival, standard induction courses of intravesical chemotherapy and immunotherapy do not improve disease-specific survival.94 However, when an induction course of BCG is followed by a series of maintenance doses consisting of weekly BCG given for 3 weeks at 3, 6, 12, 18, 24, 30, and 36 months after induction, disease-free and overall survival can be prolonged.95 In patients who fail an initial or maintenance course of intravesical therapy, it may be reasonable to try another agent; however, one must consider the risk of progression and not delay definitive treatment. Roughly 15% to 30% of patients presenting with non–muscle-invasive tumors will eventually progress to muscle invasion. Radical cystectomy remains the most effective single-modality treatment for patients with muscle-invasive bladder cancer, refractory high-risk non–muscle-invasive disease, and especially lymph node–negative disease with a reported 10-year recurrence-free survival of organ-confined lymph node–negative (<pT2N0) disease between 69% and 87%.94,95,96,97

**Surgical Considerations.** Cystectomy is indicated in the treatment of refractory NMIBC or to assert local control for muscle invasive bladder cancer (MIBC).98 Effective local control in the pelvis is achieved in 93% of cases with cystectomy. Indications for partial cystectomy are limited and generally apply to isolated tumors or those within diverticulum. Classic teaching suggests that patients with CIS should not be candidates, though the use of intravesical BCG to treat CIS may have broadened this application. For patients with MIBC, neoadjuvant systemic chemotherapy with M-VAC or gemcitabine and cisplatin (prior to cystectomy) offers a survival advantage when compared to radical cystectomy alone.98

Robotic approaches for cystectomy are increasingly used, but the urinary diversion is still usually performed through an open incision. The benefits of the robotic portion are decreased blood loss during the pelvic dissection (due to the pneumoperitoneum). However, recent evidence (randomized controlled trials of open vs. robot-assisted radical cystectomy) did not demonstrate any difference in oncologic efficacy or complication rates.

Complications of bladder cancer surgery involve bladder perforation during transurethral resection of the bladder tumor, which require catheter drainage for several days if small (common) or open repair if large and intraperitoneal (rare). Cystectomy and urinary diversion may result in prolonged ileus, bowel obstruction, intestinal anastomotic leak, urine leak, or rectal injury. A urine leak from the ureteroileal anastomoses is a common cause of ileus, intra-abdominal urinoma, abscess formation, and wound dehiscence. Deep venous thrombosis is common after cystectomy due to the advanced age of most patients, proximity of the iliac veins to the resection and lymph node dissection, and the presence of malignancy. The utility of subcutaneous heparin in the perioperative period can minimize the risk of venous thromboembolism. Contemporary series from high volume centers report readmission rates of 25%, complication rates of 50% to 60%, and perioperative mortality in the first 90 days at 5% to 10%.99,100

Urinary diversion can be accomplished using an incontinent or continent abdominal stoma or orthotopic continent reconstruction. The evolution of patient selection and surgical technique has led to improved outcomes for orthotopic diversion, although there are still patients who are better served with an ileal conduit. Motivated patients are considered for orthotopic neobladder diversion if they have a preoperative serum creatinine less than 2.0 mg/mL, normal preoperative bowel function, a negative urethral margin based on intraoperative frozen section at the time of cystectomy, and an intact sphincter after complete tumor resection.

Alternatives to cystectomy include observation, systemic chemotherapy, radiation therapy, or a combination of chemotherapy and radiation. These modalities may be required in patients who a poor surgical risk, who refuse surgery, or who are elderly.

Bladder preservation using radiation as the definitive therapy may be feasible in selected patients. In this context, modality therapy is preceded by aggressive TURBT and offers an improved rate of survival when performed in conjunction with chemotherapy. Up to 42% 5-year disease-specific survival can be achieved in patients with preserved bladders, with the best overall survival outcome in younger patients with lower stage tumors without lymphovascular or nodal involvement.

More recently, immunotherapeutic treatments have shown significant promise in the treatment of locally advanced and metastatic bladder cancer. Five agents have recently been approved for patients who have progressed on or after platinum-based chemotherapy or have progressed within 12 months of neoadjuvant or adjuvant treatment. These agents include PD-L1 inhibitors (atezolizumab, avelumab, durvalumab) and PD-1 inhibitors (nivolumab and pembrolizumab). Response rates for these agents are ~15% to 20% but may have extended median overall survival as much as 10.3 months when compared to chemotherapy.101,102

**Testicular Cancer**

Testicular cancer is the most common cancer in men age 20 to 40 years and the second most common cancer in young men age 15 to 19 years. Metastases to the testis (usually lymphoma in older men) are rare. In 2018 there were 9310 new cases and 400 deaths from the disease.93 The incidence of testis cancer varies around the world.103 It contains a heterogeneous group of tumors, of which 95% are germ cell tumors; the rest originate from stromal cells (Leydig or Sertoli cells). Germ cell tumors can be classified as either seminomatous or nonseminomatous. Seminoma constitutes more than 50% of all testis cancer. The
Stages I to IIA nonseminomatous testis cancer is potentially cured with RPLND or chemotherapy.\textsuperscript{111} Persistently high tumor markers after radical orchiectomy or high-stage metastatic germ cell tumors warrant systemic chemotherapy. Due to the high rates of teratoma or viable germ cell tumor, postchemotherapy bulky masses are resected by RPLND or other surgical procedures. The overall survival rate of localized disease is outstanding (99\% at 5 years). Patients with more advanced distant metastatic disease (stage III) have 75\% survival rates. The overall prognosis is generally better for seminomatous than nonseminomatous germ cell tumors.\textsuperscript{112}

**Surgical Considerations.** Radical orchiectomy is done through an inguinal incision extending from the external inguinal ring to the internal inguinal ring. The spermatic cord is ligated at the internal ring with long silk sutures for easier identification during a future RPLND. Integrity of the scrotal skin during orchiectomy is important. Complications of radical orchiectomy include scrotal hematoma, chronic pain, and hernia.

For RPLND, a midline incision is usually made from the xiphoid process to the pubic symphysis. All the lymphatic tissue is removed from the targeted areas using the classical split and roll technique, and all lumbar vessels are tied. Postganglionic sympathetic nerve sparing is possible in most cases for preservation of ejaculatory function.\textsuperscript{113} Robotic-assisted RPLND is growing, with faster recovery time and similar short term oncologic results.\textsuperscript{114} Complications after RPLND include bowel obstruction, excessive bleeding, chylous ascites, and ejaculatory dysfunction.

**Kidney Cancer**

Renal cell carcinoma (RCC) results in approximately 3.8\% of all new cancers, with an estimated 65,340 new cases and 14,970 deaths related to kidney cancer in 2018.\textsuperscript{91} Despite several advancements with immune-based and targeted molecular therapies demonstrating durable clinic responses, RCC still remains primarily a surgical disease and classically does not respond to conventional chemotherapy regimens or radiation therapy.

Most patients diagnosed with RCC in the modern era typically present with an incidentally discovered renal mass on abdominal radiographic imaging. Differential diagnosis of a renal mass includes malignant tumors (e.g., RCC, urothelial carcinoma, sarcomas, lymphoma, metastasis), benign tumors (e.g., cysts, angiomylipoma, oncocytoma), and inflammatory lesions (e.g., abscesses, xanthogranulomatous pyelonephritis, tuberculosis). Renal CT imaging with intravenous contrast remains the single most important radiographic test to delineate the nature of the mass. In general, any solid renal mass that enhances by more than 15 Hounsfield units is an RCC until proven otherwise. However, even if there is contrast enhancement on axial imaging, approximately 15\% to 30\% of solid renal masses are benign on final surgical pathology.\textsuperscript{115} Renal tumor biopsy can help distinguish between malignant or benign tumors, but this has not been widely adopted by the urological community, despite series showing their high diagnostic yield, concordance with surgical pathology, and safety.\textsuperscript{116-118} Biopsy remains particularly useful in patients considering surveillance or thermoablative therapy, or in patients with suspicion of metastasis or lymphoma.

Major recognized risk factors for RCC include smoking, obesity, and hypertension. Although most RCCs are discovered incidentally, some patients present with signs or symptoms
which may be the result of local tumor growth (e.g., flank pain, hematuria, perirenal hematoma), paraneoplastic syndromes (e.g., hypertension, weight loss, hypercalcemia, polycythemia/anemia, abnormal liver function tests), or metastatic disease. RCC metastasizes primarily to the lungs, lymph nodes, bone, liver, adrenal glands, and brain. Familial RCC subtypes with classical clinical manifestations are also well described. The von Hippel-Lindau disease, occurring as a result of a mutation in the tumor suppressor gene VHL (3p25-26), commonly manifests itself with clear cell RCC, pheochromocytomas, retinal angiomas, central nervous system hemangioblastomas, pancreatic cysts, and other tumors. Other familial syndromes include hereditary papillary RCC (papillary type 1 RCC), familial leiomyomatosis (papillary type 2 RCC), and Birt-Hogg-Dube syndrome (chromophobe RCC, hybrid oncocytic tumors, and oncocytoma). Familial RCC syndromes should be suspected in younger patients and patients with multicentric and/or bilateral tumors.

Clear cell RCC is the most common subtype, accounting for 70% to 80% of all RCCs. Papillary RCC occurs in 10% to 15%, type 1 being associated with a better prognosis, and type 2 a worse prognosis. Other subtypes include chromophobe RCC, collecting duct carcinoma, and unclassified type.

RCC may locally progress and cause invasion of the renal capsule and perirenal fat or the collecting system. RCC may also directly progress into the venous system in the form of a tumor thrombus that can extend into the IVC and into the right atrium. Staging is the single most important prognostic factor for RCC. Studies demonstrate a 70% to 90% 5-year survival rate for organ confined disease (stages I–II), compared to 0% to 10% for patients with systemic metastases (stage IV). Other important prognostic factors include histological subtype, tumor size, lymph node involvement, and site of metastases.

Management options for small renal masses (<4 cm) includes active surveillance, thermoablative techniques, or surgical excision (Fig. 40-9). Percutaneous or laparoscopic thermoablative techniques (cryoablation, radiofrequency ablation, high-intensity focused ultrasound) have been used to treat small renal masses, but they are associated with an increased risk of local recurrence.

Since the first laparoscopic radical nephrectomy described by Clayman et al in 1991, minimally invasive surgical approaches, including laparoscopy with robotic assistance, have virtually supplanted open procedures for localized RCC (Fig. 40-10). Partial nephrectomy is most appropriate for patients with small tumors, solitary kidney, bilateral tumors, or familial RCC. Some tumors may not be amenable to ablative therapies or partial nephrectomy, in which case radical nephrectomy would be employed.

Radical nephrectomy involves removal of the entire kidney with dissection external to Gerota’s fascia. The colon is retracted medially after incising the white line of Toldt, followed by meticulous hilar dissection with ligation of the renal artery and vein. The adrenal gland is usually spared unless the tumor involves the gland or is immediately adjacent to it. Lymphadenectomy remains controversial, and it is usually performed in patients with adenopathy on preoperative imaging or in patients with palpable lymph nodes intraoperatively. In partial nephrectomy, renal artery clamping is often performed to minimize blood loss while the tumor is excised. The goal is to remove the tumor with negative surgical margins while minimizing warm ischemia time to preserve as many functional nephrons as possible. With increasing experience, partial nephrectomy is now also performed on much more complex renal masses, including completely endophytic, central, and hilar tumors. Very large tumors or tumors with vena-caval thrombi can be removed robotically in experienced hands, but most are still removed using an open approach.

In minimally invasive surgery, both partial and radical nephrectomy can be done via either a transperitoneal or retroperitoneal approach. In open cases, a subcostal flank approach provides direct access to the retroperitoneum and is preferred for lower pole exposure, but it can limit access to the hilum, particularly with large renal masses. The anterior subcostal approach is preferred for larger renal masses. Bilateral anterior subcostal incisions (chevron incision) provides excellent vascular exposure (e.g., IVC thrombectomy, bilateral tumors). Midline incisions are usually reserved for renal trauma and for reconstructive procedures. Less commonly performed, the thoracoabdominal approach involves access usually above the 10th rib and is used for large upper pole or adrenal masses, IVC thrombectomy, or tumors involving adjacent structures. Complications include injury to adjacent organs, and for partial nephrectomy, pseudoaneurysms/arteriovenous fistula formation and delayed urinary leak.
Prostate Cancer

Prostate cancer is the most common noncutaneous cancer in men; 164,690 new cases of prostate cancer were diagnosed in 2018 and 29,430 men died from their disease. Screening for prostate cancer with detailed history, digital rectal examination, and serum prostate specific antigen (PSA) tests have changed the natural history of the disease. Since the introduction of prostate cancer screening in the mid-1980s, the incidence of metastatic prostate cancer has decreased by half. Currently 99% of newly diagnosed patients will survive more than 10 years.91

While early screening for African American patients or patients with a family history of prostate cancer is widely accepted, screening for all men is more controversial. Despite data from large randomized clinical trials showing a decrease in mortality after prostate cancer screening, the U.S. Preventive Services Task Force recommended against the routine use of prostate cancer screening.129 Its recommendation was based on the harm and toxicity of overtreatment of nonlethal disease.130 The American Urologic Association subsequently recommended informed and shared decision-making and screening for high-risk disease for men between the ages of 55 and 69 with a life expectancy more than 10 years.131

If the digital rectal examination is abnormal or if the PSA level is above expected for patients’ age and size of the prostate, a prostate biopsy is usually performed. Newer tests such as the 4K score, prostate health index, and PCA3 are sometimes used to inform the decision to proceed with biopsy. Recently, MRI fusion transrectal ultrasound-guided biopsy improved the accuracy of prostate biopsy.

Since most patients survive the disease, risk stratification systems are routinely utilized to guide staging and treatment. Clinical TNM stage, serum PSA levels, and the Gleason grading system are utilized in clinical practice. More recently, genetic testing on biopsy specimen was included in national guidelines. Historically, the Gleason scoring (GS) system included a primary and secondary score based on the most common and second most common histologic patterns. Grades range from 1 for the most differentiated to 5 for the least. The grades are added to create a resultant Gleason score.132 However, since no patients are assigned a score of less than 5 anymore, the grading system has been modified to a scale from 1 to 5. Grade one includes a GS of 3 + 3 = 6 or less, grade 2 for GS 3 + 4, grade 3 for GS 4 + 3, grade 4 for GS 4 + 4 and grade 5 for Gleason score of 9 or 10.133 Imaging studies like CT and bone scans are used to rule out metastatic disease in high-risk patients. The two most common sites of metastatic disease are pelvic/retroperitoneal lymph nodes and boney structures. Modern CT PET scans have a limited role at this point.

Treatment for localized prostate cancer is guided by cancer aggressiveness and patient’s preferences. Active surveillance is recommended for patients with low-risk disease grade 1–2, early-stage disease (cT1c), and small volume disease as determined by biopsy. Large prospective cohorts and randomized clinical trials have established the safety of this approach.134,135 The risk of progression to metastatic disease with close follow-up and repeat prostate biopsies is less than 2% in over 12 years. Radical prostatectomy and pelvic lymph node dissection (robotic, laparoscopic, or open), image modulated radiation therapy (IMRT), and brachytherapy are the standard of care for curative treatments. All provide equal cancer specific survival for low and intermediate risk cancers. For higher risk prostate cancer patients, both surgery and IMRT with androgen deprivation therapy provide excellent cancer control. Cryotherapy, or high intensity focused ultrasound (HIFU) and focal therapy are emerging options that may be acceptable for some patients with low-risk disease.

Level I evidence has established the role of adjuvant radiation therapy after radical prostatectomy for patients with positive surgical margins, extracapsular extension, and high-grade disease.136,137 After definitive treatment of localized prostate cancer, rising PSA is an extremely reliable indicator of recurrence or progression. However, it may take over 10 years for metastasis to appear on imaging studies.138 Once prostate cancer metastasizes, it is no longer curable. Medications that lower serum testosterone or androgen receptor blockers are able to control the disease, often for years. In addition, chemotherapy, immunotherapy, and radioisotope therapy at different stages of the disease increase the life expectancy of the patients or improve the quality of life. The cancer inevitably becomes resistant to these treatments. Nevertheless, patients with incurable prostate cancer can live many years, and a large number die of causes other than prostate cancer.

Over the past few years, we have witnessed major developments in the management of metastatic castrate resistant prostate cancer (mCRPC). New agents that interrupt androgen synthesis (e.g., abiraterone acetate)139,140 and new modulators of androgen receptors (e.g., enzalutamide)141,142 have significantly improved the life expectancy of patients with both androgen sensitive and resistant metastatic prostate cancer. Similarly, innovations in immunotherapy and chemotherapy delivery have advanced the management of advanced prostate cancer.

Surgical Considerations. Open radical retropubic prostatectomy is done through a lower midline incision from below the umbilicus to the pubic symphysis. After entering the space of Retzius, the external iliac, obturator, and internal iliac lymph nodes are removed. The cavernosal nerves located on the posterolateral surface of the prostate capsule are usually spared on the side(s) with low risk of extracapsular extension of the disease. Then the prostate is removed in a retrograde fashion, and the urethrovessical anastomosis is completed in an interrupted fashion.

Robotic radical prostatectomy using the da Vinci robotic surgical system (Fig. 40-11) is now the most common technique (over 90% of all patients in the United States) for the
surgical treatment of localized prostate cancer. Robotic surgery has lower blood loss and faster convalescence, less bladder neck contracture, and lower early postoperative complications. Some data show a faster return of continence and lower rates of erectile dysfunction. The most common postoperative complications include infection, urine leaks, ileus, lymphocele, and, very rarely, rectal or ureteral injury.

To minimize the impact of these side effects, researchers have used different ablative techniques to obliterc the areas of significant cancer. By avoiding the need for whole gland radiation or removal, these focal ablative therapies aim to balance the long-term impact on quality of life with survival. Laser, high-focused ultrasound, cryotherapy, and photodynamic ablations have showed similar results in early studies.

Urethral Cancer

Urethral carcinoma (UC) is a rare disease, the true incidence of which is unknown. It accounts for less than 1% of genitourinary cancers.143,144 It is a disease of the older adult. Risk factors include chronic inflammation from sexually transmitted diseases (human papillomavirus 16 and 18 in squamous cell carcinoma),145 chronic urethral stricture, and indwelling catheterization. Furthermore, urethral diverticulum and recurrent urinary tract infections increase the risk for women.

The majority of patients present with irritative and obstructive voiding symptoms, bleeding, or a palpable mass. Urothelial carcinoma is the most common histology; 29% of women have adenocarcinoma, and both genders can have squamous cell carcinoma. Untreated or refractory UC typically metastasizes through lymphatic channels to the inguinal and pelvic lymph nodes and hematologically to distant organs. Cytoscopic biopsy establishes the diagnoses. An MRI of the pelvis is extremely helpful for defining local extension of the disease while CT scans of the chest, abdomen, and pelvis identify metastatic disease. Finally, it is also important to evaluate the entire urinary tract.

The 5-year overall survival rates for distal urethral tumors is significantly better than for proximal cancers, 68% versus 40%, respectively.143,146 The median 5-year cancer-specific survival is approximately 46%.144 Prognosis is dictated by patients’ age, race, clinical stage, and location of the tumor.

If feasible, local endoscopic resection for low-volume, low-stage disease is preferable. Adjuvant intravesical instillation of Bacillus Calmette-Guérin (BCG) should be considered for patients with proximal noninvasive disease.147 Due to the paucity of robust data, management of locally advanced disease is more challenging. Either radical cystectomy or radiotherapy are acceptable options. Unfortunately, local recurrence rates are high after aggressive monotherapy (63%).148 More recent data support the use of multimodal therapy.149,150 Small series of combinations of perioperative chemotherapy, surgery, and radiation indicate the best cancer control.151

COMMON UROLOGIC CONDITIONS

Urinary Incontinence and Voiding Dysfunction

Urinary incontinence is defined as the involuntary loss of urine. This is more common in women than men for a variety of reasons, including anatomic differences such as a shorter urethra and risk factors such as childbirth. Many patients may also suffer from bothersome symptoms without leakage of urine such as overactive bladder (frequency and urgency of urination and often nocturia), or obstructive symptoms such as hesitancy, weak stream, and incomplete bladder emptying. These conditions can have a negative impact on quality of life,152–154 but they are also associated with serious health issues, including depression, anxiety, social isolation,155 and even falls and fractures in the elderly.156

Urinary incontinence can be divided into several categories, although patients (particularly women) may suffer from more than one type.157 Urge incontinence is the involuntary loss of urine associated with an urge to void. Stress leakage occurs with increases in intra-abdominal pressure, such as coughing or sneezing, and may relate to loss of sphincteric function, urethral hypermobility from pelvic floor laxity (often related to parity), or following prostate surgery in men. Overflow incontinence occurs in the setting of obstruction, with urine leakage occurring with movement causing overflow of urine from a distended bladder. Genitourinary fistulas typically result in the most severe form of incontinence with constant leakage of urine regardless of presence or absence of activity or movement. Examples include vesicovaginal or ureterovaginal fistulae most often due to gynecologic surgery, or rectourethral fistulae in men from cancer, radiation, or surgical intervention.

For urinary incontinence and voiding dysfunction, treatments vary depending on the etiology, severity, and bother of the symptom. Urge leakage and overactive bladder can be treated by (a) behavioral modification (timed voiding, adjustment to fluid intake, timing of diuretic medication, and improved constipation); (b) bladder retraining (pelvic floor physical therapy158); (c) medications (anticholinergics159 and β-3 agonists160); or (d) minimally invasive procedures (sacral neuromodulation,162 percutaneous tibial nerve stimulation,162 or bladder chemodenervation with detrusor botulinum toxin injection163).

Stress incontinence in women can be addressed by pelvic floor strengthening exercises, vaginally placed removable support with a pessary, injection of urethral bulking agent, or sling procedures using polypropylene mesh or autologous tissue. In men, stress leakage is due to either iatrogenic causes or neurologic disease. Treatments include strengthening exercises as in women, slings, or implantation of an artificial urinary sphincter. Overflow incontinence treatment is directed at the cause of obstruction, often benign prostatic enlargement in men, with bladder drainage, medications such as α-blockers or 5-α-reductase inhibitors, or surgical removal of the obstructing gland. When fistulas are present, adherence to surgical principles such as tension-free multilayer closure, nonoverlapping suture lines, and tissue interposition when possible offers the highest likelihood for success.

Erectile Dysfunction

Erectile dysfunction (ED) is defined as the inability to achieve and maintain an erection adequate for sexual intercourse. Formerly, this was known as a type of sexual dysfunction, but it is now understood that ED may be an early symptom of cardiovascular disease due to endothelial dysfunction. ED is a common disease for men later in life with a prevalence rate believed to range anywhere from 30% to 50% depending on age. Two large population-based studies, the Massachusetts Male Aging Study (MMAS) and the European Male Aging Study (EMAS), examined men age 40 to 79 years and found that ED rates increased with age.164,165
Erections are triggered via sexual stimulation setting off a cascade of events. Nitric oxide is released from nerve fibers and activating guanylyl cyclase leading to an increase in cyclic guanosine monophosphate (cGMP). The cGMP pathway leads to smooth muscle relaxation within the corpora cavernosa allowing blood to fill the lacunar spaces. Once the lacunar spaces are full, the expanded tissue compresses the subtunical venules thereby trapping blood within the penis and blocking venous outflow. Phosphodiesterase type-5 hydrolyzes cGMP to reverse the process.166

There are multiple mechanisms leading to ED including vasculogenic, neurogenic, iatrogenic, and psychologic, but often it is multifactorial. Vasculogenic ED can be a result of cardiovascular disease and endothelial dysfunction leading to cavernosal artery insufficiency. Diseases such as hypertension (odds ratio [OR] 1.35–3.04), diabetes (OR 2.57), dyslipidemia (OR 1.83), and tobacco abuse (OR 1.4) all may increase the risk for ED.167 Nerve injuries due to diseases (diabetes, Parkinson’s, multiple sclerosis, spinal cord injury) or surgery (radical prostatectomy, abdominoperineal resection, and other radical pelvic procedures) can lead to interruptions in the nerve signaling that causes nitric oxide release and therefore lead to ED. Iatrogenic causes may be a result of surgery (described earlier) or medication use, as in some antihypertensives, opiates, androgenics, and psychotherapeutics.168 Psychogenic ED, a common reaction to stress and anxiety, is a result of noradrenaline release causing smooth muscle contraction and thereby inhibiting erections.169

Treatment for ED begins with lifestyle modification by identifying any reversible risk factors such as stress/anxiety, medications, unhealthy diets, lack of exercise, and tobacco abuse.170 Medical therapy then begins with the use of phosphodiesterase type-5 inhibitors (PDE5i). These work by prolonging the activity of cGMP, leading to continued smooth muscle relaxation allowing more blood inflow into the penis. Common drugs include sildenafil, tadalafil, vardenafil, and avanafil. They differ in time to peak concentration (lowest in avanafil, sildenafil, and vardenafil), half-life (highest in tadalafil), and the impact of lipids in foods (sildenafil and vardenafil must be taken on an empty stomach). Common side effects include a headache, heartbeat, facial flushing, nasal congestion, and myalgias.171 Patients on nitrate-containing medications should not be given PDE5i due to the risk of severe hypotension. Vision related conditions like macular degeneration, retinitis pigmentosa, and nonarteritic anterior ischemic optic neuropathy are cause for increased awareness and possible ophthalmologic consult.172

Second-line options for ED include vacuum erection devices (VED), intracavernosal injections (ICI), and intraurethral suppositories. The VED is a mechanical device composed of a cylinder placed around the penis which then uses a vacuum to create negative pressure and pull blood into the penis. In order for blood to stay in the penis after the vacuum is released, a tight constriction band must be placed at the base of the penis. There is poor compliance due to difficulty with use and the common reactions of petechia, temporary paresthesia, color changes, and the penis being cold to touch.173,174 Alternatively, ICI uses vasoactive substances (prostaglandin E1 [alprostadil], papaverine, and phentolamine) either alone or in combination to trigger the erection cascade.168 Patients are trained to give themselves a self-injection when they want an erection, and it takes approximately 5 to 15 minutes until they are fully rigid if they respond. With ICI, there is greater concern for prolonged erection or priapism, so dose titration must be closely monitored. Intraurethral suppositories are composed of alprostadil in the form of a pellet which is then placed in the urethra and massaged for absorption. With suppository use, there are concerns about efficacy (only 46–65%) and compliance due to a burning sensation that limits the interest of some users.175,176

Third-line treatment of ED is with surgery placement of a penile prosthesis. There are three main types (malleable, two-piece, and three-piece). The malleable device does not inflate/dilate and merely bends in and out of position for intercourse. The two-piece and three-piece devices are inflatable and differ on the presence of a separate fluid reservoir. The two-piece device has the fluid maintained in the lower half of the penile cylinders, whereas, the three-piece device has a fluid reservoir placed in the pelvis or abdominal wall (Fig. 40-12). Overall, the inflatable prosthesis has high patient and partner satisfaction rates, >92% and >91%, respectively.177

**PEDIATRIC UROLOGY**

**Hypospadias**

Hypospadias, a condition which may be considered a form of incomplete maturation of the genitalia, is a common abnormality that occurs in 1 out of 250 to 300 newborn boys. The most obvious aspect of hypospadias is a urethral opening that is not at the tip of the glans, and 70% to 80% of affected babies will have a meatus on the mid to distal shaft or proximal glans. A lesser number will have more proximal openings, whether penoscrotal, scrotal, or perineal. In addition to an abnormally located meatus, boys usually have deficient ventral foreskin. Associated penile
curvature, more common in the severe varieties, is referred to as chordee.

No diagnostic studies are needed for the majority of boys with hypospadias as there is typically no increased risk of renal or bladder abnormalities. Children with associated cryptorchidism, especially with proximal hypospadias and a nonpalpable testis, have an increased risk of a having a coexisting disorder of sexual differentiation (DSD) and need to undergo a thorough evaluation including hormonal studies, karyotype, and pelvic ultrasonography.178

Distal hypospadias can usually be repaired in one stage with success rates of greater than 95%. Most would advocate a staged approach to proximal hypospadias with correction of penile curvature at the first stage and formal urethral reconstruction at the second.179 Adults with corrected hypospadias usually have normal sexual function and fertility.

**Urinary Tract Infections in Children**

Urinary tract infections (UTI) are common in children, and there is a greater chance of underlying anatomic abnormalities. Children may have conditions such as vesicoureteral reflux, ureteropelvic junction obstruction, ureterocele, or ectopic ureters as causes of these infections. Because of this association, in the past all children with febrile infections would undergo complete evaluations including renal ultrasonography (US) as well as invasive studies such as voiding cystourethrography (VCUG). However, defining pyelonephritis as having a positive renal cortical scan, only 30% to 40% of children with febrile UTI will have reflux. Thus the majority of children with febrile infections, and a greater percentage of those with afebrile infections (cystitis), will be anatomically normal.180 These data have led to a change in imaging guidelines for children with UTI.

Guidelines put out by the American Academy of Pediatrics have markedly changed the way children with infections are evaluated.181 These guidelines suggest that infants less than 2 months of age with febrile infections should undergo both a renal US and VCUG. Children between 2 months and 2 years who have their first documented infection only need to have a renal ultrasound performed. A VCUG is only needed if there are abnormalities detected on the ultrasound such as hydronephrosis, scarring, or other evidence of anatomic abnormality. A VCUG may also be performed if a child has recurrent infections despite empirical treatment. These guidelines do not address children older than 2 years of age but one can assume that similar algorithms of treatment would be appropriate.

There is now greater understanding that most children with UTIs, whether pyelonephritis or cystitis, have some element of bladder and/or bowel dysfunction as the major factor in the development of the infection. Thus, all children with UTIs need to have a thorough assessment of daily bladder and bowel habits. The latter may be difficult to ascertain in younger children, but bowel dysfunction, even subclinical, may be the most important factor in the development of UTIs. Behavioral therapies such as regular and complete voiding in conjunction with a bowel program should be considered the mainstay of the prevention of infections as opposed to prophylactic antibiotics.

**Prenatal Hydronephrosis**

Antenatal imaging will show hydronephrosis in nearly 1% of all babies. Though the majority of children will have benign hydronephrosis of no clinical significance, it may also be related to vesicoureteral reflux, ureteropelvic junction obstruction, ectopic ureter/ureterocele, and other upper tract abnormalities. Typically, nothing needs to be done for these children until after birth, at which point a baseline renal ultrasound can be performed. Other studies such as a VCUG or Lasix renal scans can then be done depending on the degree of dilation. Diagnosis of upper tract obstruction is usually based on progressive worsening of dilation or renal function on serial examinations.

Special consideration must be given for children with bilateral hydronephrosis or hydronephrosis associated with a solitary kidney, especially if linked to oligohydramnios. Since fetal urine production accounts for much of the amniotic fluid, low levels can be a sign of a severe abnormality of the urinary tract. Reduced amniotic fluid is of great consequence since normal lung development is dependent on normal amniotic fluid volumes and children with oligohydramnios can be born with significant pulmonary insufficiency. Boys with bilateral hydronephrosis and low amniotic fluid are at high risk for having posterior urethral valves (PUV). Boys with PUV have as much as a 25% risk of developing end stage renal disease at some point in their lives.182 Prenatal intervention such as placement of vesicoamniotic shunts have not been shown to reduce the risk of renal failure.

**Cryptorchidism**

Cryptorchidism or undescended testes (UDT) is a common condition occurring in 3% of full term and 30% of premature babies. Many of these testes will descend spontaneously due to the normal gonadotropin release that occurs in the first few months of life, so the true incidence is roughly 1% of boys. Untreated cryptorchidism will lead to testis damage, and there is evidence that permanent changes may occur by 3 years of age. Ideally, surgical treatment should occur prior to this age. UDT is usually an isolated finding, but it may occur as a part of a systemic condition such as Prader-Willi, Eagle-Barrett, or other such complex multisystem syndrome. Surgery is the treatment of choice; hormonal treatment has no role.

The consequences of untreated cryptorchidism include infertility and malignant degeneration. One study on fertility suggested that men with a history of unilateral cryptorchidism will have no difference in paternity rates compared to normal controls. In contrast, men with bilateral cryptorchidism have up to a 50% rate of infertility.183 There is data to suggest that orchidopexy in the first year of life is associated with better total sperm counts in adulthood.184 With regard to malignancy, untreated UDT has a fivefold increase risk of tumor development compared to the normal population. However, there is data to suggest that prepubertal orchidopexy is protective and that these boys only have a twofold greater risk.185

PATHOPHYSIOLOGY AND MECHANISMS OF DISEASE

The female reproductive system includes the external (vulva including the labia, clitoris, and vaginal opening) sex organs as well as the internal organs (uterus and cervix, fallopian tubes, and ovaries) that function in human reproduction. The female reproductive tract has a multitude of tightly regulated functions. The ovaries produce the ova (egg cells) and hormones necessary for maintenance of reproductive function. The fallopian tubes accommodate transit of an ovum to the uterus and provide a location for fertilization. The uterus accommodates an embryo that develops into the fetus. The cervix provides a barrier between the external and internal genital tract. Ongoing activities, such as angiogenesis and physiologic invasion, are necessary in order for the reproductive organs to fulfill their purpose and are usurped in disease. Immune surveillance is regulated in a fashion that allows implantation, placentation, and development of the fetus.

Because the pelvis contains a multitude of spatially and temporally varied functions, pathologies range from mechanical events, such as ovarian torsion or ruptured ectopic pregnancy, to infection, such as pelvic inflammatory disease, to mass effects, including leiomyomata and malignancy, that can present with similar and even overlapping symptoms and signs. An acute abdomen presentation in a woman of child bearing potential can range from pregnancy-related catastrophes, to appendicitis, to a hemorrhagic ovarian cyst.

The ongoing rupture, healing, and regrowth of the ovarian capsule and endometrium during the menstrual cycle use the same series of biologic and biochemic events that are also active in pathologic events such as endometriosis and endometriomas, mature teratomas, dysgerminomas, and progression to malignancy. Genetic abnormalities, both germ line and somatic, that may cause competence and/or promote disease are increasingly well understood. Incorporation of genetic and genomic information in disease diagnosis and assessment has altered how we diagnose and follow disease, in whom we increase our diligence in searching for disease, and ultimately how we use the drug and other therapeutic armamentarium available to the treating physician.

These points will be incorporated with surgical approaches into discussions of anatomy, diagnostic workup, infection, surgical and medical aspects of the obstetric patient, pelvic floor dysfunction, and neoplasms.

ANATOMY

Clinical gynecologic anatomy centers on the pelvis (L. basin). Apty named, the bowl-shaped pelvis houses the confluence and intersection of multiple organ systems. Understanding
those structural and functional relationships is essential for the surgeon and allows an appreciation for the interplay of sexual function and reproduction as well as a context for understanding gynecologic pathology.

**Structure and Support of the Pelvis and Genitalia**

The bony pelvis is comprised by the **sacrum** posteriorly and the **ischium**, **ilium**, and **pubic** bones anteromedially. It supports the upper body and transmits the stresses of weight bearing to the lower limbs in addition to providing anchors for the supporting tissues of the pelvic floor.1 The opening of the pelvis is spanned by the muscles of the pelvic diaphragm (Fig. 41-1). The muscles of the pelvic sidewall include the **iliacus**, the **psoas**, and the **obturator internus** muscle (Fig. 41-2). These muscles contract tonically and include, from anterior to posterior, bilaterally, the **pubococcygeus**, **puborectalis**, **iliococcygeus**, and **coccygeus** muscles. The first two of these muscles contribute fibers to the fibromuscular perineal body. The **urogenital hiatus** is bordered laterally by the **pubococcygeus** muscles and anteriorly by the **symphysis pubis**. It is through this muscular defect that the urethra and vagina pass, and it is the focal point for the study of disorders of pelvic support such as cystocele, rectocele, and uterine prolapse.

1. Gynecologic causes of acute abdomen include PID and tubo-ovarian abscess, ovarian torsion, ruptured ectopic pregnancy, septic abortion. Pregnancy must be ruled out early in assessment of reproductive age patients presenting with abdominal or pelvic pain.
2. The general gynecology exam must incorporate the whole physical examination in order to adequately diagnosis and treat gynecologic disorders.
3. Benign gynecologic pathologies that are encountered at the time of surgery include endometriosis, endometriomas, fibroids, and ovarian cysts.
4. It is critical that abnormal lesions of vulva, vagina, and cervix are biopsied for diagnosis before any treatment is planned; postmenopausal bleeding should always be investigated to rule out malignancy.
5. Pelvic floor dysfunction (pelvic organ prolapse, urinary and fecal incontinence) is common; 11% of women will undergo a reconstructive surgical procedure at some point in their lives.
6. Pregnancy confers important changes to both the cardiovascular system and the coagulation cascade. Trauma in pregnancy must be managed with these changes in mind.
7. Early-stage cervical cancer is managed surgically, whereas chemoradiation is preferred for stages Ib2 and above.
8. Risk-reducing salpingo-oopherectomy is recommended in women with BRCA1 or BRCA2 mutations.
9. Optimal debulking for epithelial ovarian cancer is a critical element in patient response and survival. The preferred postoperative therapy for optimally debulked advanced-stage ovarian epithelial ovarian cancer is intraperitoneal chemotherapy.
10. Long-term sequelae of intestinal and urologic injury can be avoided by intraoperative identification.

![Figure 41-1](image-url) Deeper muscles of the pelvic floor.
Vulva

The labia majora form the cutaneous boundaries of the lateral vulva and represent the female homologue of the male scrotum (Fig. 41-4). The labia majora are fatty folds covered by hair-bearing skin in the adult. They fuse anteriorly over the anterior prominence of the symphysis pubis, the mons pubis. The deeper portions of the adipose layers are called Colles fascia and insert onto the inferior margin of the perineal membrane, limiting spread of superficial hematomas inferiorly. Adjacent and medial to the labia majora are the labia minora, smaller folds of connective tissue covered laterally by non–hair-bearing skin and medially by vaginal mucosa. The anterior fusion of the labia minora forms the prepuce and frenulum of the clitoris; posteriorly, the labia minora fuse to create the fossa navicularis and posterior fourchette. The term vestibule refers to the area medial to the labia minora bounded by the fossa navicularis and the clitoris. Both the urethra and the vagina open into the vestibule. Skene’s glands lie lateral and inferior to the urethral meatus. Cysts, abscesses, and neoplasms may arise in these glands.

Erectile tissues and associated muscles are in the space between the perineal membrane and the vulvar subcutaneous tissues (see Fig. 41-1). The clitoris is formed by two crura and is suspended from the pubis. Overlying the crura are ischiocavernosus muscles, which run along the inferior surfaces of the ischiopubic rami. Extending medially from the inferior end of the ischiocavernosus muscles are the superficial transverse perinei muscles. These terminate in the midline in the perineal body, caudal and deep to the posterior fourchette. Vestibular bulbs lie just deep to the vestibule and are covered laterally by bulbocavernosus muscles. These originate from the perineal body and insert into the body of the clitoris. At the inferior end of the vestibular bulbs are Bartholin’s glands, which connect to the vestibular skin by ducts.

Vagina

The vagina is an elastic fibromuscular tube opening from the vestibule running superiorly and posteriorly, passing through the perineal membrane. The lower third is invested by the superficial and deep perineal muscles; it incorporates the urethra in its anterior wall and has a rich blood supply from the vaginal branches of the external and internal pudendal arteries. The upper two-thirds of the vagina are not invested by muscles. This portion lies in opposition to the bladder base anteriorly and the rectum and posterior pelvic cul-de-sac superiorly. The cervix opens into the posterior vaginal wall bulging into the vaginal lumen.

Uterus

The typically pear-shaped uterus consists of a fundus, cornua, body, and cervix. It lies between the bladder anteriorly and the rectosigmoid posteriorly. The endometrium lines the inside cavity and has a superficial functional layer that is shed with menstruation and a basal layer from which the new functional layer is formed. Sustained estrogenic stimulation without associated progestin maturation can lead to hyperplastic changes or carcinoma. Adenomyosis is a condition in which benign endometrial glands infiltrate into the muscle or myometrium of the uterus. The myometrium is composed of smooth muscle and the contraction of myometrium is a factor in menstrual pain and is essential in childbirth. The myometrium can develop benign smooth muscle neoplasms known as leiomyoma or fibroids.

Cervix

The cervix connects the uterus and vagina and projects into the upper vagina. The vagina forms an arched ring around the cervix described as the vaginal fornices—lateral, anterior, and posterior. The cervix is about 2.5–cm long with a fusiform endocervical canal lined by columnar epithelium lying between an internal and external os, or opening. The vaginal surface of the cervix is covered with stratified squamous epithelium, similar to that lining the vagina. The squamo-columnar junction, also referred to as the transformation zone, migrates at different stages of life and is influenced by estrogenic stimulation. The transformation zone develops as the columnar epithelium is replaced by squamous metaplasia. This transformation zone is
vulnerable to human papilloma virus (HPV) infection and resultant premalignant changes. These changes can be detected by microscopic assessment of cervical cytological (or Pap) smear. If the duct of a cervical gland becomes occluded, the gland tends to form a retention cyst or Nabothian follicle.

**Fallopian Tubes**

The bilateral fallopian tubes arise from the upper lateral cornua of the uterus and course posterolaterally within the upper border of the broad ligament. The tubes can be divided into four parts. The interstitial part forms a passage through the myometrium. The isthmus is the narrow portion extending about 3 cm from the myometrium. The ampulla is thin-walled and tortuous with its lateral end free of the broad ligament. The infundibulum is the distal end fringed by a ring of delicate fronds or fimbriae. The fallopian tubes receive the ovum after ovulation. Peristalsis carries the ovum to the ampulla where fertilization occurs. The zygote transits the tube over the course of 3 to 4 days to the uterus. Abnormal implantation in the fallopian tube is the most common site of ectopic pregnancies. The tubes may also be infected by ascending organisms, resulting in tubo-ovarian abscesses. Scarring of the fallopian tubes can lead to hydrosalpinx. Recent evidence suggests most high-grade serous ovarian cancer originates in the fallopian tubes.

**Ovaries**

The ovaries are attached to the uterine cornu by the proper ovarian ligaments, or the utero-ovarian ligaments. The ovaries are suspended from the lateral pelvis by their vascular pedicles, the infundibulopelvic ligaments (IP) or ovarian arteries. These are also called the suspensory ligaments of the ovaries, and correspond to the genital vessels in the male. The IP’s are paired branches from the abdominal aorta arising just below the renal arteries. They merge with the peritoneum over the psoas major muscle and pass over the pelvic brim and the external iliac vessels. The ovarian veins ascend at first with the ovarian arteries, then track more laterally. The right ovarian vein ascends directly into the inferior vena cava while the left vein drains into the left renal vein. Lymphatic drainage follows the arteries to the para-aortic lymph nodes. The ovaries are covered by a single layer of cells that is continuous with the mesothelium of the peritoneum. Beneath this is a fibrous stroma within which are embedded germ cells. At ovulation, an ovarian follicle ruptures through the ovarian epithelium.

**Fibrovascular Ligaments and Avascular Tissue Planes**

Figure 41-5 is a view of the internal genitalia and deep pelvis as one would approach the pelvis from a midline abdominal incision. The central uterus and uterine cervix are supported by the pelvic floor muscles (Fig. 41-5). They are suspended by
the lateral fibrous cardinal, or Mackenrodt’s ligament, and the uterosacral ligaments, which insert into the paracervical fascia medially and into the muscular sidewalls of the pelvis laterally. Posteriorly, the uterosacral ligaments provide support for the vagina and cervix as they course from the sacrum lateral to the rectum and insert into the paracervical fascia. Emanating from the uterine cornu and traveling through the inguinal canal are the round ligaments, eventually attaching to the subcutaneous tissue of the mons pubis. The peritoneum enfolding the adnexa (tube, round ligament, and ovary) is referred to as the broad ligament, which separates the pelvic cavity into an anterior and posterior component.

The peritoneal reflections in the pelvis anterior and posterior to the uterus are referred to as the anterior and posterior cul-de-sacs. The latter is also called the pouch or cul-de-sac of Douglas. On transverse section, seven avascular, and therefore important, surgical planes can be identified (Fig. 41-6). These include the right and left lateral paravesical and right and left pararectal spaces, and from anterior to posterior, the retropubic or prevesical space of Retzius and the vesicovaginal, rectovaginal, and retrorectal or presacral spaces.

These avascular tissue planes are often preserved and provide safe surgical access when the intraperitoneal pelvic anatomy is distorted by tumor, endometriosis, adhesions, or infection. Utilizing the avascular retroperitoneal planes, the ureter can be traced into the pelvis as it crosses the distal common iliac arteries laterally into the pararectal space and then courses inferior to the ovarian arteries and veins until crossing under the uterine arteries into the paravesical space just lateral to the cervix. After traveling to the cervix, the ureters course downward and medially over the anterior surface of the vagina before entering the base of the bladder in the vesicovaginal space.

Vasculature and Nerves of the Pelvis

The rich blood supply to the pelvis arises largely from the internal iliac arteries except for the middle sacral artery originating at the aortic bifurcation and the ovarian arteries originating from the abdominal aorta. There is also collateral flow and anastomoses to the pelvic vessels from the inferior mesenteric artery. The internal iliac, or hypogastric, arteries divide into anterior and posterior branches. The latter supply lumbar and gluteal branches. From the anterior division of the hypogastric arteries arise the obturator, uterine, pudendal, middle rectal, inferior gluteal, along with superior and middle vesical arteries (see Fig. 41-2).

The major motor nerves found in the pelvis are the sciatic, obturator, and femoral nerves (Fig. 41-3). Also important to the pelvic surgeon are the ilioinguinal, iliohypogastric and genitofemoral nerves, which arise as upper abdominal nerves, but are encountered on the most caudal portion of the anterior abdominal wall and the ventral portion of the external genitalia. Sympathetic fibers course along the major arteries and parasympathetics form the superior and inferior pelvic plexus. The pudendal nerve arises from S2–S4 and travels laterally, exiting the greater sciatic foramen, hooking around the ischial spine and sacrospinous ligament, and returning via the greater sciatic foramen. It travels through Alcock’s canal and becomes the sensory and motor nerve of the perineum (see Figs. 41-1 and 41-3). The motor neurons serve the tonically contracting urethral and anal sphincter, and direct branches from the S2–S4 nerves serve the levator ani muscles. During childbirth and other excessive straining, this tethered nerve (along with the levator ani muscles) is subject to stretch injury and is at least partially responsible for many female pelvic floor disorders.

EVALUATION AND DIAGNOSIS

Elements of a Gynecologic History

A complete history is a seminal part of any assessment (Table 41-1). Many gynecologic diseases can present with broad constitutional symptoms, occur secondary to other conditions, or be related to medications. A full history should include particular attention to family history, organ system history, including breast, gastrointestinal, and urinary tract symptoms, and a careful medication, anesthesia, and surgical history. The key elements of a focused gynecologic history include the following:

- Date of last menstrual period
- History of contraceptive and postmenopausal hormone use
- Obstetrical history
- Age at menarche and menopause (method of menopause, [e.g., drug, surgical])
- Menstrual bleeding pattern
- History of pelvic assessments, including cervical smear and HPV DNA results
- History of pelvic infections, including HPV and HIV status
- Sexual history
- Prior gynecologic surgery(s)

The Gynecologic Examination

For many young women, their gynecologist is their primary care physician. When that is the case, it is necessary that a full medical and surgical history be taken and that, in addition to the pelvic examination, the minimum additional examination should include assessment of the thyroid, breasts, and cardiopulmonary system. Screening, reproductive counseling, and age-appropriate health services should be available to women of all ages with or without a routine pelvic examination, but the decision to proceed with regular, annual pelvic examinations in otherwise healthy women is controversial. The U.S. Preventive Services Task Force recently evaluated the current evidence regarding the balance of benefits and harms of performing screening pelvic examinations in asymptomatic, nonpregnant adult women and concluded that the evidence is insufficient.

Figure 41-6. The avascular spaces of the female pelvis.
The pelvic examination starts with a full abdominal examination. Inguinal node evaluation is performed before placing the patient’s legs in the dorsal lithotomy position (in stirrups). A flexible, focused light source is essential, and vaginal instruments including speculums of variable sizes and shapes (Graves and Pederson), including pediatric sizes, are required to assure that the patient’s anatomy can be fully and comfortably viewed. A warmed lubricated speculum is inserted into the vagina and gently opened to identify the cervix if present or the vaginal apex if not. To avoid confusing the location of pelvic pain with immediate speculum exam, or if there is a concern that a malignancy is present, careful digital assessment of a vaginal mass and location may be addressed prior to speculum placement in order to avoid abrading a vascular lesion and inducing hemorrhage. The speculum would then be inserted just short of the length to the mass in order to view that area directly before advancing. An uncomplicated speculum exam includes examination of the vaginal sidewalls, assessment of secretions, including culture if necessary, and collection of the cervical cytologic specimen and HPV test if indicated (see “Common Screening”).

A bimanual examination is performed by placing two fingers in the vaginal canal; one finger may be used if patient has significant vaginal atrophy or has had prior radiation with stenosis (Fig. 41-7). Carefully and sequentially assess the size and shape of the uterus by moving it against the abdominal hand, and the adnexa by carefully sweeping the abdominal hand down the side of the uterus. The rectovaginal examination, consisting of one finger in the vagina and one in the rectal vault, is used to further examine and characterize the location, shape, fixation, size, and complexity of the uterus, adnexa, cervix, and anterior and posterior cul-de-sacs. The rectovaginal exam also allows examination of the uterosacral ligaments from the back of the uterus sweeping laterally to the rectal finger and the sacrum, as well as assessment of the rectum and anal canal for masses.

It is critical that presurgical assessments include a full general examination. This is particularly important with potential oncologic diagnoses or infectious issues in order to assure that the proposed surgery is both safe and appropriate. Issues such as sites of metastatic cancer or infection, associated bleeding and/
or clotting issues and history, and drug exposure, allergies, and current medications must be addressed.

**Commonly Used Testing**

**β-Human Chorionic Gonadotropin Testing.** Qualitative urinary pregnancy tests for human chorionic gonadotropin (β-hCG) are standard prior to any surgery in a woman of reproductive age and potential, regardless of contraception history. In addition, serum quantitative β-hCG testing is appropriate for evaluation of suspected ectopic pregnancy, gestational trophoblastic disease, or ovarian mass in a young woman. In the case of ectopic pregnancy, serial levels are required when a pregnancy cannot be identified in the uterine cavity by imaging. As a general rule, 85% of viable, very early intrauterine pregnancies will have at least a 66% rise in the β-hCG level over 48 hours.

**Microscopy of Vaginal Discharge.** During a speculum exam, a cotton-tipped applicator is used to collect the vaginal discharge; it is smeared on a slide with several drops of 0.9% normal saline to create a saline wet mount. A cover slide is placed and the slide is evaluated microscopically for the presence of mobile trichomonads (*Trichomonas vaginalis*) or clue cells (epithelial cells studded with bacteria, seen in bacterial vaginosis; Table 41-2). A potassium hydroxide (KOH) wet mount is the slide application of the collected vaginal discharge with 10% KOH; this destroys cellular elements. The test is positive for vaginal candidiasis when pseudohyphae are seen (see Table 41-2).

**Chlamydia/Gonorrhea Testing.** Nucleic acid amplification testing (NAAT) has emerged as the diagnostic test of choice for *N gonorrhoea* and *C trachomatis*. A vaginal swab, endocervical swab, and/or urine sample, can be used for this test.

**Cervical Cancer Screening and Prevention.** HPV infection is required for the development of epithelial cervical carcinomas (squamous and adenocarcinomas), and HPV DNA can be identified in virtually all primary cervical malignancies. HPV is a ubiquitous double-stranded DNA virus commonly acquired in the female lower genital tract through sexual contact. After entry into the cell, the HPV protein E6 degrades the tumor suppressor p53, resulting in deregulation of cell cycle arrest. E7 inactivates the tumor suppressor RB and releases E2F transcription factors, causing cellular hyperproliferation. More than 100 HPV types have been identified, and up to 40 of these subtypes infect the anogenital region. At least 12 are considered high-risk or oncogenic, and HPV genotypes 16 and 18 cause approximately 70% of cervical cancers worldwide.4

Recent cervical cytology guidelines have increased the intervals between screenings for most women given the known natural history of HPV-related cervical dysplasia progression to cancer and the high negative predictive value of a negative HPV test.6 The current recommendations call for cervical smear screening every 3 to 5 years in women ages 21 to 65 years. If an

+ = positive; – = negative; KOH = potassium hydroxide.
HPV test performed at the same time also is negative, testing should be repeated every 5 years for women ages 30 to 65 years. Screening is not recommended for women age older than 65 or without a cervix (prior hysterectomy) unless they have a history of high-grade precancerous lesions. Women with a history of cervical dysplasia, HPV infection, or cervical cancer need more frequent screening based on their diagnosis. Primary high-risk HPV (hrHPV) screening is also an acceptable alternative to cytologic screening for women ages 30-65 because of an increased detection of high-grade squamous intraepithelial lesion (HSIL) and increased negative predictive value.6

**HPV Vaccine.** Three HPV vaccines have been approved by the U.S. Food and Drug Administration (FDA).7 In 2006, a quadrivalent (4vHPV) vaccine was approved that targets HPV 16 and 18, which cause 70% of cervical cancers, and HPV genotypes 6 and 11, which cause 90% of genital warts. In December 2014, a nine-valent vaccine (9vHPV) was introduced to replace the 4vHPV vaccine, which includes protection against the HPV strains covered by the first generation of 4vHPV as well as five other HPV strains responsible for 20% of cervical cancers (HPV-31, HPV-33, HPV-45, HPV-52, and HPV-58).7 The 9vHPV may be used to continue or complete a series started with a different HPV vaccine product. Vaccination with 9vHPV after completion of 4vHPV at least 12 months earlier is safe and may provide protection against additional HPV strains. A bivalent vaccine that targets HPV genotypes 16 and 18 with a different adjuvant that may have led to higher immunogenicity was approved in 2009 but is no longer marketed in the United States.

Vaccination generates high concentrations of neutralizing antibodies to HPV L1 protein, the antigen in all HPV vaccines. The vaccines are highly immunogenic, activating both humoral and cellular immune responses. Multiple randomized clinical trials have demonstrated nearly 100% efficacy in the prevention of the HPV subtype-specific precancerous cervical cell changes.7,8 These major clinical trials have used prevention of HSIL as the efficacy endpoints. Vaccination does not protect women who are already infected with HPV-16 or -18 at the time of vaccination.

Current recommendations include HPV vaccination for boys and girls at age 11 or 12 years. (Vaccination can be started at age 9.) The Advisory Committee on Immunization Practices (ACIP) also recommends vaccination for females aged 13 through 26 years and males aged 13 through 21 years not adequately vaccinated previously. Catch-up vaccination is also recommended through age 26 years for gay, bisexual, and other men who have sex with men, transgender people, and for immunocompromised persons (including those with HIV infection) not adequately vaccinated previously.8 Two doses are given 6 to 12 months apart for patients with an intact immune system, age less than 15 years; three doses are recommended for those ages 15 to 26 years and immunocompromised persons.10 Cervical cancer screening continues to play an important role in detection and treatment of premalignant cervical lesions and prevention of cervical cancer in these high-risk patients and is currently recommended following HPV vaccination.

**Serum Cancer Antigen 125.** Cancer antigen (CA) 125 is a large membrane glycoprotein belonging to the wide mucin family commonly used as a tumor marker in patients known to have ovarian cancer. An elevated CA-125 in the patient without known ovarian cancer should be interpreted in conjunction with patient information and symptoms as well as imaging. In the setting of an adnexal mass, the serum CA-125 test may help with triage of a patient to the appropriate surgical management. The test should be used with caution as it is a nonspecific test and may be elevated with multiple benign conditions including endometriosis, fibroids, infection, and pregnancy and may even vary with the menstrual cycle. For these reasons, the CA-125 test is less useful in the premenopausal woman for triaging an adnexal mass. In the postmenopausal woman, a CA-125 greater than 35 in the setting of a complex adnexal mass merits referral of the patient to a gynecologic oncologist.10

**Common Office Procedures for Diagnosis**

**Vulvar/Vaginal Biopsy.** Any abnormal vulvar or vaginal lesion including skin color changes, raised lesions, or ulcerations should be biopsied. Local infiltration with local anesthetic is followed by a 3- to 5-mm punch biopsy appropriate to the lesion. The specimen is elevated with Adson forceps and cut from its base with scissors. The vaginal biopsy can sometimes be difficult to perform because of the angle of the lesion. After injection with local anesthetic, traction of the area with Allis forceps and direct resection of the lesion with scissors or cervical biopsy instrument (Schubert, Kevorkian, etc) can achieve an adequate biopsy.

**Colposcopy and Cervical Biopsy.** In cases of an abnormal Pap smear cytology or positive HPV testing, a colposcopy is performed for a histologic evaluation. A colposcope is used to achieve 2x to 15x magnification of the cervix. Once the cervix is visualized, cervical mucus, if present, is removed, and then 3% acetic acid is applied to the cervix for one minute. This application dehydrates cells and causes dysplastic cells with dense nuclei to appear white. The lining of the cervix consists of squamous epithelium on the ectocervix, whereas columnar epithelium lines the endocervical canal. The ectocervix therefore appears smooth and pale pink in color while the endocervix forms epithelial fronds or “grape-like” structures visible through the colposcope. The junction between columnar and squamous cell types is called the squamocolumnar junction (SCJ), which in younger women is usually visible on the ectocervix. When columnar epithelium extends onto the ectocervix, it appears as a red zone surrounding the os and is called ectropion or ectopy. The transformation zone (TZ) is the area between mature squamous epithelium distally and columnar epithelium proximally, and it is the site of active squamous metaplasia. For colposcopy to be deemed adequate, the entire SCJ must be visualized during an adequate colposcopy. Areas with acetowhite, punctuation, mosaicism, or atypical blood vessels seen during colposcopy may represent dysplasia or cancer and should be biopsied. A green filter enhances visualization of blood vessels by making them appear darker in contrast to the surrounding epithelium.

An alternative to dilute acetic acid is Lugol’s solution—a concentrated solution of iodine that reacts with the glycogen in normal squamous epithelium to make it appear dark brown. High-grade CIN lesions have low amounts of glycogen because the epithelium is poorly differentiated, and hence they do not turn brown with Lugol’s solution. This is termed Lugol’s nonstaining or Lugol’s negative. Historically, this used to be referred to as the Schiller’s test. Lugol’s can be useful for determining whether a colposcopically equivocal area warrants biopsy: Lugol’s staining areas are most likely normal epithelium, whereas Lugol’s nonstaining areas may be CIN, metaplasia, or inflammation.
Endometrial Biopsy. Endometrial sampling should be performed before planned hysterectomy if there is a history of bleeding between periods, heavy and/or frequent menstrual periods, or postmenopausal bleeding. A patient with the potential for pregnancy should have a pregnancy test before the procedure. A pipelle endometrial biopsy can be performed in the office and is a cost-effective and safe procedure that is generally well tolerated by patients. The pipelle is a flexible polypropylene suction cannula with an outer diameter of 3.1 mm. The pipelle is inserted through the endocervix after cervical cleaning, and the depth of the uterine cavity is noted. If difficulty in entering the endometrium with the pipelle is encountered, a tenaculum may be used to straighten the cervix and/or an OS-finder may be useful in overcoming resistance within the endocervix. The endometrial specimen is obtained by pulling on the plunger within the pipelle, creating a small amount of suction. The pipelle is rotated and pulled back from the fundus to the lower uterine segment within the cavity to access all sides. Additional passes may be needed in order to acquire an adequate amount of tissue. If office biopsy is not possible due to patient discomfort or cervical stenosis, a dilatation and curettage in the operating room may be indicated depending on the clinical circumstances.

Evaluation for Fistula. When a patient presents with copious vaginal discharge, the provider should be concerned about a fistula with the urinary or gastrointestinal tract. A simple office procedure can be performed when there is a concern for a vesicovaginal fistula. A vaginal tampon is placed followed by instillation of sterile blue dye through a transurethral catheter into the bladder; a positive test is blue staining of the tampon. If the test is negative, one can evaluate for a ureterovaginal fistula. The patient is given phenazopyridine, which changes the color of urine to orange. If a tampon placed in the vagina stains orange, the test is positive. Alternatively, the patient can be given an intravenous injection of indigo carmine.

Rectal fistula must be considered when a patient reports stool evacuation per vagina. It can be identified in a similar fashion using a large Foley catheter placed in the distal rectum through which dye may be injected, or with the use of an oral charcoal slurry and timed examination. Common areas for fistulae are at the vaginal apex, at the site of a surgical incision, or around the site of a prior episiotomy or perineal repair after a vaginal delivery.

BENIGN GYNECOLOGIC CONDITIONS

Vulvar Lesions

Patients presenting with vulvar symptoms should be carefully interviewed and examined, and a vulvar biopsy should be obtained whenever the diagnosis is in question, the patient does not respond to treatment, or premalignant and malignant disease is suspected. Vulvar conditions such as contact dermatitis, atrophic vulvovaginitis, lichen sclerosis, lichen planus, lichen chronicus simplex, Paget’s disease, Bowen’s disease, and invasive vulvar cancer are common particularly in postmenopausal women. Systemic diseases like psoriasis, eczema, Crohn’s disease, Behçet’s disease, vitiligo, and seborrheic dermatitis may also involve the vulvar skin.

Leukoplaikias. There are three types of leukoplaikia, a flat white abnormality. Lichen sclerosis is the most common cause of leukoplaikia. There are two peaks of onset: prepubertal girls and perimenopausal or postmenopausal women. Classically, it results in a figure-of-eight pattern of white epithelium around the anus and vulva resulting in variable scarring and itching, and less commonly pain. Diagnosis is confirmed with biopsy, and treatment consists of topical steroids. An established association between lichen sclerosis and vulvar squamous cell carcinoma estimates risk of malignant transformation up to 5%. Lichen planus is a cause of leukoplakia with an onset in the fifth and sixth decade of life. Lichen planus, in contrast to lichen sclerosis which is limited to the vulva and perianal skin, can involve the vagina and oral mucosa, and erosions occur in the majority of patients leading to a variable degree of scarring. Patients usually have a history and dysuria and dyspareunia, and complain of a burning vulvar pain. Histology is not specific, and biopsy is recommended. Treatment is with topical steroids. Systemic steroids are indicated for severe and/or unresponsive cases.

Lichen simplex chronicus is the third cause of leukoplaikia, but is distinguished from the other lichen diseases by epidermal thickening, absence of scarring, and a severe intolerable itch. Intense scratching is common, and contributes to the severity of the symptoms and predisposes the cracked skin to infections. Treatment consists of cessation of the scratching which sometimes requires sedation, elimination of any allergen or irritant, suppression of inflammation with potent steroid ointments, and treatment of any coexisting infections.

Bartholin’s Cyst or Abscess. Bartholin’s glands, great vestibular glands, are located at the vaginal orifice at the four and eight o’clock positions; they are rarely palpable in normal patients. They are lined with cuboidal epithelium and secrete mucus material to keep the vulva moist. Their ducts are lined with transitional epithelium, and their obstruction secondary to inflammation may lead to the development of a Bartholin’s cyst or abscess. Bartholin’s cysts or abscesses are usually asymptomatic and are easily diagnosed on examination. Infections are usually polymicrobial. Treatment consists of incision and drainage and placement of a Word catheter, a small catheter with a balloon tip, for 2 to 3 weeks to allow for formation and epithelialization of a new duct. Recurrent cysts or abscesses may require marsupialization, but on occasion these necessitate excision of the whole gland. Marsupialization is performed by incising the cyst or abscess wall and securing its lining to the skin edges with interrupted sutures. Cysts or abscesses that fail to resolve after drainage and those occurring in patients over 40 years old should be biopsied to exclude malignancy.

Molluscum Contagiosum. Molluscum contagiosum presents with dome-shaped papules and are caused by the pox virus. The papules are usually 2 to 5 mm in diameter and classically have a central umbilication. They are spread by direct skin contact, and present on the vulva, as well as abdomen, trunk, arms, and thighs. Lesions typically clear in several months, but they can be treated with cryotherapy, curettage, or cantharidin, a topical blistering agent.

Genital Ulcers. The frequency of the infectious etiologies of genital ulcers varies by geographic location. The most common causes of sexually transmitted genital ulcers in young adults in the United States are, in descending order of prevalence, herpes simplex virus (HSV), syphilis, and chancroid. Other infectious causes of genital ulcers include lymphogranuloma venerum and granuloma inguinale. Noninfectious etiologies include Behçet’s disease, neoplasms, and trauma. Table 41-3 outlines a rational approach to their evaluation and diagnosis.
### Vulvar Condyloma

Condylomata acuminata (anogenital warts) are viral infections caused by HPV. Genital infection with HPV is the most common sexually transmitted infection in the United States today. HPV 6 and 11 are the most common low-risk types and are implicated in 90% of cases of genital warts. Women with immunosuppression due to HIV or solid organ transplant are at higher risk of vulvar condyloma than immunocompetent women. Genital warts are skin-colored or pink and range from smooth flattened papules to verrucous papilliform lesions. Lesions may be single or multiple and extensive. Diagnosis should be confirmed with biopsy as verrucaous vulvar cancers can be mistaken for condylomata. If small, self-administered topical imiquimod 5% cream or trichloroacetic acid for in-office applications may be tried. Extensive lesions may require surgical modalities that include cryotherapy, laser ablation, cauterization, and surgical excision.

### Paget’s Disease of the Vulva

Paget’s disease of the vulva is an intraepithelial disease of unknown etiology that affects

mostly postmenopausal women in their sixth decade of life. It causes chronic vulvar itching and is sometimes associated with an underlying invasive vulvar adenocarcinoma or invasive cancers of the breast, cervix, or gastrointestinal tract. Grossly, the lesion is variable but usually confluent, raised, erythematous to violet, and waxy in appearance. Biopsy is required for diagnosis; the disease is intraepithelial and characterized by Paget’s cells with large pale cytoplasm. Treatment is assessment for other potential concurrent adenocarcinomas and then surgical removal by wide local resection of the involved area with a 2-cm margin. Free margins are difficult to obtain because the disease usually extends beyond the clinically visible area. Intraoperative frozen section of the margins can be done; however, Paget’s vulvar lesions have a high likelihood of recurrence even after securing negative resection margins.

**Vulvar Intraepithelial Neoplasia.** Two pathologically distinct premalignant lesions of the vulva are currently recognized. Vulvar intraepithelial neoplasia (VIN) of usual type (uVIN) is caused by the HPV virus, tends to occur in younger women, and presents as multifocal disease. VIN of differentiated type (dVIN) develops independently of HPV and is typically unifocal and seen in postmenopausal women. VIN is similar to its cervical intraepithelial neoplasia (CIN) counterpart in the cervix. In 2012, the pathologic terminology of HPV-related disease in the anogenital region was harmonized into a two-tier system where LSIL is equivalent to uVIN 1 and HSIL encompasses uVIN 2 and uVIN 3. Additional risk factors for the development of VIN include HIV infection, immunosuppression, smoking, vulvar dermatoses such as lichen sclerosis, CIN, and a history of cervical cancer. Vulvar pruritus is the most common complaint in women with symptoms. Lesions may be vague or raised, and they may be velvety with sharply demarcated borders. Diagnosis is made with a vulvar skin biopsy and multiple biopsies are sometimes necessary. Evaluation of the perianal and anal area is important as the disease may involve these areas. Once invasive disease is ruled out, treatment usually involves wide surgical excision; however, the treatment approaches may also include 5% imiquimod cream, CO₂ laser ablation, or cavitation ultrasonic surgical aspiration (CUSA), and depends on the number of lesions and their severity. When laser ablation is used, a 1-mm depth in hair-free areas is usually sufficient, while hairy lesions require ablation to a 3-mm depth because the hair follicles’ roots can reach a depth of 2.5 mm. Unfortunately, VIN tends to recur in up to 30% of cases, and high-grade lesions will progress to invasive disease in approximately 10% of patients if left untreated.

**Vaginal Lesions**

**Vaginitis (see Table 41-2).** Vaginal symptoms are extremely common, accounting for over 10 million office visits per year in the United States. The causes of vaginal complaints are commonly infectious in origin, but they include a number of noninfectious causes, such as chemicals or irritants, hormone deficiency, foreign bodies, systemic diseases, and malignancy. Symptoms include abnormal vaginal discharge, pruritus, irritation, burning, odor, dyspareunia, bleeding, and ulcers. A purulent discharge from the cervix should always raise suspicion of upper genital tract infection even in the absence of pelvic pain or other signs.

Normal vaginal discharge is white or transparent, thick, and mostly odorless. It increases during pregnancy, with use of estrogen-progesterin contraceptives, or at mid-cycle around the time of ovulation. Complaints of foul odor and abnormal vaginal discharge should be investigated. Candidiasis, bacterial vaginosis, and trichomoniasis account for 90% of vaginitis cases. The initial workup includes pelvic examination, vaginal pH testing, microscopy, vaginal cultures if microscopy is normal, and gonorrhea/Chlamydia NAAT (see earlier section, “Common Screening and Testing”). The pH of normal vaginal secretions is 3.8 to 4.4, which is hostile to growth of pathogens, and pH greater than or equal to 4.9 is indicative of a bacterial or protozoal infection. Treatment of vaginal infection before anticipated surgery is appropriate, particularly for BV, which may be associated with a higher risk for vaginal cuff infections (Fig. 41-8).

**Bacterial Vaginosis** Bacterial vaginosis (BV) accounts for 50% of vaginal infections. It results from reduction in concentration of the normally dominant lactobacilli and increase in concentration of anaerobic organisms like *Gardnerella vaginalis, M hominis, Bacteroides* species, and others. Diagnosis is made by microscopic demonstration of clue cells. The discharge typically produces a fishy odor upon addition of KOH (amine or Whiff test). Initial treatment is usually a 7-day course of metronidazole.

**Vulvovaginal Candidiasis** Vulvovaginal candidiasis (VVC) is the most common cause of vulvar pruritus. It is generally caused by *C albicans* and occasionally by other *Candida* species. It is common in pregnancy, diabetics, patients taking antibiotics, and in immunocompromised hosts. Initial treatment is usually with topical antifungals, although one dose oral antifungal treatments is also effective.

**Trichomonas Vaginalis** Trichomoniasis is a sexually transmitted infection of a flagellated protozoan and can present with malodorous, purulent discharge. It is typically diagnosed with visualization of the trichomonads during saline wet mount microscopy. Initial treatment is usually a 7-day course of metronidazole.

**Gartner’s Duct Cyst.** A Gartner’s duct cyst is a remnant of the Wolffian tract; it is typically found on the lateral vaginal walls. Patients can be asymptomatic or present with complaints of dyspareunia or difficulty inserting a tampon. If symptomatic, these cysts may be surgically excised or marsupialized. If surgery is planned, preoperative magnetic resonance imaging (MRI) should be obtained to determine the extent of the cyst and verify the diagnosis.

**Vaginal Condyloma.** The etiology and treatment of vaginal condyloma is similar to vulvar condyoma (see earlier section, “Vulvar Condyloma”).

**Vaginal Intraepithelial Neoplasia.** Vaginal intraepithelial neoplasia, or VIN, is similar to VIN and is classified based on the degree of epithelial involvement as mild (I), moderate (II), severe (III), or carcinoma in situ. Upwards of 65% to 80% of VaIN or vaginal cancers are associated with HPV infection. Typically, a patient will have a history of cervical dysplasia and a prior hysterectomy. The majority of lesions are located in the upper one-third of the vagina. Lesions are usually asymptomatic and found incidentally on cytological screening. Biopsy at the time of colposcopy is diagnostic and rules out invasive disease. VaIN is treated with laser ablation, surgical excision, or topical 5-FU therapy.
Cervical Lesions

Benign Cervical Lesions. Benign lesions of the cervix include endocervical polyps, nabothian cysts (clear, fluid filled cysts with smooth surfaces), trauma (such as delivery-related cervical tear or prior cervical surgery), malformation of the cervix, and cervical condyloma. For endocervical polyps, exploration of the base of the polyp with a cotton swab tip to identify that it is cervical and not uterine and to identify the stalk characteristics can help identify the appropriate surgical approach. Small polyps with identifiable base can be removed by grasping the polyp with ring forceps and slowly rotating it until separated from its base. Use of loop electroexcisional procedure (LEEP) is appropriate for larger lesions. Laser or other ablative procedures are appropriate for condyloma proven by biopsy.

Cervical Intraepithelial Neoplasia. Following HPV exposure, dysplastic changes are common. Low grade dysplasia (cervical intraepithelial neoplasia [CIN] I) can be observed and will most often regress to normal within 2 years. However, for girls or women in whom HPV infection is persistent, progression to high-grade cervical dysplasia (CIN II or III) usually require additional treatment due to the high risk of transformation to malignancy. Excisional procedures serve the therapeutic purpose of removal of dysplastic cells, and a diagnostic purpose as histologic review to rule out concomitant early stage cervical cancer can be performed. Either a LEEP or cold knife conization (CKC) may be used for surgical excision of the squamocolumnar junction (SCI) and outer endocervical canal. Risks of both procedures include bleeding, postprocedure infection, cervical stenosis, and risk of preterm delivery with subsequent pregnancies. The benefit of a LEEP is that it can be performed in the office under local anesthesia. A looped wire attachment for a standard monopolar electrosurgical unit is used to perform a LEEP excision. Loops range in a variety of shapes and sizes to accommodate different sizes of cervix. Optimally, one pass of the loop should excise the entire SCI. Hemostasis of the remaining cervix is achieved with the ball electrode and ferrous sulfate paste (Monsel’s solution).

A cervical cold knife conization allows for an excision where the margin status is not obscured by cauterized artifact. This may be particularly useful when the endocervical margin is of interest, or in cases of adenocarcinoma in situ and microinvasive squamous cell carcinoma, where margin status dictates the type and need for future therapy. After injection with dilute vasopressin and the placement of stay sutures at three and nine o’clock on the cervix, a #11 blade is used to circumferentially excise the conical biopsy. Hemostasis is achieved with the cautery or Monsel’s solution.

Uterine Corpus

The average age of menarche, or first menstrual period, in the United States is 12 years and 5 months. Duration of normal menstruation is between 2 to 7 days, with a flow of less than 80 mL, cycling every 21 to 35 days.27 Nonpregnant patients, who present with heavy bleeding and are 35 years of age and older or have risk factors for endometrial cancer, must be ruled out for malignancy as the first step in their management (see earlier section, “Endometrial Biopsy”).

Abnormal Uterine Bleeding. The classification of abnormal uterine bleeding (ABU) has been recently updated.28 Abnormal uterine bleeding may be heavy (AUB/HMB) or intermenstrual (AUB/IMB) and is further divided into acute and chronic categories. Acute AUB is an episode of heavy bleeding that is of sufficient quantity to require immediate intervention to prevent further blood loss. Acute AUB may occur in the setting of chronic AUB. Women with acute AUB should be assessed
rapidly to determine acuity, determine most likely etiology of bleeding, and choose appropriate treatment. Chronic AUB is abnormal uterine bleeding present for most of previous 6 months.

The many causes of AUB are further divided into two categories: structural causes and nonstructural causes. Structural causes include polyps, adenomyosis, leiomyomata, and malignancy. Nonstructural causes can include coagulopathy, ovulatory dysfunction, endometrial effects, and iatrogenic causes. Clinical screening for underlying disorders of hemostasis is recommended in women with heavy menses since menarche, and other risk factors such as bleeding with dental work, epistaxis one or more times per month, or a family history of bleeding symptoms. Poly-, oligo-, and amenorrhea are menstrual cycles of less than 21 days, longer than 35 days, or the absence of uterine bleeding for 6 months or a period equivalent to three missed cycles.

**Endometrial Polyps.** Endometrial polyps are localized hyperplastic growth of endometrial glands and stroma around a vascular core forming sessile or pedunculated projections from the surface of the endometrium. Endometrial polyps are rarely neoplastic (<1%) and may be single or multiple. Many are asymptomatic; however, they are responsible for about 25% of cases of abnormal uterine bleeding, usually metrorrhagia. Polyps are common in patients on tamoxifen therapy and in peri- and postmenopausal women. Up to 2.5% of patients with a polyp may harbor foci of endometrial carcinoma. Diagnosis can be made with saline-infused hysterosonography, hysterosalpingogram, or by direct visualization at the time of hysteroscopy. Definitive treatment, in the absence of malignancy, involves resection with operative hysteroscopy or by sharp curettage.

**Adenomyosis.** Adenomyosis refers to ectopic endometrial glands and stroma situated within the myometrium. When diffuse, it results in globular uterine enlargement secondary to hyperplasia and hypertrophy of the surrounding myometrium. Adenomyosis is very common, tends to occur in parous women, and is frequently an incidental finding at the time of surgery. Symptoms include menorrhagia, dysmenorrhea, and diffuse globular uterine enlargement. MRI typically reveals islands within the myometrium with increased signal intensity. Definitive diagnosis is obtained via hysterectomy and pathologic examination.

**Uterine Leiomyomas.** Leiomyomas, also known colloquially as fibroids, are the most common female pelvic tumor and occurs in response to growth of the uterine smooth muscle cells (myometrium). They are common in the reproductive years, and by age 50. Leiomyomas are described according to their anatomic location (Fig. 41-9) as intramural, subserosal, submucosal, pedunculated, and cervical. Rarely, they can be ectopic. Most are asymptomatic; however, abnormal uterine bleeding caused by leiomyomas is the most common indication for hysterectomy in the United States. Other manifestations include pain, pregnancy complications, and infertility. Pain may result from degenerating myomas that outgrow their blood supply or from compression of other pelvic organs such as the bowel, bladder, and ureters. Hormonal changes during pregnancy can cause significant enlargement of preexisting myomas, which may lead to significant distention of the uterine cavity resulting in recurrent miscarriages, fetal malpresentations, intrauterine growth restriction, obstruction of labor or abnormal placenta- tion, and the subsequent need for cesarean delivery, abortion, preterm labor, and pain from degeneration.

Menorrhagia resulting from leiomyomas can be severe at times, requiring hospitalization or transfusion. Examination typically reveals an enlarged and irregular uterus. Diagnosis is usually made by transvaginal ultrasonography. Other diagnostic modalities, including MRI, computed tomography (CT), and hysterosalpingogram or saline-infused hysterosalpingography, are especially useful in the cases of submucosal and intracervical myomas. Management options of leiomyomas are tailored to the individual patient depending on her age and desire for fertility and the size, location, and symptoms of the myomas. Conservative management options include oral contraceptive pills (OCPs), medroxyprogesterone acetate, GnRH agonists, uterine artery embolization, myomectomy, and hysterectomy. Uterine artery embolization is contraindicated in patients planning future pregnancy and may result in acute degeneration of myomas requiring hospitalization for pain control. Myomectomy is indicated in patients with infertility thought secondary to fibroids and for those with symptomatic fibroids who wish to preserve their reproductive capacity. Hysterectomy is the only definitive therapy. Treatment with GnRH agonists for 3 months prior to surgery may be administered in anemic patients, and it may allow them time to normalize their hematocrit, avoiding transfusions; GnRH also decreases blood loss at hysterectomy and shrinks the myomas by an average of 30%. The latter may make the preferred vaginal surgical approach more feasible.

**Endometrial Hyperplasia.** Endometrial hyperplasia is caused by chronic unopposed hyperestrogenic state (relative absence of progesterone) and is characterized by proliferation of endometrial glands resulting in increased gland-to-stroma ratio. It can be asymptomatic or, more commonly, result in abnormal vaginal bleeding. Hyperplasia can be either simple or complex, based on the architecture of the glands. Of greater importance is the presence or absence of nuclear atypia, described by the WHO classification. A classic retrospective review suggested that untreated endometrial hyperplasia progresses to malignancy in 1%, 3%, 8%, and 29% of cases of simple, complex, simple with atypia, and complex hyperplasia with atypia, respectively. A more modern prospective study noted that of patients who had complex atypical hyperplasia on endometrial biopsy performed prior to hysterectomy, 42.5% had cancer at the time of hysterectomy. Simple and complex hyperplasias can be treated with progesterins, and women should have repeat
endometrial sampling in 3 to 6 months. Atypical hyperplasia is considered a premalignant condition and is treated ideally with simple hysterectomy. If preservation of fertility is desired or surgery is contraindicated, treatment with high-dose progestins such as megestrol acetate 40 to 160 mg per day or with a progestosterone IUD usually reverses these lesions. Close follow-up and repeated sampling are necessary.

The reliability of the pathologic diagnosis of complex atypical hyperplasia is poor, and better and more objective classifications predictive of malignant endometrial behavior are needed. These observations led to the new classification of endometrial intraepithelial neoplasia (EIN). In 2014, the WHO Classification system introduced the diagnosis of EIN into a binary system that aligns with clinical options: hyperplasias are divided into hyperplasia without atypia, and EIN. The new classification is intended to have clinical implications: hyperplasia without atypia may be managed with hormonal therapy, while EIN should be considered a premalignant lesion.

The new classification moves the focus away from cytologic atypia and puts more emphasis on glandular crowding and complexity. While atypia is still important, proliferations can get to EIN without it. For example, the diagnosis of EIN includes cases that lack overt cytologic atypia but show a distinct population from the background epithelium. Morphometric data is utilized to calculate the so-called D-score, which takes into account percentage of stroma, glandular complexity, and gland pleomorphism in an objective manner. A D-score of less than 1 connotes a high rate of progression to endometrial cancer and therefore a diagnosis of EIN. EIN is more predictive than CAH of underlying endometrial malignancy. Most pathology reports are provided with both diagnoses as the transition is made.

Clinicians should be careful to not confuse EIN with endometrial intraepithelial carcinoma (EIC). EIC is a precursor lesion for serous endometrial cancer, and women with a preoperative diagnosis of EIC should always have hysterectomy and appropriate surgical staging performed.

Procedures Performed for Structural Causes of Abnormal Uterine Bleeding

Dilation and Curettage. The patient is placed on the operating table in a lithotomy position, and the vagina and cervix are prepared as for any vaginal operation. The cervix is grasped on the anterior lip with a tenaculum. Some traction on the cervix is necessary to straighten the cervical canal and the uterine cavity. A uterine sound is inserted into the uterine cavity, and the depth of the uterus is noted. The cervical canal is then systematically dilated beginning with a small cervical dilator. Most operations can be performed after the cervix is dilated to accommodate a number 8 or 9 Hegar dilator or its equivalent. Dilatation is accomplished by firm, constant pressure with a dilator directed in the axis of the uterus (Fig. 41-10). The endometrial cavity is then systematically scraped with a uterine curette. Using the largest curette available or suction curettage is a safer choice than a small curette, which tends to cause perforation with less pressure. Uterine perforation is the major complication of dilatation and curettage, diagnosed when the operator finds no resistance to a dilator or curette. Laparoscopy can identify any damage to vessels or bowel if clinically indicated. A uterine perforation through the fundus of the uterus with a dilator or uterine sound is low risk for injury and may be observed without laparoscopy if there is no significant vaginal bleeding noted.
Hysteroscopy. Hysteroscopy, like laparoscopy, has gained widespread support for use both for diagnosis and treatment of intrauterine pathology and for ablation of the endometrium as an alternative to hysterectomy for the treatment of abnormal uterine bleeding. Hysteroscopes can have an objective lens that is offset from the long axis from 0° to 30°.

Diagnostic Hysteroscopy The diagnostic hysteroscope usually has an external diameter of 5 mm. Some diagnostic sheaths allow passage of flexible instruments for biopsy and cutting. Following dilation of the cervix, a diagnostic hysteroscope is placed, and the uterine cavity is distended with the media of choice. Inspection of the cavity includes identifying the uterine fundus, cornua, and any other anomalies to include polyps, leiomyomas, or uterine septum. A dilation and curettage or directed polypectomy with forceps can be performed following identification.

Newer office hysteroscopes can be used to perform hysteroscopy in the office. A paracervical block is placed, and a flexible 3-mm hysteroscope is used. Generally, office hysteroscopy is performed only for diagnostic purposes.

Operative Hysteroscopy An operative hysteroscope is wider than a diagnostic hysteroscope and usually has an integral unipolar or bipolar resecting loop identical to a urologic resectoscope. Electrolyte contacting media are incompatible with conventional monopolar resectoscopic instruments, but electrolyte-free isotonic solutions such as 5% mannitol, 1.5% glycine and 3% sorbitol are acceptable. Large volume deficits have been associated with secondary hyponatremia and hypervolemia due to their metabolism to free water after intravasation. Fluid-management systems are available to monitor the amount of distension media lost during hysteroscopy in order to prevent fluid overload. When fluid deficits reach 1000 to 1500 mL, the procedure should be terminated, and the patient’s serum electrolytes should be assessed. If bipolar instruments are used, resectoscopic instruments can be used without the unique issues related to electrolyte-free hypotonic solutions.

Hysteroscopic Polypectomy Removal of an intrauterine polyp can be performed following diagnostic hysteroscopy through grasping with a polyp forceps. Alternatively, using operative hysteroscopy, the base of the polyp is incised with hysteroscopic scissors. The hysteroscope, sleeve, and polyp are removed simultaneously because most polyps will not fit through the operating channel. Extremely large polyps may have to be removed piecemeal. Any residual base of the polyp may be removed with biopsy forceps.

Endometrial Ablation A common treatment for abnormal uterine bleeding in the absence of endometrial hyperplasia is ablation of the endometrium. Historically, this was performed with an operative hysteroscope using an electrosurgical “roller ball,” where the endometrium was destroyed down to the myometrium in a systematic fashion. Currently, hysteroscopic endometrial ablation has been widely supplanted by various devices, including heated free fluid, cryotherapy, thermal balloon, microwave, and radiofrequency electricity. Most ablation techniques result in amenorrhea in approximately half the patients and decreased menstruation in another third of the patients over the first year of therapy. Subsequent hysterectomy following endometrial ablation is common with rates as high as 40%. Ablation is not recommended in postmenopausal women.

Myomectomy Myomectomy (Fig. 41-11) is the removal of fibroids, and it can be treatment for abnormal uterine bleeding, bulk symptoms, or infertility. Hemostasis during myomectomy can be aided medically by direct injection of dilute vasopressin. Submucosal leiomyoma can be removed safely hysteroscopically. Because myoma tissue is relatively dense, a power cutting instrument is required. The most common method is use of electrosurgery. Both pedunculated and submucosal fibroids are shaven into small pieces with the hysteroscopescope. Stalk resection should only be done to release a pedunculated fibroid if it is 10 mm or less in size; larger fibroids are difficult to remove in one piece without excessive cervical dilatation.

Subserosal, or pedunculated fibroids may require an open or laparoscopic approach depending on the size and location or the leiomyoma. In addition to vasopressin, hemostasis can be further managed through the placement of a Penrose drain around the base of the uterus, pulled through small perforations in the broad ligament lateral to the uterine blood supply on either side and clamped to form a tourniquet for uterine blood flow. An incision is then made through the uterine serosa into the myoma. The pseudocapsule surrounding the tumor is identified, and the tumor is bluntly dissected out with scissors, or bluntly if open. Vessels to the myoma are dissected with the electrosurgical unit. Several myomas may be removed through a single incision, depending upon size. The uterine incisions are then closed with absorbable sutures to obliterate the dead space and provide hemostasis. The uterine serosa is closed with a 3-0 absorbable suture, placed subserosally if possible. Because myomectomies are associated with considerable postoperative adhesion formation, barrier techniques are used to decrease adhesion formation.

During a laparoscopic myomectomy, hemostasis is assisted by intrauterine injection of dilute vasopressin (10 U in 50 mL) at the site of incision, similar to an open procedure. This is usually performed percutaneously with a spinal needle. Pedunculated leiomyomas can be excised at the base using scissors or a power instrument. Intramural leiomyomas require deep dissection into the uterine tissue, which must be closed subsequently with laparoscopic suturing techniques. Removing the specimen may require morcellation; this should be performed after placement of the specimen in a bag. Although power morcellators were previously used for this purpose, an FDA warning in 2014 has virtually eliminated their use. Severe complications including damage to surrounding bowels and vascular structures caused by the spinning blade of the morcellator were reported. Multiple reports of benign tissues such as leiomyoma and endometriosis scattering and dispersing onto abdominal organ surfaces leading to inflammation, infection, and intestinal obstruction often requiring additional surgical interventions and treatments were made. The unintentional dissemination of malignant cells worsens prognosis if an undiagnosed malignancy (most frequently leiomyosarcoma) was morcellated. Although contained morcellation (in a bag) may reduce these risks, informed consent to the patient is prudent.

Total Abdominal Hysterectomy (Fig. 41-12) After the abdomen is entered, the upper abdomen is examined for evidence of extrapelvic disease, and a suitable retractor is placed in the abdominal incision. The uterus is grasped at either cornu with clamps and pulled up into the incision. The round ligament is identified and divided. The peritoneal incision is extended from the round ligament to just past the ovarian hilum, lateral the infundibulopelvic ligament, if the ovaries are to be removed. The retroperitoneal space is bluntly opened, the ureter identified on the medial leaf of the broad ligament, and the
infundibulopelvic ligament isolated, clamped, cut, and suture-ligated; a similar procedure is carried out on the opposite side. If the ovaries are to be left in situ, the ureter is identified and an opening below the utero-ovarian ligament and fallopian tube created. The fallopian tube and utero-ovarian ligament are clamped, cut, and ligated. The bladder is mobilized by sharply dissecting it free of the anterior surface of the uterus and cervix. Clamps are placed on the uterine vessels at the cervicouterine junction, and the vessels are cut and suture-ligated. The cardinal ligaments are then serially clamped, cut, and ligated. Following division of the remaining cardinal ligaments, the uterus is elevated and the vagina clamped. The cervix is amputated from the vagina with scissors or a knife. Sutures are placed at each lateral angle of the vagina, and the remainder of the vagina is closed with a running or interrupted absorbable suture. Pelvic reperitonealization is not necessary.

**Transvaginal Hysterectomy** (Fig. 41-13) Vaginal hysterectomy is the preferred approach in patients in whom the uterus descends and the pubic arch allows enough space for a vaginal operation. A bladder catheter may be placed before the procedure and the patient is placed in a lithotomy position. A weighted vaginal speculum is placed in the vagina, and the cervix is grasped with a tenaculum and pulled in the axis of the vagina. Injection of the cervix and paracervical tissue with analgesic with epinephrine may be helpful in defining planes and decreasing obscuring bleeding. A circumferential incision may be made with a scalpel or scissors. The posterior cul-de-sac is identified and entered with scissors. A long, weighted speculum is then placed through this opening into the peritoneal cavity. Metzenbaum scissors are used to dissect anteriorly on the cervix down to the pubocervical-vesical fascia, reflecting the bladder off the lower uterine segment. When the peritoneum of the anterior cul-de-sac is identified, it is entered with the scissors, and a retractor is placed in the defect. The uterosacral ligaments are identified, doubly clamped, cut, and ligated. Serial clamps are placed on the parametrial structures above the uterosacral ligament; these pedicles are cut and ligated. At the cornu of the uterus, the tube, round ligament, and utero-ovarian ligament of the ovary are doubly clamped and cut. The procedure is carried out usually concurrently on the opposite side, and the uterus is removed. The pelvis is inspected for hemostasis; all bleeding must be meticulously controlled at this point.

The pelvic peritoneum is closed with a running purse-string suture incorporating the uterosacral and ovarian pedicles, those that were held. This exteriorizes those areas that might tend to bleed. The sutures attached to the ovarian pedicles are cut. The vagina may be closed with interrupted mattress stitches,
Figure 41-12. Hysterectomy.
incorporating the uterosacral ligaments into the corner of the vagina with each lateral stitch. On occasion, the uterus, which is initially too large to remove vaginally, may be reduced in size by morcellation (Fig. 41-14). After the uterine vessels have been clamped and ligated, serial wedges are taken from the central portion of the uterus in order to reduce the uterine mass. This procedure will allow the vaginal delivery of even very large uterine leiomyomas.

**Laparoscopic Hysterectomy**

The advantages of laparoscopy over laparotomy include decreased postoperative pain, shorter hospital stays, and reduced blood loss. Laparoscopy has been used to augment vaginal hysterectomy to avoid laparotomy in patients with known pelvic adhesions, endometriosis, or to ensure removal of the entire ovary if oophorectomy is planned or an adnexal mass is present. Over 20% of benign hysterectomies performed in the United States are estimated to be performed laparoscopically.46

Although multiple variations in technique exist, there are three basic laparoscopic approaches for hysterectomy: laparoscopic-assisted vaginal hysterectomy (LAVH), total laparoscopic hysterectomy (TLH), and laparoscopic supracervical hysterectomy (LSH). The technically simplest is the LAVH. A multiple-port approach is used to survey the peritoneal cavity, and any pelvic adhesions are lysed. The round ligaments are then occluded and divided, and the utero-ovarian ligament is divided. The course of the ureter and any adhesions or implants, such as endometriosis that might place the ureter in the way of the surgical dissection, are carefully dissected. Next, the proximal uterine blood supply is dissected for identification and then occluded with a laparoscopic energy device. When the ovaries are removed, the infundibulopelvic ligaments containing the ovarian vessels are divided. If the ovaries are conserved, the utero-ovarian ligament and blood vessels are divided and occluded. In many cases, the posterior cul-de-sac is also incised laparoscopically and the uterosacral ligaments separated with an energy device. The amount of dissection that is done prior to the vaginal portion depends on individual patient characteristics and operator comfort with the vaginal approach, and it may include as little as ovarian and adhesion management to full dissection, including bladder dissection, with only the last vaginal incision done by the vaginal approach. During a TLH, the vaginal incision is performed laparoscopically, and the vaginal incision may be closed with laparoscopic suturing. This procedure is used for the indications listed earlier and also when lack of uterine descent makes the vaginal approach impossible.

**Figure 41-12. (Continued)**
During an LSH, the uterine vessels are divided after the bladder is dissected from the anterior uterus. The ascending branches of the uterine arteries are occluded, and the entire uterine fundus is amputated from the cervix. The endocervix is either cauterized or cored out. The fundus is then morcellated and removed an abdominal port. The end result is an intact cervix, with no surgical dissection performed below the uterine artery. This approach avoids both a large abdominal incision and a vaginal incision. The risks of LSH including subsequent bothersome bleeding from the remaining endometrium or endocervix and cancer risk from the residual cervical stump combining with concerns about power morcellation (see earlier section, “Myomectomy”) have made this procedure less attractive.

Benign Ovarian and Fallopian Tube Lesions
The most common ovarian benign findings include functional follicular cysts, endometriomas (due to ovarian endometriosis), and serous cystadenomas or cystadenofibromas. These can present with varying degrees of pelvic pain, or sometimes be completely asymptomatic. Ultrasound is the best initial imaging modality for evaluating ovarian abnormalities.

Ovarian Cystectomy. When a cystic lesion persists or causes pelvic pain, surgical intervention is usually justified. Performing a cystectomy with ovarian preservation is recommended in women who desire future fertility. Whether the cystectomy is performed laparoscopically or by laparotomy, the procedure is
initiated with inspection of the peritoneal cavity, peritoneum, diaphragm, liver, and pelvis. In the absence of signs of malignancy, pelvic washings are obtained, and the ovarian capsule is incised superficially sharply or with the electrosurgical unit. The cyst is shelled out carefully through the incision. During laparoscopy, it is placed in a bag, intact if possible, and the bag opening is brought through a 10-mm port. If a cyst should rupture before removal, contents are aspirated thoroughly, and the cyst wall is removed and sent for pathologic evaluation. The peritoneal cavity is copiously rinsed with Ringer’s lactate solution. This is especially important when a dermoid cyst is ruptured because the sebaceous material can cause a chemical peritonitis unless all the visible oily substance is carefully removed. A cyst may need to be drained to facilitate removal, but only after bag edges are completely out of the abdomen assuring no leakage within the abdomen. Hemostasis of the ovary is achieved with bipolar electrocoagulation, but the ovary is usually not closed. If there are solid growths within the cyst, it should be sent for frozen section to verify the absence of the malignancy. If malignancy is detected, immediate definitive surgery is recommended.

**Removal of Adnexa.** Indications for removal of adnexae include persistent ovarian cyst, pelvic pain, concern for malignancy, and risk reduction surgery in women with genetic predisposition for ovarian or endometrial cancers (BRCA1/2 mutation carrier, Lynch syndrome). In general, the peritoneum lateral to the infundibulopelvic (IP) ligament is incised in a parallel fashion to allow retroperitoneal dissection and identification of the ureter. Once this has been accomplished, the IP ligament is ligated with suture or an energy source (ultrasonic or bipolar). The remaining posterior leaf of the broad ligament is incised toward the uterus in a direction parallel to the utero-ovarian ligament to avoid ureteral injury. The fallopian tube and utero-ovarian ligaments are then ligated with either suture or an energy source. If performed laparoscopically, the specimen(s) is/are removed in a bag as described earlier.

**Tubal Sterilization.** As in diagnostic laparoscopy, a one- or two-port technique can be used. Fallopian tubes are occluded in the mid-isthmic section, approximately 3 cm from the cornua, using clips, elastic bands, or bipolar electrosurgery. With electrosurgery, approximately 2 cm of tube should be desiccated. Pregnancy rates after any of these techniques have been reported in the range of 3 per 1000 women. Complete removal of the fallopian tube (salpingectomy) at the time of tubal sterilization for the purposes of ovarian cancer prevention has recently become more common.27

A transvaginal tubal occlusion technique may also be used for tubal sterilization. A routine hysteroscopy is first performed to inspect the cavity and identify the tubal ostia. The tubal insert introducer sheath is then placed into the working channel of the hysteroscope. The insert is then threaded into the fallopian tube. Following this procedure, the patient must undergo a hysterosalpingogram to confirm tubal occlusion at 3 months post procedure. Prior to the hysterosalpingogram, the patient is counseled to use a reliable birth control method. Transvaginal tubal sterilization has been associated with perforation of the uterus and/or fallopian tubes, identification of inserts in the abdominal or pelvic cavity, persistent pain, and suspected allergic or hypersensitivity reactions.

**Other Benign Pelvic Pathology**

**Chronic Pelvic Pain.** Chronic pelvic pain is defined as pain below the umbilicus that has lasted at least 6 months or causes functional disability, requiring treatment. While there can be gastrointestinal and urologic causes of chronic pelvic pain, gynecologic causes are frequently identified. Odentimes, a surgical evaluation is needed for diagnosis and/or intervention. The most common gynecologic causes of chronic pelvic pain include endometriosis, adenomyosis, uterine leiomyomas, and adhesive disease.

**Endometriosis** Endometriosis is the finding of ectopic endometrial glands and stroma outside the uterus. It affects 10% of the general population, and it is an incidental finding at the time of laparoscopy in more than 20% of asymptomatic women. Chronic pelvic pain (80%) and infertility (20–50%) are the two most common symptoms.27 The pathophysiology of endometriosis is poorly understood; etiologic theories explaining dissemination of endometrial glands include retrograde menstruation, lymphatic and vascular spread of endometrial glands, and coelomic metaplasia. Endometriosis commonly involves the ovaries, pelvic peritoneal surfaces, and uterosacral ligaments. Other possible sites include the rectovaginal septum, sigmoid colon, intraperitoneal organs, retroperitoneal space, ureters, incisonal scars, umbilicus, and even the thoracic cavity. Involvement of the fallopian tubes may lead to scarring, blockage, and subsequent infertility. Ovarian involvement varies from superficial implants to large complex ovarian masses called endometriomas or “chocolate cysts.” Endometriomas are found in approximately one-third of women with endometriosis and are often bilateral.

While endometriosis can be totally asymptomatic, complaints vary from mild dyspareunia and cyclic dysmenorrhea, to debilitating chronic pelvic pain with dysmenorrhea. Less common manifestations include painful defecation, hematochezia, and hematuria if there is bowel and/or bladder involvement. Catamarnial pneumothorax has been reported from endometriosis implanted in the pleura. Pelvic examination in symptomatic patients typically demonstrates generalized pelvic tenderness, nodularity of the uterosacral ligaments, and at times a pelvic mass may be appreciated if an endometrioma is present. The severity of symptoms does not correlate with the degree of clinical disease present. Endometriosis commonly causes of elevations in serum CA-125. Definitive diagnosis usually requires laparoscopy and visualization of the pathognomonic endometriotic implants. These appear as blue, brown, black, white, or yellow lesions that can be raised and at times puckered giving...

Data from Centers for Disease Control and Prevention. 2015 Sexually Transmitted Diseases Treatment Guidelines: Pelvic Inflammatory Disease.

Surgical management for endometriosis varies depending on the age and fertility desires of the patient. A diagnostic laparoscopy with biopsies may be indicated to confirm the diagnosis of endometriosis. If endometriosis is suspected, an operative laparoscopy with ablation of endometriotic implants usually decreases the severity of pelvic pain. Ablation of endometriotic implants can be performed with CO₂ laser or electrosurgery, and/or resection of deep endometriotic implants. Endometriomas can cause pain and if found should be treated by ovarian cystectomy. Complete resection of the cyst wall is required as recurrence of the endometrioma is common after partial removal. Unfortunately, endometriosis is a chronic disease, and conservative therapy, medical or surgical, provides only temporary relief, with the majority of patients relapsing with 1 to 2 years. For patients with severe debilitating symptoms who do not desire future fertility and have not responded to conservative management extirpative surgery to remove the uterus, ovaries, and fallopian tubes; this intervention is curative and should be considered.

Although endometriosis is not generally thought to be a premalignant lesion, there is an increased risk of type I ovarian cancer in women with a history of endometriosis. Molecular evidence that endometriosis is likely a precursor lesion to clear cell carcinoma and endometrioid carcinomas includes the presence of mutations in both PIK3CA and ARID1A in benign endometriotic lesions in close proximity, suggesting that loss of expression of these genes likely occurs early in the development of endometrioid carcinomas.

Pelvic Adhesive Disease
Pelvic adhesions usually are related to previous surgery, endometriosis, or infection, the latter of which can be either genital (i.e., pelvic inflammatory disease) or extragenital (e.g., ruptured appendix) in origin. Adhesions can be lysed mechanically and preferably with minimal cautery.

Pelvic Inflammatory Disease. Pelvic inflammatory disease (PID) is an inflammatory disorder of the upper female genital tract, including any combination of endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis. Sexually transmitted organisms, especially N gonorrhoeae and C trachomatis, are implicated in many cases although microorganisms that comprise the vaginal flora (e.g., anaerobes, G vaginalis, Haemophilus influenzae, enteric Gram-negative rods, and Streptococcus agalactiae) have been implicated as well. PID can additionally result from extension of other pelvic and abdominal infections, such as appendicitis and diverticulitis, or may be precipitated by medical procedure, such as hysterosalpingography, endometrial biopsy, or dilation and curettage.

The presentation of PID can be subtle. Differential diagnosis includes appendicitis, cholecystitis, inflammatory bowel disease, pyelonephritis, nephrolithiasis, ectopic pregnancy, and ovarian torsion. Long-term sequelae can include infertility, chronic pelvic pain, and increased risk of ectopic pregnancy. Because of the severity of these sequelae, presumptive treatment is recommended in young, sexually active women experiencing pelvic or lower abdominal pain, when no cause for the illness other than PID can be identified and if cervical motion tenderness, uterine tenderness, or adnexal tenderness is present on examination. Because of the psychosocial complexity associated with a diagnosis of PID, additional criteria should be used to enhance the specificity of the minimum clinical criteria when possible. These include the following: oral temperature >101°F (>38.3°C); abnormal cervical mucopurulent discharge or cervical friability; presence

them a “gunpowder” appearance. Biopsy is not routinely done but should be obtained if the diagnosis is in doubt.

Treatment is guided by severity of the symptoms and whether preservation of fertility is desired and varies from expectant, to medical, to surgical. Expectant management is appropriate in asymptomatic patients. Those with mild symptoms can be managed with oral contraceptive pills and/or non-steroidal anti-inflammatory analgesia; moderate symptoms are treated with medroxyprogesterone acetate. Severe symptoms are treated with gonadotropin releasing hormone (GnRH) agonists to induce medical pseudomenopause.
of abundant numbers of white blood cells on saline microscopy of vaginal fluid; elevated erythrocyte sedimentation rate; elevated C-reactive protein; and laboratory documentation of cervical infection with *N gonorrhoeae* or *C trachomatis*. Laparoscopy can be used to obtain a more accurate diagnosis of salpingitis and a more complete bacteriologic diagnosis and is often useful in ruling out other causes of peritonitis. Laparoscopic findings may include swollen erythematous tubes with purulent exudates.55

Several outpatient parenteral and oral antimicrobial regimens have been effective in achieving clinical and microbiologic cure. Hospitalization for intravenous antibiotics may be necessitated in cases of where surgical emergencies cannot be ruled out, tubo-ovarian abscess is identified, pregnancy, severe illness (nausea and vomiting, or high fever), inability to follow or tolerate an outpatient oral regimen; or failure of outpatient oral antimicrobial therapy. Treatment of a tubo-ovarian abscess may include placement of a percutaneous drain in addition to intravenous antibiotics.55

Surgical intervention becomes necessary if medical therapy fails or if the patient becomes unstable. Hysterectomy and bilateral salpingo-oophorectomy is the procedure of choice; however, conservative surgery must be considered in young patients desiring future fertility. The abdomen should be explored for metastatic abscesses, and special attention must be paid to bowel, bladder, and ureteral safety due to the friability of the infected tissue and the adhesions commonly encountered at the time of surgery. Placement of an intraperitoneal drain and mass closure of the peritoneum, muscle, and fascia with delayed-absorbable sutures is advised. Conservative surgery, when feasible, may be attempted by laparoscopy and may involve unilateral salpingo-oophorectomy or drainage of the abscess and liberal irrigation of the abdomen and pelvis.53

### PREGNANCY-RELATED SURGICAL CONDITIONS

Many pregnant women will undergo invasive diagnostic procedures for prenatal diagnosis, and in the United States, nearly one-third of all births are cesarean deliveries.56 About 1 in 500 pregnant women will require surgery for nonobstetrical issues.57,58 Diagnostic challenges and physiologic changes due to pregnancy, as well as the unique anesthesia risks and potential risks to the pregnancy, should be kept in mind whether the primary surgeon is an obstetrician, gynecologist, or a general surgeon (Table 41-5).58

Trauma in the obstetric patient requires stabilization of the mother while considering the fetal compartment.58,59 Trauma-related hypovolemia may be compounded by pregnancy-induced decreases in systemic vascular resistance, and when supine, the weight of the gravid uterus on the vena cava. When feasible, a left lateral tilt should be instituted to improve venous return to the right heart. Later in pregnancy, the small bowel is displaced into the upper abdomen, making it vulnerable to complex injury from penetrating upper abdominal trauma. Though small bowel is displaced from the pelvis, the dramatic increase in pelvic blood flow can lead to rapid blood loss due to penetrating pelvic trauma, fractures, or avulsion of pelvic vessels. Gastric motility is decreased increasing the risk of aspiration. Peritoneal signs may be attenuated by the stretching of the abdominal wall. Several coagulation factors are also increased in pregnancy, increasing the likelihood for thromboembolic events, but also giving the unsuspecting surgeon false security when low-normal levels are observed during resuscitative efforts. Only the third trimester fetus has any ability to autoregulate in the context of decreased uterine blood flow and oxygen delivery. In the third trimester, perimortem cesarean delivery should be considered as part of maternal resuscitation in cases of maternal hemodynamic collapse. Though treating the maternal compartment is the primary concern, it should also be recognized that the fetus will be impacted significantly by maternal hypotension, as blood may be shunted away from the uterus.

### Conditions and Procedures Performed Before Viability

#### Amniocentesis/Chorionic Villus Sampling. Noninvasive prenatal testing has for the most part replaced invasive fetal testing. Amniocentesis is a procedure in which amniotic fluid is aspirated from the uterine cavity and sent for genetic or laboratory testing typically under ultrasound guidance with a 20- to 22-gauge needle. This procedure may be used to confirm abnormal noninvasive testing.

#### Miscarriage and Pregnancy Terminations. Spontaneous pregnancy loss is common. Although the miscarriage rate among women who know they are pregnant is roughly 10% to 20%, if the start of pregnancy is set to fertilization, rates are as high as 50%. Chromosomal abnormalities are the underlying cause of miscarriage and are present in over half of cases. Patient may report cramping, bleeding and passage of tissue. If products of conception are not passed, diagnosis can be made by transvaginal ultrasound if an empty gestational sac is identified or an embryo is noted not to have a heartbeat. Treatment can include expectant management, medical management with misoprostol, or surgical management with dilation and curettage.50

Half of all pregnancies in the United States are unintended, and many of these are undesired. Additional reasons for termination of pregnancy include fetal anomalies such as trisomies, fetal infections, and maternal health. Medical terminations are

available up to 10 weeks of gestation, and surgical terminations can be performed to viability. Rates of pregnancy termination have been declining due decreasing access to abortion services and widespread availability of long-acting contraceptives (LARC). LARCs are safe, effective, easy to use and protect against unintended pregnancy for up to 10 years.61

Up to 15 weeks’ gestation, manual vacuum aspiration can be used following cervical dilation to mechanically evacuate the fetus or embryo, placenta, and membranes by suction using a manual syringe. Alternatively, cervical dilation and suction curettage can be performed. The uterine cervix is grasped with a tenaculum, then mechanically dilated occasionally using adjunctive prostaglandins, and an appropriately sized vacuum cannula is inserted into the uterus and rotated on its axis to remove the products of conception. Dilation and extraction is performed for pregnancies in the second trimester. The additional cervical dilation required at greater gestational ages is usually a two-step (often over 2 days) process. Osmotic dilators are placed within the cervix a day prior to the procedure and expand as water is absorbed, passively dilating the endocervical canal. These are removed immediately prior to the procedure and mechanical dilation is then performed as needed. Forceps are then used to remove fetal parts. Curettage of the postabortal uterus must be approached carefully because the uterus is extremely soft and perforation can occur with very little warning. Complications are rare (particularly when contrasted to the risks of pregnancy and term delivery) but include infection, hemorrhage due to uterine atony, cervical lacerations, uterine perforations, and inadvertent bowel injury from the vacuum cannula or forceps.

**Cerclage.** Cervical insufficiency is defined as painless cervical dilation leading to recurrent second trimester pregnancy loss, or shortened cervical length as determined by transvaginal ultrasound, or advanced cervical change before 24 weeks’ gestation in a woman with either prior preterm birth/loss or significant risk factors for insufficiency. A cervical cerclage refers to a procedure in which suture or synthetic tape is used to circumferentially reinforce the cervix to improve pregnancy outcome in at-risk patients.62 Shirodkar and McDonald techniques have been described63,64; both involve transvaginally placing a non-absorbable suture at the uterocervical junction to lengthen and close the cervix. An abdominal cerclage of the lower uterine segment performed laparor by laparotomy can be considered for a patient with a severely shortened or absent cervix who has previously failed a transvaginal cerclage.

**Ectopic Pregnancies.** Extraterine pregnancies are most commonly located along the fallopian tubes but can also implant on the ovary. Rarely, implantation can occur primarily on other abdominal organs or peritoneal surfaces. A high index of suspicion and early diagnosis typically includes an abnormal rise in β-hCG assays and presence of an adnexal mass on transvaginal ultrasound. Early ectopic pregnancies can be managed medically with a methotrexate injection; however, close follow-up with twice-weekly β-hCG testing is required. Laparoscopy is the definitive management and can be used either as primary treatment or when medical management fails. The tube should be removed (salpingectomy) in its entirety if the ectopic is identified within the fallopian tube. This can be performed using a vessel sealing device or even an endo-loop and endo-shears. Laparotomy is reserved for unstable patients with a known hemoperitoneum where Kelly clamps can be placed along the mesosalpinx to control bleeding. Cornual ectopic pregnancies may require wedge resection of the uterine serosa and myometrium, which is then closed in two layers.65 Linear salpingostomy along the antimesenteric border and removal of the products of conception is now rarely used due to low rates of postoperative tubal function and high recurrent ectopic pregnancies presumably due to scarring.

**Conditions and Procedures Performed After Viability**

**Obstetric Lacerations and Repair.** At the time of vaginal delivery, perineal lacerations are common. These lacerations involve, in varying degrees, the vaginal mucosa, the muscular elements inserting onto the perineal body, the levator ani, and in 4% to 5% of vaginal deliveries, the anal sphincter or anorectal mucosa. Although episiotomies were historically cut prophylactically to prevent unstructured tearing of the perineum, this practice has fallen out of favor as the benefit of episiotomy has not been demonstrated.

**Perineal Laceration** First-degree tears involve only the perineal skin and may or may not need to be reapproximated. Second-degree tears involve the perineal body and can generally be repaired with some variation using a single continuous, nonlocking suture technique, typically a 2-0 or 3-0 synthetic absorbable suture. The apex of the vaginal epithelium is approximated first including epithelium and underlying tissue to build up the rectovaginal septum. Upon reaching the hymenal ring, the perineal body and bulbocavernous muscle are approximated, and a transition stitch is placed from the vaginal mucosa, which was repaired along a horizontal plane, to the deep perineal layer, which lies in a vertically-oriented plane. A running closure is then completed incorporating the deep perineal tissues from the introitus to the extent of the perineal defect.

At this point, the perineal skin is closed from inferior to superior in a subcuticular fashion and tied just inside the introitus.

Third-degree lacerations extend through the perineal body and involve the external anal sphincter, while fourth-degree lacerations involve the internal anal sphincter and rectal mucosa. When present, third- and fourth-degree lacerations should be repaired first before proceeding with the second-degree repair. This is accomplished by first closing the anal mucosa, and then identifying and closing the internal anal sphincter in a second layer. The external anal sphincter is then identified, and the muscular cylinder is reconstructed by suturing the severed ends together using either an end-to-end or overlapping technique. Although these are typically straightforward layered closures, knowledge of the anatomy is important. Incomplete reconstruction, particularly of third- or fourth-degree lacerations, can contribute to future pelvic floor disorders, as well as the development of fistulae or incontinence.

**Cervical and Vaginal Lacerations** Significant lacerations to the cervix or vagina may also occur during childbirth, particularly with instrumented deliveries or macrosomic infants. These lacerations may present as persistent bleeding, not readily recognized due to their location, and often in association with a firmly contracted uterus. Vaginal lacerations may be repaired primarily but should only be closed after deeper tissues are inspected to insure no active bleeding. Cervical lacerations can be repaired in a running, locking fashion, insuring that the apex of the laceration is incorporated in the closure. If the apex is challenging to reach, the closure can be started more distally using the suture to apply traction so that the apex may be closed.
Puerperal Hematoma. Trauma during childbirth can occasionally result in significant hematoma formation with or without a visible laceration. These hematomas may hide significant blood loss and most commonly occur in the vulva, paravaginal, and pelvic retroperitoneum. Typical presentation is pain and mass effect. Small hematomas can be managed conservatively with close observation and patient monitoring. Though there are no evidence-based size criteria, an unstable patient or expanding hematomas should prompt surgical intervention. After the hematoma is incised and drained, diffuse venous oozing is usually encountered rather than a single bleeding vessel. Hemostasis can be achieved using electrocautery or fine absorbable suture, though caution must be used due to the proximity of bowel, bladder, and ureters to some hematomas. Pressure on the vulva or packing the vagina, rather than the hematoma cavity, may prevent further bleeding.

Cesarean Deliveries. Typical indications for cesarean delivery include nonreassuring fetal status, breech or other malpresentations, triplet and higher order gestations, cephalopelvic disproportion, failure to progress in labor, placenta previa, and active genital herpes. Previous low transverse cesarean delivery is not a contraindication to subsequent vaginal birth after cesarean; however, much of the increase in cesarean delivery in the past two decades is attributable to planned repeat cesareans. Cesarean deliveries typically are performed via a lower anterior (caudal) uterine transverse incision because there is decreased blood loss, and the uterine rupture rate with future pregnancies is about 0.5% (Fig. 41-15). A prior classical cesarean delivery is an absolute indication for a planned repeat cesarean delivery because of a high rate of uterine rupture during labor, unlike with the lower anterior uterine transverse incision. Abdominal access is obtained by a Pfannenstiel, Maylard or vertical incision. Once the abdomen is entered, a vesicouterine reflection is created if a low transverse uterine incision is planned. The uterine incision is then made and extended laterally, avoiding the uterine vessels. After amniotomy, the baby is delivered, and the uterus is closed. Approximately 1000 mL of blood is typically lost during a cesarean delivery. Along with rapid closure of the uterine incision, uterotonics, such as intravenous oxytocin, are administered. A classical, vertical, uterine incision is made in certain very early viable gestations, or in the case of certain transverse lies or abnormal placentation. Infection, excessive blood loss due to uterine atony, and urinary tract and bowel injuries are potential complications at the time of cesarean delivery. The risk of those injuries, as well as abnormal placentation (placenta accreta, increta, and percreta) rises with each subsequent cesarean delivery. Bleeding can only be controlled in some instances by performing a cesarean hysterectomy.

Postpartum Hemorrhage. Postpartum hemorrhage is an obstetrical emergency that can follow either vaginal or cesarean delivery. Hemorrhage is usually caused by uterine atony, trauma to the genital tract, or rarely, coagulation disorders. Hemorrhage may also be caused by abnormal placentation (also called morbidly adherent placenta). Management consists of mitigating potential obstetric causes while simultaneously acting to avert or treat hypovolemic shock. In the absence of atony, the genital tract should be thoroughly evaluated for trauma. Atony is the most common cause of postpartum hemorrhage. It is typically treated with fundal massage and uterotonics such as oxytocin, methylergonovine, carboprost tromethamin, and misoprostol. When aggressive medical management fails, surgical management may be necessary and life-saving.

Uterine Curettage. Retained products of conception may result in uterine atony. It may be possible to remove retained products via manual extraction or with ring forceps. Bedside ultrasound may be helpful in localization. When clinical suspicion is high, uterine curettage is indicated. A blunt, large curette, banjo curette, is introduced and removal of retained tissue typically results in contraction of the myometrium and cessation of bleeding.

Procedures Short of Hysterectomy. As bleeding from postpartum hemorrhage becomes increasingly acute, interventions short of hysterectomy should be carried out expeditiously while supporting the hemodynamic status of the patient and preparing for possible definitive surgery. A number of techniques for packing and tamponade of the uterus have been described, including a balloon device reported by Bakri and colleagues.

These are typically left in place for 24 to 36 hours and appear to be safe and often effective conservative measures short of laparotomy and hysterectomy. The B-Lynch compression suture may control bleeding of atony at the time of cesarean section. A suture is placed through the hysterotomy, around the fundus of the uterus anterior to posterior, and then through the posterior lower uterine segment, to the contralateral side. At this point, the steps are reversed with the suture brought around the fundus posterior to anterior, through the contralateral side of the hysterotomy, and then tied in the midline to compress the uterus. Additional procedures described include the O’Leary uterine artery ligation and the hypogastric artery ligation. “O’Leary stitches” are a series of sutures placed around the branches of the uterine artery and through the myometrium, resulting in compression of the vessels against the uterus. Hypogastric artery ligation entails the isolation of the internal iliac artery at its bifurcation with the external iliac artery. The hypogastric artery is ligated at least 3 cm distal to the bifurcation to avoid compromising the posterior division.

Postpartum/Cesarean Hysterectomy. A cesarean or postpartum (absent a prior cesarean delivery) hysterectomy involves the same steps as in a nonpregnant patient, but it is distinctly different due to the engorged vessels and the pliability of the tissues. If a cesarean section has been performed, occasionally the
incision can be used for traction to keep the vessels and tissues attenuated. Vascular pedicles should be secured with clamps, but not ligated until both uterine arteries have been secured, to fully control bleeding. Lack of typical anatomic landmarks requires careful identification of the ureters and the dilated cervix visually or by palpation, to separate from the bladder and vagina (Fig. 41-16). This procedure is often done for life-threatening hemorrhage, thus appropriate blood products, including packed red blood cells, fresh frozen plasma, platelets, and fibrinogen should be on call and are usually required. Fibrinogen is typically elevated in a pregnant woman, such that a low-normal fibrinogen level can be cause for alarm, and further fibrinogen may be required before consumptive coagulopathy reverses. A massive transfusion protocol is helpful.

Abnormal Placenta...tion rate in the United States. When cytotrophoblasts invade decidualized endometrium and encounter a uterine scar, they do not encounter the normal myometrial signals to stop invasion. In the setting of a placenta previa, the presence of a uterine scar is a particular risk for placenta accreta with rates of 11%, 40%, and 61% for one, two, or three prior cesarean deliveries, respectively. Ultrasound or MRI can assist in the diagnosis, depending on the experience and comfort of the imager.

Women at risk for abnormal placenta should ideally be identified during pregnancy and be prepared for cesarean section followed by cesarean hysterectomy. Since the blood supply to the gravid uterus is 500 cc per minute, these surgeries have the potential to have very high blood loss, which can then lead to the development of disseminated intravascular coagulation. Over 50% of cases require more than 4 units of blood transfused.

Unintentional bladder or ureteral injuries are common as well due to impaired visualization and poor dissection planes. For these reasons, patients with suspected placenta accreta should be delivered in a tertiary care center with a multidisciplinary team that has the capacity for massive blood transfusion protocol. While some sites have implemented protocols involving interventional radiology with placement of occlusive balloons in the uterine arteries prior to delivery, these protocols have not been shown to decrease morbidity or overall blood loss. Postoperative embolization should be available. Even with scheduled delivery in a well-resourced setting with a highly experienced and prepared multidisciplinary team, the morbidity of abnormal placentation is high. ICU stays are common, and maternal mortality as high as 7% has been reported.

Delayed hysterectomy where the placenta is left in situ after delivery of the baby if there is not significant bleeding and the mother is stable is advocated by certain centers but remains controversial. The risks of leaving the placenta in utero include later hemorrhage, infection, and sepsis. Planned hysterectomy at 6 to 12 weeks postpartum is recommended unless subsequent fertility is strongly desire.

PELVIC FLOOR DYSFUNCTION

Pelvic floor disorders can be categorized, from a urogynecologic perspective, into three main topics: female urinary incontinence and voiding dysfunction, pelvic organ prolapse, and disorders of defecation. Approximately 11% of women will undergo surgery for incontinence or prolapse. The normal functions of support, storage, and evacuation can be altered by derangements in neuromuscular function both centrally and peripherally and through acquired changes in connective tissue. Reconstructive surgeons aim to repair or compensate for many of these losses.

Evaluation

Diagnostic evaluations, in addition to the history and examinations previously described, can aid in the diagnosis of many pelvic floor disorders. Cystoscopy, multichannel urodynamics, and/or fluoroscopic evaluation of the urinary tract can be obtained for patients with urinary incontinence or voiding dysfunction. Defecography, anal manometry, and endorectal ultrasound may be useful for diagnosis of defecatory dysfunction. A standardized examination called the pelvic organ prolapse quantification (POP-Q) helps to clarify which vaginal compartment, and therefore which specific structure, has lost its anatomic integrity in women with uterovaginal prolapse. Finally, dynamic MRI and pelvic floor electromyography has growing utility for all three disorders.

Surgery for Pelvic Organ Prolapse

Many factors are important in determining which reconstructive operation is optimal for a given patient with pelvic organ prolapse. Surgical decisions are often based on case series and expert opinions that may not have universal applicability. However, the few reports with the highest level of evidence suggest that failure rates for prolapse reconstruction may be twice as high using the vaginal approach when compared with the abdominal route.

Colporrhaphy. Anterior colporrhaphy, also known as an “anterior repair,” is performed for a symptomatic cystocele. The procedure begins with incision of the anterior vaginal epithelium...
in a midline sagittal direction. The epithelium is dissected away from the underlying vaginal muscularis. The vaginal muscularis is plicated with interrupted delayed absorbable stitches, after which the epithelium is trimmed and reapproximated. The vaginal canal is therefore shortened and narrowed proportionate to the amount of removed epithelium. Posterior colporrhaphy is performed for a symptomatic rectocele. This procedure is performed in a similar manner, often including the distal pubococcygeus muscles in the plication. Recently, in attempts to decrease surgical failures alluded to previously, many surgeons have opted to utilize grafts and meshes to augment these vaginally performed procedures. Unfortunately, the apparent number of postoperative complications, including mesh erosion, pelvic pain, and dyspareunia, prompted the FDA to publish a warning encouraging a much more limited use of vaginal mesh for prolapse repair until greater surveillance and more rigorous studies could be completed.77

**Sacropinous and Uterosacral Ligament Fixations.** Both the sacropinous ligament fixation (SSLF) and uterosacral ligament fixation (USLF) procedures are vaginal procedures that suspend the apex of the vagina using native tissue for treatment of apical prolapse. The sacropinous ligament is found embedded in and continuous with the coccygeus muscle, which extends from the ischial spine to the lateral surface of the sacrum. The procedure begins with entry into the rectovaginal space, usually by incising the posterior vaginal wall at its attachment to the perineal body. The space is developed to the level of the vaginal apex and the rectal pillar is penetrated to gain access to the pararectal space. A long-ligature carrier is used to place sutures medial to the ischial spine, through the substance of the ligament-muscle complex. Structures at risk in this procedure include the pudendal neurovascular bundle, the inferior gluteal neurovascular bundle, the lumbosacral plexus, and sciatic nerve. After the stitches are placed, the free ends are sewn to the undersurface of the vaginal cuff. The sacropinous stitches are tied to firmly approximate the vagina to the ligament without suture bridging.

When using the uterosacral ligaments for repair of prolapse, it is important to recall that these structures are not “ligaments” in the true sense of the word, but rather condensations of smooth muscle, collagen, and elastin. Several support sutures are placed from the lateral-most portion of the vaginal cuff to the distal-most part of the ligament, and the medial vaginal cuff to the proximal ligament. Intraoperative evaluation of the lower urinary tract is important to confirm the absence of ureteral compromise.

**Colpocleisis.** Colpocleisis is reserved for patients who are elderly, who do not wish to retain coital ability, and for whom there is good reason not to perform a more extensive reconstructive operation. A colpocleisis removes part or all of the vaginal epithelium, obliterating the vaginal vault and leaving the external genitalia unchanged. The procedure can be performed with or without a hysterectomy. Successive purse-string sutures through the vaginal muscularis are used to reduce the prolapsed organs to above the level of the levator plate.

**Sacrocolpopexy.** The procedure with the lowest risk of recurrence for patients with prolapse of the vaginal apex is an abdominal sacral colpopexy. In these patients, the natural apical support structure, the cardinal–uterosacral ligament complex, is often damaged and attenuated. The abdominal placement, as opposed to vaginal placement, of graft material to compensate for defective vaginal support structures is well described.78 Apical support defects rarely exist in isolation, and the sacrocolpopexy may be modified to include the anterior and posterior vaginal walls as well as the perineal body in the suspension. Sacrocolpopexies can be performed via laparotomy as well as via laparoscopy or robotically. Like rectopexies and low anterior resections, deep pelvic access is needed. Significant suturing at varied angles is required. The advent of the DaVinci robotic laparoscopic system has made visualization and adequate placement of the mesh and sutures easier to perform when using the minimally invasive approach.

During a sacrocolpopexy, a rigid stent (usually an EEA sizer) is placed into the vagina to facilitate its dissection from the overlying bladder and rectum and to allow the graft material to be spread evenly over its surface. A strip of synthetic mesh is fixed to the anterior and posterior vaginal walls. The peritoneum overlaying the presacral area is opened, extending to the posterior cul-de-sac. The sigmoid colon is retracted medially, and the anterior surface of the sacrum is skeletonized. Two to four permanent sutures are placed through the anterior longitudinal ligament in the midline, starting at the S2 level and proceeding distally. The sutures are passed through the graft at an appropriate location to support the vaginal vault without tension. The peritoneum is then closed with an absorbable running suture. The most dangerous potential complication of sacrocolpopexy is sacral hemorrhage.

**Surgery for Stress Urinary Incontinence**

Stress incontinence is believed to be caused by lack of urethrovaginal support (urethral hypermobility) or intrinsic sphincter deficiency (ISD). ISD is a term applied to a subset of stress-incontinent patients who have particularly severe symptoms, including urine leakage with minimal exertion. This condition is often recognized clinically as the low pressure or “drainpipe” urethra. The urethral sphincter mechanism in these patients is severely damaged, limiting coaptation of the urethra. Standard surgical procedures used to correct stress incontinence share a common feature: partial urethral obstruction that achieves urethral closure under stress.

**Burch Procedure.** Despite the wide acceptance of midurethral sling procedures, a retropubic urethropexy procedure called the Burch procedure is still performed for stress incontinence.79 The space of Retzius is approached extraperitoneally, from an abdominal approach, allowing the bladder to be mobilized from the surrounding adipose tissue and lateral pelvis. Two pairs of large-caliber nonabsorbable sutures are placed through the periurethral vaginal wall, one pair at the midurethra and one at the urethrovesical junction. Each stitch is then anchored to the ipsilateral Cooper’s (iliopubic) ligament. The sutures are tied to give preferential support to the urethrovesical junction relative to the anterior vaginal wall without overcorrection. Long-term outcome studies up to 10 years have shown the Burch procedure yields cure rates of 80% to 85%.

**Tensionless Sling.** The tension-free vaginal tape (TVT) is a modified sling that uses a strip of polypropylene mesh. Unlike traditional sling procedures, the mesh is positioned at the midurethra, not the urethrovesical junction, and it is not sutured or otherwise fixed into place. Advantages of TVT include the ability to perform the procedure under local anesthesia on an outpatient basis. Small subepithelial tunnels are made bilaterally to the descending pubic rami through an anterior vaginal wall incision. A specialized conical metal needle coupled to a handle is used to drive one end of the sling through the perineal membrane, space of Retzius, and through one of two small suprapubic stab incisions. The tape is set in place without any
tension after bringing up the other end of the tape through the other side. Recently, multiple modifications have been made to carry the tape through the bilateral medial portions of the obturator space (TVT-O). Risks of the procedure include visceral injury from blind introduction of the needle, bleeding, and nerve and muscle injury in the obturator space. Additionally, voiding dysfunction and delayed erosion of mesh into the bladder or urethra has been seen.

**Urethral Bulking Injections.** A transurethral or periurethral injection of bulking agents is indicated for patients with intrinsic sphincter deficiency. Several synthetic injectable agents, such as polydimethylsiloxane and calcium hydroxyapatite are now used, as glutaraldehyde cross-linked (GAX) bovine dermal collagen is no longer commercially available.\(^8^0\) Anesthesia is easily obtained by using intraurethral 2\% lidocaine jelly and/or transvaginal injection of the perirectal tissues with 5 mL of 1\% lidocaine. The material is injected underneath the urethral mucosa at the bladder neck and proximal urethra at multiple positions, until mucosal bulk has improved. Patients must demonstrate a negative reaction to a collagen skin test prior to injection. The long-term cure rate is 20\% to 30\%, with an additional 50\% to 60\% of patients demonstrating improvement.\(^7^2\) Repeat injections are frequently necessary because of migration and dissolution of the collagen material.

**Mesh in Reconstructive Pelvic Surgery.** As noted earlier, pelvic reconstructive surgery frequently uses polypropylene mesh to augment procedures in the hopes of providing lasting repair. However, use of permanent mesh is associated with complications, most notably mesh erosion. In 2011, the FDA issued an updated statement to stipulate the risks when using transvaginally inserted mesh for prolapse.\(^8^1\) Ultimately, this has led to categorizing transvaginal mesh products as class III devices in 2016. In addition to appropriate patient selection, and extensive informed consent, the American Urogynecologic Society recommends appropriate training to perform the procedures and manage the complications.\(^8^2,8^3\)

**GYNECOLOGIC CANCER**

**Vulvar Cancer**

Vulvar cancer is the fourth most common gynecologic cancer. The mean age at diagnosis is 65, though this has trended down over the last several decades.\(^8^4\) Evidence supports an HPV-dependent pathway of carcinogenesis with risk factors similar to VIN in approximately 60\% of cases. A second pathway independent of HPV is associated with chronic inflammation, vulvar dystrophy.\(^8^5\) Patients usually present with a vulvar ulcer or mass. Pruritis is a common complaint, and vulvar bleeding or enlarged inguinal lymph nodes are signs of advanced disease. Careful evaluation of the patient is necessary to rule out concurrent lesions of the vagina and cervix. Biopsy is required and should be sufficiently deep to allow evaluation of the extent of stromal invasion. Vulvar carcinomas are squamous in 90\% of cases. Other less common histologies include melanoma (5\%), basal cell carcinoma (2\%), and soft tissue sarcomas (1–2\%).

Spread of vulvar carcinoma is by direct local extension and via lymphatic microembolization. Hematogenous spread is uncommon except for vulvar melanoma. Lymphatic spread seems to follow a stepwise, predictable pattern traveling from superficial, above the cribiform fascia, to deep inguino-femoral nodes and ultimately the pelvic, external iliac, nodal basin
radical local excision are adequate. Patients with IB tumors have deeper invasion but negative nodes and therefore carry an excellent prognosis. Stage II includes patients with local extension and negative nodes and therefore carry a prognosis similar to other node-negative patients.

Stage III disease includes patients with lymph node metastases, and stage IV disease is either locally advanced or distant metastasis. Treatment options for stage III and stage IV disease include (a) chemoradiation followed by limited resection if needed; (b) radical vulvectomy; and (c) radical vulvectomy coupled with pelvic exenteration. External beam radiotherapy combined with radiosensitizing chemotherapy of cisplatin and 5-fluorouracil (5-FU) is emerging as the preferred initial management of advanced disease, followed by limited surgical resection of residual disease. Reconstruction of the vulva and groin, if needed, can be accomplished using grafts and rotational or myocutaneous flaps depending on the size and type of defect.

Inguinoemoral lymphadenectomy is indicated beyond clinical stage IA. Unilateral lymphadenectomy is recommended for lateralized lesions or bilateral for central lesions that cross the midline, or those involving the perirectal area (Figs. 41-19 and 41-20). Complications of complete inguinoemoral lymphadenectomy include wound dehiscence or infection and lymphedema. Sentinel lymph node biopsy (SLNB) is an alternative to inguinoemoral lymphadenectomy for selected patients with stage I or II disease and no palpable inguinoemoral nodes. SLNB appears to be effective in detecting inguinoemoral lymph node metastases without increasing the risk of groin recurrence while avoiding the morbidities associated with complete inguinoemoral lymphadenectomy. Several prospective studies support this approach. However, it is recognized that successful SLNB depends on operator experience. Surgeons with limited experience in SLNB (have performed fewer than 10 of these procedures) may choose to perform complete groin node dissection or use this procedure only for tumors that are less than 2 cm in size.

Nodal failure in the groin and pelvis is difficult to treat successfully, and attention to primary management of these areas is key. Postoperative adjuvant inguinal and pelvic radiotherapy is indicated when inguinal lymph nodes are positive and is superior to pelvic lymphadenectomy, which has been largely abandoned. It is also indicated when the vulvectomy margins are positive or close positive for disease and further surgical management is not anatomically feasible.

**Vaginal Cancer**

Vaginal carcinoma is a rare gynecologic malignancy and accounts for about 3% of cancers affecting the female reproductive system. Squamous cell carcinomas account for 85% to 90% of cases; more than two-thirds of vaginal cancers are diagnosed in women 60 years of age or older. Risk factors are similar to other HPV-related cervical and vulvar cancers. Rare clear cell carcinoma of the vagina is associated to in utero exposure to diethylstilbestrol (DES), which is now largely of historical interest due to aging of the exposed cohort. Patients with vaginal cancer usually present with postmenopausal and/or postcoital bleeding and may also complain of vaginal discharge, vaginal mass, dysuria, hematuria, rectal bleeding, or pelvic pain, which may be indicative of advanced disease. Diagnosis is made via biopsy of suspicious lesions, which may require colposcopic guidance.
Vaginal cancer is staged clinically by pelvic exam, chest X-ray, cystoscopy, and proctoscopy (Table 41-7). Vaginal cancer spreads by local extension to adjacent pelvic structures, by lymphatic embolization to regional lymph nodes, and, less commonly, via the hematogenous route. Lymphatic drainage is complex, but in general, lesions in the upper vagina drain to the pelvic lymph nodes while lesions involving the lower third drain to the inguinofemoral lymph nodes.

Stage I disease, involving the upper vagina, may be treated surgically or with intracavitary radiation therapy. Surgery consists of a radical hysterectomy, upper vaginectomy, and bilateral pelvic lymphadenectomy. Stage I disease in the mid to lower vagina is treated with radiation and concurrent chemotherapy. External beam pelvic radiation is the mainstay of treatment for stages II to IV and may be followed by intracavitary radiation fields for women with locally advanced disease. Staging factors in this disease, and positron emission tomography scans are useful in pretreatment planning and determination of radiation fields for women with locally advanced disease. Staging and management options are outlined in Table 41-8.

Data from Pecorelli S: Revised FIGO staging for carcinoma of the vulva, cervix, and endometrium, Int J Gynaecol Obstet. 2009 May;105(2):103-104.
Procedures for Cervical Cancer Treatment. Certain cervical cancers that are confined to the cervix may be treated surgically. Very small lesions (less than 7 mm wide, less than 3 mm deep) with no LVSI may be treated with simple hysterectomy. In a woman who desires future fertility, a cone biopsy with negative surgical margins may be an acceptable alternative. Any tumor larger than this (larger than stage IA1) should be treated with radical hysterectomy or in special cases radical tracheectomy for fertility preservation. Some authors advocate a large cone biopsy with lymph node dissection for stage IA2 tumors in patients who desire future fertility, though this recommendation is somewhat controversial. Tumors that are greater than 4 cm in size are most often treated with chemoRT even if they are confined to the cervix, given the high likelihood of need for postoperative radiotherapy due to cervical risk factors.

Radical Hysterectomy This procedure may be performed via laparotomy, or increasingly via a minimally invasive (laparoscopic or robotic) approach. The key elements are dissection of the pelvic and paraaortic nodes and the dissection of the parametrium from the pelvic sidewall to allow en bloc removal with the uterus. The principle steps of an open procedure are demonstrated in Fig. 41-21. In contrast to a typical simple hysterectomy, the radical hysterectomy involves dissection much closer to the bowel, bladder, ureters, and great vessels, resulting in a higher complication rate to these organs. Additionally, disruption of the
nerves supplying the bladder and the rectum, which traverse the cardinal and uterosacral ligaments, may result in temporary or long-term bladder and bowel dysfunction. Radical hysterectomies allow for the maintenance of the ovaries since the incidence of metastases to this area is very low, providing a clear advantage of surgery over radiation therapy in the younger patient.

**Radical Trachelectomy** Interest in fertility preservation with stages IA1 and 2, and stage IB1 lesions has led to the development of methods of radical trachelectomy with uterine preservation. This procedure depends on an adequate blood supply to the uterus from the ovarian anastamoses, as the cervical portion is removed. The lower uterine segment closed with a cerclage and attached directly to the vaginal cuff. The rates of recurrence, pregnancy outcomes, and the best surgical candidates for this surgery are still under study, but there are sufficient numbers and experience, both obstetric and surgical, to suggest that this procedure is oncologically safe and allows live births.

**Pelvic Exenteration for Recurrent Disease (Fig. 41-22)** Cervical cancer recurrences after primary surgical management are treated with radiation. Surgery may be a consideration in selected patients with recurrent cervical cancer who have received maximal radiation therapy. If the recurrence is locally confined with no evidence of spread or metastatic disease, then pelvic exenteration may be considered. Attempted exenteration procedures are aborted intraoperatively if metastatic disease is found. Exenteration is tailored for the disease size and location and may be supravelvator or extend below the levator ani muscle and require vulvar resection. Reconstruction of the pelvis may require a continent urinary pouch (if radiation enteritis is limited) or ileal conduit and colostomy, as well as rebuilding of the pelvic floor and vagina with grafts or myocutaneous flaps.

**Uterine Cancer**

**Endometrial Cancer.** Endometrial cancer is the most common gynecologic malignancy and fourth most common cancer in women. It is most common in menopausal women in the fifth decade of life; up to 15% to 25% of cases occur prior to menopause, and 1% to 5% occur before age 40. Risk factors for the most common type of endometrial cancer include increased exposure to estrogen without adequate opposition by progesterone, either endogenous (obesity, chronic anovulation) or exogenous (hormone replacement). Additional risk factors include diabetes, Lynch II syndrome (hereditary nonpolyposis coli syndrome), and prolonged use of tamoxifen. Tamoxifen is a mixed agonist/antagonist ligand for the estrogen receptor. It is an agonistic in the uterus and an antagonistic to the breast and ovary. Protective factors for endometrial cancer include smoking and use of combination oral contraceptive pills. Adenocarcinomas are the most prevalent histologic type.

Endometrial adenocarcinomas have historically been divided into type I and type II tumors with five classic histologic subtypes. Type I tumors are estrogen-dependent endometrioid...
histology and have a relatively favorable prognosis; they can be broken down further by presence or absence of microsatellite instability. Type II endometrial cancers are estrogen-independent, aggressive, and characterized by nonendometrioid, serous or clear cell, histology, or carcinosarcoma. Emerging data, however, suggest that the molecular features could provide reproducible subtypes that have the potential to guide and refine treatment. The most comprehensive molecular study of endometrial cancer to date has been The Cancer Genome Atlas, which included a combination of whole genome sequencing, exome sequencing, microsatellite instability assays, copy number analysis, and proteomics. Molecular information was used to classify 232 endometrial cancer patients into four groups: POLE ultramutated, MSI hypermutated, copy number low, and copy number high that correlated with progression-free survival. Two practical pared-down classification systems to identify four molecular subgroups with distinct prognostic outcomes have been described.

Postmenopausal bleeding is the most common presentation of endometrial cancer and often permits early stage diagnosis, resulting in a favorable prognosis. Abnormal bleeding should prompt endometrial evaluation and sampling, which is usually done with an office endometrial biopsy, though at times requires operative curettage or diagnostic hysteroscopy. Transvaginal ultrasonography (TVUS) often reveals a thickened endometrial stripe. An endometrial stripe measuring 5 mm or more in a postmenopausal patient with vaginal bleeding raises concern and should be followed by endometrial sampling; patients with stripe of 4 mm or less rarely have occult malignancy, and TVUS may thus be used to triage patients before invasive endometrial sampling. Even with a normal endometrial stripe, endometrial sampling should be performed for persistent postmenopausal bleeding. Uterine cancer is surgically staged and is graded based on the degree of histologic differentiation of the glandular components (Table 41-9). Grade is an important prognostic factor, independent of stage.

Treatment is surgical, and most commonly involves hysterectomy, bilateral salpingo-oophorectomy, peritoneal cytology, and resection of any gross disease. Evidence supports equivalent oncologic outcomes with minimally invasive approaches. The inclusion and utility of lymphadenectomy remains an area of controversy. If a lymph node dissection is performed, it may be performed via laparotomy or laparoscopy. Generally, the bilateral pelvic and para-aortic lymph nodes are removed. The pelvic node dissection includes: bilateral removal of nodal tissue from the distal one-half of each common iliac artery, the anterior and medial aspect of the proximal half of the external iliac artery and vein, and the distal half of the obturator fat pad anterior to the obturator nerve. Most of the pelvic lymph nodes lie anterior, medially, and posteriorly to the external and internal iliac vessels and the obturator nerve. There are a few nodes that lie lateral to these structures, between the vessels and the pelvic sidewall, and are generally removed in a complete dissection. The para-aortic lymph nodes include resection of nodal tissue over the distal vena cava from the level of the inferior mesenteric artery to the mid right common iliac artery and between the aorta and the left ureter from the inferior mesenteric artery to the left mid common iliac artery. Some also advocate resection of lymph nodes between the IMA and the gonadal vessels, as some uterine fundal tumors may drain directly into these lymph nodes.

The need for postoperative intervention is individualized based on the histology, stage, and risk factors such as age, lymphvascular space invasion, and histology. Early-stage patients...
are typically cured with surgery alone, while patients with high-intermediate risk factors, as defined by collaborative trials groups, commonly receive intracavitary brachytherapy to decrease local recurrence.\textsuperscript{108,109} Patients with advanced disease and high-grade histologies commonly receive platinum-based chemotherapy with or without radiation.

Similar to the case with vulvar cancer described earlier, sentinel node biopsy is becoming more prevalent in endometrial cancer. A sentinel lymph node biopsy may be considered in apparent uterine-confined malignancy when there is no metastasis demonstrated by imaging studies or no obvious extratumor disease at exploration. For this procedure, most frequently the cervix is injected with ICG dye, and the immunofluorescence detecting camera is used eitherrobotically or laparoscopically to identify the sentinel node. If no node is mapped, a full lymphadenectomy is generally advised.\textsuperscript{110}

**Lynch Syndrome.** Lynch syndrome, a cancer family syndrome also known as hereditary nonpolyposis colorectal cancer (HNPCC), is an autosomal dominant inherited predisposition to develop colorectal carcinoma and extracolonic cancers, predominantly including tumors of the uterus and ovaries, now also including breast cancer.\textsuperscript{111} Genes involved in HNPCC are those required for proper single-strand DNA repair via the mismatch repair pathway; most commonly involved are \textit{MLH1}, \textit{MSH2}, \textit{MSH6}, and \textit{PMS2}. The risk of colorectal carcinoma is as high as 75% by age 75 years. Affected women have a 40% and 10% lifetime risk of developing uterine and ovarian cancers, respectively. Surveillance has not been proven to identify disease in early stage for these patients, though it is recommended and should include annual cervical cytology, mammography, transvaginal ultrasonography, CA-125 measurements, and an endometrial biopsy. Risk-reducing salpingo-oophorectomy with hysterectomy is now being recommended for women who have completed childbearing, ideally 5 to 10 years earlier than the first case of endometrial or ovarian cancer in the family. Dysregulation of the mismatch repair pathway leads to the microsatellite instability phenotype, now known to be associated with susceptibility to select immunotherapies.

**Uterine Sarcomas.** Uterine sarcomas arise from the uterine muscle and connective tissue elements and are typically aggressive tumors with a poorer prognosis compared to the more common endometrial carcinomas. The most common histopathologic types are endometrial stromal sarcomas, undifferentiated endometrial sarcomas, and leiomyosarcomas. Risk factors are challenging to assess but may include prior pelvic radiation and tamoxifen exposure. Patients typically present with bleeding or mass effects, although some are discovered incidentally at the time of hysterectomy for other indications. Leiomyosarcoma is the most common uterine sarcoma, and hysterectomy with salpingooophorectomy is the treatment of choice. Lymph node metastases are rare in sarcomas in general, and in the absence of palpable nodes or extrauterine disease. There are limited data to support cytoreduction when extraterine disease is present. The benefits of adjuvant therapy are unknown. Advanced disease is typically treated with systemic chemotherapy.\textsuperscript{112}

**Ovarian Cancer**

**Epithelial Ovarian, Tubal, and Primary Peritoneal Cancer.** Ovarian cancer is a rare disease affecting 1 in 70 women with a median age at diagnosis of 62 years.\textsuperscript{90} Epithelial malignancies make up the vast majority of ovarian cancers. The majority of women (70%) are diagnosed with advanced staged disease leading to the poor survival associated with this malignancy. Survival in advanced disease is due both to late diagnosis and lack of effective second-line cytotoxic therapy for the majority of patients who relapse following initial clinical complete response to platinum-based chemotherapy. Despite multiple prospective population based trials evaluating the use of CA-125, ultrasound, or combinations of these tests for early detection of disease, a mortality benefit to screening programs has not been demonstrated.\textsuperscript{113-116} Symptoms for either benign or malignant ovarian tumors are nonspecific but frequent, and they include bloating, pelvic or abdominal pain, difficulty eating or feeling full quickly, and urinary symptoms of urgency or frequency,\textsuperscript{117} which form the basis of an ovarian cancer symptom index (Table 41-10). When newly developed and persistent, these symptoms should prompt an evaluation specifically targeted for identification of gynecologic malignancy.

The histologic heterogeneity of ovarian cancer has long been recognized, but with the emergence of more robust clinicopathologic, molecular, and genetic data over the past decade these distinctions have become more clearly defined. Type I tumors consist of low-grade serous (LGS), low-grade endometrioid, clear cell carcinomas (CCC), and mucinous carcinomas and are characterized by mutations in \textit{KRAS}, \textit{BRAF}, \textit{PTEN}, \textit{PIK3CA}, \textit{CTNNB1}, \textit{ARID1A}, and \textit{PPP2R1A}. Type II ovarian cancers are the most common of the ovarian cancer histotypes, consisting of high-grade serous (70%), high-grade endometrioid, carcinosarcoma, and undifferentiated carcinomas. Type II tumors are defined by \textit{TP53} mutations, which are rare in type I cancers.\textsuperscript{118-121} Each of these types have distinct risk factors and potential precursor lesions.\textsuperscript{121}

Risk factors for development of ovarian cancer include hormonal factors such as early menarche, late menopause, and nulliparity. The use of oral contraceptives reduces risk of ovarian carcinoma—this risk reduction persists for up to 30 years after cessation of use.\textsuperscript{122} Additionally, tubal ligation and hysterectomy decrease population level epithelial ovarian cancer risk. Genetic predisposition to breast or ovarian cancer is the most important risk factor for the development of ovarian cancer, and 18% to 24% of ovarian carcinomas may arise in conjunction with a hereditary predisposition.\textsuperscript{123-126} Germline genetic mutations are far more common among type II ovarian cancers, while endometriosis and hormonal factors predispose to type I ovarian malignancies.\textsuperscript{121,126,129}

Since 2007, the National Comprehensive Cancer Network guidelines began recommending that all women diagnosed with ovarian cancer receive genetic testing as up to 20% of ovarian cancer patients are \textit{BRCA1}/\textit{2} mutation carriers.\textsuperscript{127-130,134} Although family history of breast and/or epithelial ovarian cancer is one of the strongest factors for lifetime risk of having breast or epithelial ovarian cancer, up to 50% of women with ovarian cancer who test positive for a \textit{BRCA} mutation have no family history of either malignancy, supporting the importance of testing all women with a personal diagnosis of ovarian cancer, regardless of family history. The identification of deleterious mutations allows for cascade testing. Relatives of the affected patient are referred for genetic testing limited to the identified mutation. The lifetime risk for the development of ovarian cancer for carriers of mutations in the \textit{BRCA1} and \textit{BRCA2} genes
is estimated to be between 20% and 45% and 10% and 20%, respectively.\textsuperscript{123,130,135}

One of the challenges associated with early detection of ovarian cancer has historically been the lack of an identifiable precursor lesion. In 2001, however, “dysplastic changes” in the fallopian tubes removed from women with increased risk of developing ovarian carcinoma were first described.\textsuperscript{136} Subsequent careful microscopic examination using a newly developed “sectioning and extensively examining of the fimbriated end” protocol (SEE-FIM) of the grossly normal fallopian tubes and ovaries from women with \textit{BRCA1/2} mutations revealed occult tubal cancer and precancers designated as serous tubal intraepithelial carcinoma. The relationship between serous tubal intraepithelial carcinomas and high-grade serous and endometrioid cancers is supported by the ubiquitous presence of \textit{TP53} mutations and their typical location within the fimbriated end of the fallopian tube.\textsuperscript{118,121,137} High-grade, serous epithelial cancers of the ovary, fallopian tube, and peritoneum are now recognized to have a common fallopian tubal precursor lesion and often combined under the rubric of epithelial ovarian cancer (HGSOC).

For women at increased risk of ovarian cancer, the only confirmed prevention strategy is risk-reducing salpingo-oophorectomy.\textsuperscript{138,139} The lifetime risk of HGSOC is reduced to under 3\% with risk-reducing salpingo-oophorectomy. A modern understanding of the fallopian tube as the site of origin for many ovarian cancers has led to the suggestion that opportunistic salpingectomy could be implemented as a potential cancer prevention strategy in the general population. Scandinavian population-based cohort studies have demonstrated a significant decrease in epithelial ovarian cancer following salpingectomy.\textsuperscript{140,141} Opportunistic salpingectomy is feasible among women undergoing tubal ligation, hysterectomy, or other pelvic surgery.\textsuperscript{142}

\textbf{Early Staged Ovarian Cancer.} Early stage epithelial ovarian cancer has an excellent outcome. Low grade, stages IA and B disease can be cured in up to 90\% to 95\% of cases by a complete surgical procedure. The prevailing position in the United States is that such patients do not benefit from chemotherapy.\textsuperscript{143}

The standard of care for women with stages IC and II, and all women with grade 3 or clear cell histology, is adjuvant chemotherapy with 3 to 6 cycles of platinum- and taxane-based chemotherapy.\textsuperscript{144}

\textbf{Advanced Ovarian Cancer.} A pelvic mass with ascites, an omental cake, and an elevated CA-125 is pathognomonic for advanced ovarian cancer. CT scan is the imaging modality of choice to evaluate the upper abdomen and potential resectability of disease. Concerning physical or radiographic exam findings should prompt referral to a gynecologic oncologist (Table 41-10), as studies demonstrate inferior patient outcome for women who have had primary surgery by nongynecologic oncologists.

The objectives of surgery in ovarian cancer are threefold. The first is to make the histologic diagnosis. The second is to assess the extent of disease through complete surgical staging (Tables 41-11 and 41-12). When epithelial ovarian cancer is identified on frozen section and disease is grossly limited to the pelvis, complete staging with node dissection will upstage nearly one-third of patients.\textsuperscript{145} The third objective is (when feasible) surgical cytoreduction or debulking. The extent of disease upon entering the abdomen and the residual disease upon completion of the debulking surgery are independent prognostic variables for patient outcome. The Gynecologic Oncology Group has defined optimal residual disease as residual tumor ≤1 cm in the largest diameter. However, more contemporary data suggest that the most favorable survival outcomes are associated with complete cytoreduction to no gross residual disease.\textsuperscript{146} Decisions about the benefits and risks of radical debulking for individual presentations and diverse pathology depend on the age and medical stability of the patient, as well as the pathologic type of the cancer.

The publication of two randomized prospective trials of neoadjuvant chemotherapy (NACT) for ovarian cancer has led to a questioning of the dogma of maximum surgical effort. Both trials revealed no survival difference compared to primary debulking.\textsuperscript{147,148} In a patient who is medically compromised or in whom complete primary cytoreduction is unlikely, neoadjuvant...

Chemotherapy followed by interval debulking may be more appropriate and is supported by recent randomized controlled trials. Typically, treatment with NACT includes three cycles of platinum-based chemotherapy prior to open debulking, then three additional cycles after surgery. Diagnostic laparoscopic evaluation prior to cytoreductive surgery has been suggested as a means to avoid unnecessary laparotomy, resulting in suboptimal cytoreduction. Patients deemed not to be candidates for cytoreduction could proceed immediately to NACT at the time of tissue collection for definitive diagnosis. A Fagotti predictive index ≥8 (Table 41-13) is a predictor of suboptimal cytoreduction in advanced ovarian cancer with reasonable sensitivity and high specificity.149 These recommendations currently apply to HGSO, clear cell cancer, and high-grade endometrioid ovarian...
cancers. Low-grade tumors are less chemotherapy sensitive, and primary surgical resection is recommended when feasible. Standard of care adjuvant therapy of advanced stage epithelial ovarian cancer remains intravenous platinum- and taxane-based chemotherapy. In 2006, the National Cancer Institute issued a clinical alert indicating that combination intravenous/intraperitoneal platinum/taxane postoperative chemotherapy should be considered first line for women with optimally cytoreduced EOC. This was the result of completion and analysis of three independent randomized clinical trials showing a significant survival advantage for intraperitoneal therapy. Intraperitoneal (IP) therapy is administered via an implanted 9.6 French venous port catheter with the port placed over the right or left costal margin. The catheter is tunneled caudad with insertion through the fascia in the lower abdomen and the tip in the pelvis. The IP catheter may be placed at the time of surgical debulking via an open laparotomy approach or prior to initiating chemotherapy via a laparoscopic approach. In some centers, the IP catheter may be placed by interventional radiology with CT guidance.

Patients who have suboptimally debulked advanced stage disease and/or who are not candidates for intraperitoneal therapy should receive intravenous adjuvant chemotherapy. Interest has increased in both dose dense IV chemotherapy dosing as well as incorporation of biologic agents.

Secondary cytoreduction upon recurrence can be considered (Table 41-14). Patients who have had a disease-free

</table>
period of at least 12 months following an initial complete clinical response to surgery and initial chemotherapy, who have no evidence of carcinomatosis on imaging, and who have disease that can be completely resected are considered optimal candidates. A randomized controlled trial reported in abstract form demonstrated a benefit of secondary cytoreduction under strict entry criteria (DESKTOP3); the GOG-0213 study of secondary cytoreduction is maturing. Debunking surgery done after subsequent relapses or in women with early recurrence has not been shown to result in an outcome benefit and should be used only to palliate disease complications.

The most common cause of palliative surgery is bypass of bowel obstruction. The majority of women with advanced ovarian cancer will eventually develop and potentially die from malignant bowel obstruction. While management of these cases is controversial, in some cases surgical correction has been shown to prolong life and improve quality of life.153 Nonsurgical options include placement of a venting gastrostomy tube, performed endoscopically or surgically. Management of malignant bowel obstruction in women with recurrent advanced disease should be individualized.

Chemotherapy is the mainstay of therapy for recurrent EOC. Treatment approaches are based upon platinum sensitivity.154 Referral to an oncologist with specific expertise in chemotherapeutic treatment of ovarian cancer and access to clinical trials is important. In determining secondary and subsequent therapy, consideration of prior therapies, sites of disease, organs at risk from cancer, organs sustaining injury from prior therapy, and quality of life desires of patient should be taken into consideration.

**Ovarian Germ Cell Tumors.** Ovarian germ cell tumors occur most commonly in women under age 30. The most common benign germ cell neoplasm is the mature cystic teratoma; approximately 1% of teratomas contain a secondary malignancy arising from one of the components, most commonly squamous cell cancer and most commonly in postmenopausal women. Malignant germ cell tumors often grow and disseminate rapidly and are symptomatic. The rapid growth may be accompanied by torsion or rupture, producing an acute abdomen and the need for emergent intervention. Because they are derived from primordial germ cells, many produce characteristic tumor markers. Immature teratomas comprise a significant proportion of malignant germ cell tumors and may be associated with elevated lactate dehydrogenase (LDH) or α-fetoprotein (AFP). Excluding teratomas, the most common malignant germ cell tumor is dysgerminoma, made up of pure undifferentiated germ cells. Bilaterality occurs in up to 15% of patients; lactate dehydrogenase is commonly elevated, and elevated b-hCG may occur.

Less common malignant germ cell tumors include endodermal sinus or yolk sac tumors, embryonal carcinomas, mixed germ cell neoplasms, polyembryomas, and choriocarcinomas. Endodermal sinus tumors may have elevated AFP levels in the blood while embryonal and mixed germ cell tumors may have elevated β-hCG, LDH, or AFP. Tumor markers are useful to follow during surveillance and definitive therapy. Other than completely resected stage I, grade I immature teratoma, adjuvant chemotherapy with a platinum-containing regimen has been historically recommended.155 Because of the high response rates to chemotherapy and the long-term toxicity of treatment, a “watch and wait” approach with treatment only upon recurrence has been suggested as safe for selected, well-staged patients with germ cell tumors.156 The cure rate remains high, near 90% even when metastatic disease is present; recurrent disease is more difficult to eradicate.155

Fertility preservation is the standard surgical approach for ovarian germ cell tumors as disease tends to be diagnosed at stage I, and salvage chemotherapy is overall extremely successful. Staging should include removal of the involved ovary, biopsy of any suspicious areas, pelvic and para-aortic node dissection, and omentectomy. Hysterectomy or removal of the second ovary is rarely indicated.

Growing teratoma syndrome is a rare sequela of germ cell malignancies. Characteristically, during or after chemotherapy slow-growing tumors will increase in size and may even compress surrounding organs. Malignant transformation within these masses has been described. Treatment is with surgical resection.157

**Ovarian Sex Cord-Stromal Tumors.** Sex cord-stromal cell tumors, rare tumors, are derived from cells that support and surround the oocyte and can present with symptoms referable to endocrine activity of the tumor. These include granulosa cell tumors (female differentiated), fibroma-thecomas, and Sertoli-Leydig cell tumors (male differentiated). Granulosa cell tumors are the most common in this group and are a low-grade malignancy with fewer than 3% bilaterality. They are treated with conservative surgery, similar to germ cell tumors in young women.153 Hysterectomy and bilateral salpingo-oophorectomy is recommended for women who have completed childbearing. Nodal staging can be safely omitted in the absence of grossly involve nodes and fertility preservation is possible in disease limited to one ovary, the most common presentation. Debunking surgery is recommended for more extensive disease. These tumors and the thecomas in the same class often stimulate estrogen production and can be found in association with endometrial hyperplasia and cancer (5%). Granulosa cell tumors can recur over a prolonged period given their low rate of proliferation and tendency for local or intraperitoneal recurrence. Inhibin has been shown to be elaborated by these tumors and often is followed to identify recurrence of the disease. The Sertoli/Leydig cell tumors can present with virilization as a primary symptom. Evaluation of the ovary when this symptom is found is always of value.

**Gestational Trophoblastic Disease.** Gestational trophoblastic disease (GTD) is a spectrum of abnormal pregnancy–related trophoblastic proliferations. Premalignant histologic types include partial and complete hydatidiform moles. Primary surgery for diagnosis and initial therapy is a suction dilatation and curettage. Clinically, partial moles present as missed abortions and usually resolve with observation. Partial moles are triploid, usually XXX, which can result from dispermic fertilization of an egg. A previously described classical presentation of hyperemesis gravidarum, hyperthyroidism, preeclampsia, pulmonary trophoblastic embolization, and uterine size larger than dates is rarely seen today because of routine ultrasound assessments during early pregnancy. Even in the first trimester, however, a characteristic “snow storm” appearance may be seen on ultrasound. Pathologic examination will demonstrate no fetal tissue and have a diploid karyotype resulting from paternal duplication occurring after loss of maternal genetic material, or occasionally
with dispermic fertilization of an empty egg. Often associated theca lutein ovarian cysts, which can be greater than 6 cm in diameter, are seen on ultrasound. They should be followed without surgical intervention as they resolve with removal or treatment of the GTD. Following uterine evacuation, patients with molar pregnancies must be followed closely with weekly β-hCGs until normal for 3 weeks and then monthly for at least 6 months. Contraception should be provided to allow for surveillance. Any increase in β-hCG should trigger further evaluation and consideration of chemotherapy.

Invasive moles, choriocarcinoma, and placental site trophoblastic tumors are malignant disorders. Invasive moles are diagnosed following the diagnosis of a molar pregnancy if any of the following are demonstrated: (a) a plateau of β-hCG lasts for four measurements over a period of 3 weeks or longer; (b) a rise in β-hCG for three consecutive weekly measurements over at least a period of 2 weeks or more; or (c) β-hCG level remains elevated for 6 months or more. Metastatic GTD can present on the cervix, vagina, liver, lung, or brain and should not be managed surgically. In a woman of reproductive age, a diagnosis of metastatic GTN can be made without biopsy if a β-hCG is found to be elevated in the setting of widespread metastatic disease. In fact, given the incidence of bleeding complications biopsy is not recommended.

Chemotherapy is the primary recommended therapy. Per 2000 FIGO staging and classification, a risk score of 6 and below is classified as low risk and above 6 is considered high risk (Table 41-15). Low-risk patients are treated with single agent chemotherapy (methotrexate or actinomycin-D); high-risk patients receive multiagent chemotherapy. In either case, chemotherapy continues until β-hCG levels have normalized. Modern salvage and cure rates are high, with 5-year survival of high-risk patients reported as high as 90%. Twelve months of surveillance with contraception is recommended following treatment in order to allow complete surveillance for relapse.

Beyond dilation and curettage, surgery may have a role in the management of GTD. Hysterectomy is recommended for placental site trophoblastic tumors for which metastasis is rare. Laparotomy may be indicated in the cases of uncontrolled intra-abdominal or uterine bleeding. Neurosurgery may be required if there is intracranial bleeding or increased intracranial pressure due to metastatic disease.

**MINIMALLY INVASIVE GYNECOLOGIC SURGERY**

**Hysteroscopy**

See earlier section, “Hysteroscopy” under “Procedures Performed for Structural Causes of Abnormal Uterine Bleeding.”

**Laparoscopy**

The standard method for gynecologic laparoscopy follows the same methods as all minimally invasive surgery. In general, a camera port is placed near the umbilicus. Sometimes it must be placed more cephalad if the patient has a larger fibroid uterus. Two additional ports are placed laterally, usually just superior and medial to the anterior superior iliac spines. Single site laparoscopic procedures may improve cosmesis and reduce postoperative pain, but challenges including lack of triangulation and instrument crowding at the umbilicus make this technique challenging to apply to more complex procedures.

**Robotic Surgery**

Over the last decade, there has been increased use of robotics for gynecologic surgery. With the DaVinci robotic system, the surgeon sits at a console and visualizes the operative field with three-dimensional optics. The use of robotic surgery has been described for virtually every gynecologic procedure that has been performed abdominally or laparoscopically. The laparoscopic instruments are “wristed” and move as the surgeon’s hands/fingers move the actuators at the console. Robotic surgery

uses a camera port, two to three robotic ports, and an accessory port. More meticulous dissection, improved visualization, and ability to operate with lower intra-abdominal pressures make the robotic platform advantageous, especially in obese patients. Longer set-up time and increased cost, however, are distinct disadvantages. The robotic unit costs up to $2.3 million and is associated with annual maintenance costs of $180,000 a year.\(^{162}\)

There is significant data to support robotic surgery in gynecologic malignancy; however, most procedures can be performed successfully with either robotic or laparoscopic platform depending on operator comfort and skill set. One large study suggested a lower conversion to laparotomy rate for robotic versus laparoscopic hysterectomy, but this was not statistically significant: conversion to laparotomy for laparoscopic hysterectomy was 9.9% compared with 4.9% for robotic cases (\(P = .06\)).\(^{163}\)

Complications Pertinent to Gynecologic Surgery

Abdominal Wall Vessels. The vessel at greatest risk of injury during the lateral trocar placement is the inferior epigastric artery. The superficial epigastric vessels and the superficial circumflex iliac vessels can be injured as well (Fig. 41-23). The primary methods to avoid vessel injury are knowledge of the vessels at risk and their visualization prior to trocar placement, when possible. The superficial vessels often can be seen and avoided by transillumination of the abdominal wall with the laparoscope. In contrast, the larger inferior epigastric vessels cannot be seen by transillumination because of their deeper location; these vessels often can be seen laparoscopically and avoided as they course along the peritoneum between the lateral umbilical fold of the bladder and the insertion of the round ligament into the inguinal canal. Anatomic variation and anastomoses between vessels make it impossible to know the exact location of all the abdominal wall vessels. For this reason, other strategies also should be used to avoid vessel injury, including the use of trocars with conical tips rather than pyramid tips and the use of the smallest trocars possible lateral to the midline.

Intestinal Injury. Another potentially serious complication of laparoscopic surgery is injury to either small or large intestines. An estimated incidence of bowel injury during laparoscopic gynecologic surgery is estimated to be 0.13%, 41% of which had a delayed diagnosis.\(^{164}\) Bowel injury can occur at the time of trocar insertion, especially if the patient has had previous abdominal procedures that often result in bowel adhesions to the anterior abdominal wall peritoneum, but rates appear similar regardless of entry technique. Due to the proximity of surgery to the bowel, thermal injury due to electrosurgery is also frequently implicated in intestinal injury. Time to diagnosis in these cases is typically several days postoperatively as a thermal injury takes time to mature and necrose.

Urologic Injuries. A risk of injury to the urogenital tract is inherent to gynecologic surgery due to proximity. Prevention of injury and intraoperative recognition and repair are crucial to avoiding long-term sequelae. Most urogenital fistulae are the result of unrecognized injuries to the urogenital tract at the time of surgery.

Bladder Injury. Placement of a Foley catheter prior to gynecologic surgery is critical to reducing risk of bladder injuries. Bladder injury during open or laparoscopic surgery results from retroperitoneal perforation during lower trocar placement or during sharp dissection of the bladder from the lower uterine segment during hysterectomy. The latter of these two situations is usually recognized intraoperatively; the first sign of the former may be postoperative hematuria, lower-port incisional drainage, or pneumoturia during laparoscopy. Once diagnosed, large defects require layered closure, whereas smaller defects usually close spontaneously within days or weeks with the aid of transurethral catheter drainage.

Ureteral Injury. Although ureteral injury is rare, occurring in less than 1% of gynecologic procedures, it is the most serious of the complications related to gynecologic surgery, particularly if unrecognized.\(^{165,166}\) There are three anatomic locations where the ureter is at risk during gynecologic procedures (see Fig. 41-5): (a) the ureter descends over the pelvic brim as it courses over the bifurcation of the common iliac artery into the external and internal iliac arteries just below the ovarian vessels; (b) in the pelvis, the ureter courses along the lateral aspect of the broad ligament to enter the base of the broad ligament; and (c) the ureter is found less than 2 cm lateral to the cervix, passing under the uterine artery and then medially over the anterior vaginal fornix before entering the trigone of the bladder—this is the most common location of ureteral injury. Ureteral injuries, including complete ligation, partial resection, or thermal injuries, usually will manifest within hours to days of surgery. Complete obstruction most often manifests as flank pain, whereas the first sign of partial or complete transection may be symptoms of intra-abdominal irritation caused by urine leakage. Transperitoneal thermal injuries resulting from fulguration of endometriosis may be similar to those after transection, but the appearance of symptoms may be delayed several days until tissue necrosis occurs.

Routine cystoscopy following hysterectomy is advocated by some gynecologists. For procedures performed for prolapse or incontinence where injury to the urinary tract is highest, routine cystoscopy is recommended. Consideration of a surgeon’s individual complication rate and the difficulty of an individual procedure are considerations for the provision of routine cystoscopy.\(^{166}\)

Vaginal Vault Dehiscence. This complication of hysterectomy seems to be more common in laparoscopic and robotic

\[\text{Figure 41-23. Location of anterior abdominal wall blood vessels.}\]
surgery. This may be due to the use of cautery in dividing the vaginal cuff or in the method of vaginal closure when done minimally invasively. Vaginal closure of the cuff appears to decrease the rate of vaginal cuff dehiscence in MIS hysterectomy.

Hemodynamically stable women without bowel evisceration may be candidates for transvaginal repair without abdominal exploration. Vaginal approach may also be appropriate in select cases of evisceration in which the bowel can be completely evaluated vaginally. Since bowel evisceration can lead to peritonitis and sepsis, all women with bowel eviscerations are considered to have a surgical emergency, and surgery should not be delayed for imaging. In most cases of bowel evisceration, evaluation of the bowel by laparoscopy or laparotomy is indicated to ensure bowel integrity.

OVERVIEW

Neurologic surgery provides the operative and nonoperative management (i.e., prevention, diagnosis, evaluation, treatment, critical care, and rehabilitation) of disorders of the central, peripheral, and autonomic nervous systems (ANSs). Such disorders include those of the brain, meninges, skull and skull base, and their blood supply, including surgical and endovascular treatment of disorders of the intracranial and extracranial vasculature supplying the brain and spinal cord; disorders of the pituitary gland; disorders of the spinal cord, meninges, and vertebral column, including those that may require treatment by fusion, instrumentation, or endovascular techniques; and disorders of the cranial and spinal nerves throughout their distribution.

An accurate history is the first step toward neurologic diagnosis. A history of trauma or of neurologic symptoms is of obvious interest, but general constitutional symptoms are also important. Neurologic disease may have systemic effects, while diseases of other systems may affect neurologic function. The patient’s general medical ability to withstand the physiologic stress of anesthesia and surgery should be understood. A detailed history from the patient and/or family, along with a reliable physical examination, will clarify these issues.

NEUROANATOMY

An understanding of neuroanatomy is the foundation of comprehensive neurologic examination and diagnosis. Salient features will be considered, from cephalad to caudal. The cerebral hemispheres (or telencephalon) consist of the cerebral cortex, underlying white matter, the basal ganglia, hippocampus, and amygdala. The cerebral cortex is the most recently evolved part of the nervous system. Its functions are mapped to discrete anatomic areas. The frontal areas are involved in executive function, decision making, and restraint of emotions. The motor strip, or precentral gyrus, is the most posterior component of the frontal lobes, and is arranged along a homunculus with the head inferior and lateral to the lower extremities superiorly and medially. The motor speech area (Broca’s area) lies in the left posterior inferior frontal lobe in almost all right-handed people and in up to 90% of left-handed people. The parietal lobe lies between the central sulcus anteriorly and the occipital lobe posteriorly. The postcentral gyrus is the sensory strip, also arranged along a homunculus. The rest of the parietal lobe is involved with awareness of one’s body in space and relative to the immediate environment, body orientation, and spatial relationships. The occipital lobes are most posterior. The visual cortex is arrayed along the apposing
medial surfaces of the occipital lobes. The left occipital lobe receives and integrates data from the left half of each retina. A left occipital lesion would therefore result in an inability to see objects right of center. The temporal lobes lie below the Sylvian fissures. The hippocampus, amygdala, and lower optic radiations (Meyer’s loops) are important components of the temporal lobe and are involved in memory, emotion, and vision, respectively. The receptive speech area (Wernicke’s area) typically is found in the area of the left posterior superior temporal lobe and inferior parietal lobe. The basal ganglia include the caudate, putamen, globus pallidus, subthalamic nucleus, substantia nigra, and nucleus accumbens. These structures are involved in the selection, activation and termination of movement, and facilitate learning of appropriate context-dependent motor behaviors.

Lying deep to the cerebral hemispheres is the diencephalon, which includes the thalamus and hypothalamus. The thalamus is a key processor and relay circuit for most motor and sensory information traveling to or from cortex. The hypothalamus regulates homeostasis via the autonomic and neuroendocrine systems.

The brain stem consists of the midbrain (mesencephalon), pons (metencephalon), and medulla (myelencephalon). Longitudinal fibers run through the brain stem, carrying motor and sensory information between the cerebral hemispheres and spinal cord. The corticospinal tract is the major motor tract, while the medial lemniscus and spinothalamic tracts are the major sensory tracts. The nuclei of cranial nerves III through XII are also located within the brain stem. These nerves relay the motor, sensory, and special sense functions of the eye, face, mouth, and throat.

The cerebellum arises from the dorsal aspect of the brain stem. It integrates somatosensory, vestibular, and motor information for coordination and timing of movement. Midline, or vermian, lesions lead to truncal ataxia. Lateral, or hemispheric, lesions lead to tremor and dyscoordination in the extremities.

The ventricular system is the cerebrospinal fluid (CSF)—containing contiguous space inside the brain, continuous with the subarachnoid space outside the brain. The paired lateral ventricles consist of temporal, occipital, and frontal horns, as well as the main body. CSF travels from each lateral ventricle through the foramina of Monroe to the third ventricle, located between the left and right thalami. CSF then drains through the cerebral aqueduct to the fourth ventricle within the brain stem. The foramen of Magendie (midline) and paired foramina of Luschka (lateral) drain to the subarachnoid space. The approximate CSF volume in an average adult is 150 mL, and the choroid plexus produces approximately 500 mL of CSF per day.

The spinal cord starts at the bottom of the medulla and extends caudally through the spinal canal to the first lumbar vertebra, approximately. Motor tracts (efferent pathways) continue from the brain stem down via the lateral and anterior corticospinal tracts to anterior horn cells, and then exit via ventral nerve roots. Sensory information (afferent pathways) enters via dorsal nerve roots, travels cranially via the dorsal columns ( proprioception and fine touch) or spinothalamic tract (pain and temperature), and into the brain stem. Paired nerves exit the spinal cord at each level. There are 31 pairs: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal.

The dorsal and ventral nerve roots at each level fuse to form mixed motor-sensory spinal nerves and spread through the body to provide innervation to muscles and sensory organs. The C5–T1 spinal nerves intersect in the brachial plexus and divide to form the main nerve branches to the arm, including the median, ulnar, and radial nerves. The L2–S4 spinal nerves intersect in the lumbar sacral plexus, and divide to form the main nerve branches to the leg, including the femoral and sciatic nerves.

The principal motor tract of the spinal cord is the corticospinal tract. It is a two-neuron path, including an upper motor neuron and a lower motor neuron. The upper motor neuron cell body is located within the motor strip of the cerebral cortex. The axon travels through the internal capsule to the brain stem, decussates at the brain stem–spinal cord junction, and travels down the contralateral corticospinal tract to the lower motor

Key Points

1. Neurologic surgery specializes in primarily surgical management of central, peripheral, and autonomic nervous system disorders.
2. Although clinical examination is paramount, neurosurgical diagnosis and treatment are aided largely by a variety of modalities, such as magnetic resonance imaging and intracranial pressure monitoring.
3. The common treatment goals for traumatic brain and spinal injury are aimed at preventing secondary insults of hypoxia and hypotension.
4. Aneurysmal subarachnoid hemorrhage remains one of the most morbid and intensive neurosurgical diseases. Endovascular therapy is a growing technology that allows for safer securing of ruptured aneurysms.
5. Brain tumors can arise from primary or metastatic tissues. Treatment typically involves resection, followed by radiation and/or chemotherapy, depending on the type and grade of tumor.
6. Spinal instrumentation is used for surgical stabilization of many types of spinal instability, including traumatic, infectious, oncologic, and degenerative.
7. Infection of the nervous system is a serious and prevalent medical problem. Operative management is indicated for most conditions in which there is symptomatic compression of neural structures.
8. Functional neurosurgery via device implantation is a rapidly evolving discipline that has already become the standard of care in treating medically refractory Parkinson’s disease and essential tremor. A wider variety of deep brain stimulation targets will treat additional neuropsychiatric diseases.
9. Stereotactic radiosurgery is a powerful treatment option for intracranial disease, whether it is primary or adjunct. Gamma knife surgery can be used to treat tumors, vascular malformations, and cranial neuralgias.
The lower motor neuron axon then travels via peripheral nerves to its target muscle. Damage to upper motor neurons typically results in hyperreflexia and mild atrophy. Damage to lower motor neurons results in flaccidity and significant atrophy.

The two major sensory tracts are three-neuron pathways. Fine touch and proprioceptive signals enter the spinal cord via the dorsal root ganglia and then ascend ipsilaterally via the dorsal columns. Then they synapse and decussate in the lower medulla, travel up the contralateral medial lemniscus to make a second synapse in the thalamus, and then finally ascend to the sensory cortex. Pain and temperature fibers first synapse in the dorsal horn of the spinal cord at their entry level, decussate, and then travel up the contralateral spinothalamic tracts to the thalamus. The second synapse occurs in the thalamus, and the output axons ascend to the sensory cortex.

The aforementioned motor and sensory tracts together constitute the somatic nervous system. In addition to this system, the ANS is the other constituent of the nervous system. The ANS carries messages for homeostasis and visceral regulation from the central nervous system (CNS) to target structures such as arteries, veins, the heart, sweat glands, and the digestive tract. CNS control of the ANS arises particularly from the hypothalamus and the nucleus of the tractus solitarius. The ANS is divided into the sympathetic, parasympathetic, and enteric systems. The sympathetic system drives the “fight or flight” response, using epinephrine to increase heart rate, blood pressure, blood glucose, and temperature, as well as to dilate the pupils. It arises from the thoracolumbar spinal segments. The parasympathetic system promotes the “rest and digest” state and uses acetylcholine to maintain basal metabolic function under nonstressful conditions. Parasympathetic fibers arise from cranial nerves III, VII, IX, and X, and from the second to fourth sacral segments. The enteric nervous system controls the complex synchronization of the digestive tract, especially the pancreas, gallbladder, and small and large bowels. It can run autonomously but is regulated by the sympathetic and parasympathetic systems.

**NEUROLOGIC EXAMINATION**

The neurologic examination is divided into several components and generally is done from head to toe. First, one must assess mental status. A patient may be awake, lethargic (will follow commands and answer questions, but then returns to sleep), stuporous (difficult to arouse), or comatose (no purposeful response to voice or pain). Cranial nerves may be thoroughly tested in the awake patient, but pupil reactivity, eye movement, facial symmetry, and gag are the most relevant measures when mental status is impaired. Motor testing is based on maximal effort of major muscle groups in those able to follow commands, while assessing for amplitude and symmetry of movement to deep central pain may be all that is possible for stuporous patients. Table 42-1 details scoring for motor assessment tests. Characteristic motor reactions to pain in patients with depressed mental status include withdrawal from the central nervous system (CNS) to target structures. T1 sequences made before and after gadolinium administration are useful for detecting neoplastic and infectious processes. T2 sequences facilitate assessment of

It is critical to document sensory patterns in spinal cord injury (SCI) patients. Muscle stretch reflexes should be examined. Often comparing left to right or upper extremity to lower extremity reflexes for symmetry is the most useful for localizing a lesion. Check for ankle-jerk clonus or up-going toes (Babinski’s test). Presence of either is pathologic and signifies upper motor neuron disease.

**Diagnostic Studies**

**Plain Films.** Plain X-rays of the skull may demonstrate fractures, osteolytic or osteoblastic lesions, radiolucent foreign bodies, or pneumocephaly (air in the head). Plain films of the cervical, thoracic, and lumbar spine are used to assess for evidence of bony trauma or soft tissue swelling suggesting fracture. Spinal deformities and osteolytic or osteoblastic pathologic processes also will be apparent. However, the use of plain films has decreased given the rapid availability and significantly increased detail of computed tomography (CT) scans. They are typically used for assessing alignment in patients with known fractures, for intraoperative localization, and postoperative assessment of spinal instrumentation.

**Computed Tomography.** The noncontrast CT scan of the head is an extremely useful diagnostic tool in the setting of new focal neurologic deficit, decreased mental status, or trauma. It is rapid and almost universally available in hospitals in the United States. Its sensitivity allows for the detection of acute hemorrhage. Fine-slice CT scanning of the spine is helpful for defining bony anatomy and pathology and is the method of choice for identifying fractures of the spine. By providing an assessment of spinal alignment, CT scans can provide an indirect assessment of ligamentous injury, for example, “Rule of Spence” for assessing transverse ligament injury during Jefferson fractures (see “Spine Trauma” section later in this chapter). Conventional contrast-enhanced CT scan will help show neoplastic or infectious processes. In the current era, contrast CT generally is used for those patients who cannot undergo magnetic resonance imaging (MRI) scanning due to pacemakers or metal in the orbits (see following section for discussion of CT angiography, venography, and perfusion).

**Magnetic Resonance Imaging.** Magnetic resonance imaging (MRI) provides excellent imaging of soft tissue structures in the head and spine. It is a complex and evolving science. Several of the most clinically useful MRI sequences are worth describing. T1 sequences made before and after gadolinium administration are useful for detecting neoplastic and infectious processes. T2 sequences facilitate assessment of

*aAdd the three scores to obtain the Glasgow Coma Scale (GCS) score, which can range from 3 to 15. Add “T” after the GCS if intubated and no verbal score is possible. For these patients, the GCS can range from 3T to 10T.*
noninvasive alternative for the initial screening assessment and follow-up of patients with suspected or known vascular lesions, as well as the evaluation of vasospasm. Similarly, fine-slice time-of-flight axial images can be reformatted in three dimensions to build MRI angiograms and MRI venograms. MRI angiograms can detect stenosis of the cervical carotid arteries or intracranial aneurysms >3 mm in diameter. MRI venograms can assess the dural venous sinuses for patency or thrombosis. Two-dimensional time of flight imaging performs vascular reconstructions purely based on flow and does not require gado
dium contrast administration.

**CT and MR Perfusion.** Perfusion scans have recently emerged as a method to a global assessment of the vascular integrity in the cerebral hemispheres, which is very important in the assessment of ischemic stroke (see “Stroke”). CT perfusion scans generate quantitative color maps that indicate various physiologic parameters such as cerebral blood flow (CBF), cerebral blood volume (CBV), and mean transit time (MTT) through quantitative analysis of rapidly acquired image sequences during intravenous contrast administration. Similar to perfusion CT, perfusion MRI can be used to generate quantitative color maps of relative cerebral CBV and MTT. These perfusion-based measures can be used along with diffusion-weighted imaging in the evaluation of ischemic stroke, particularly to identify an ischemic “penumbra” or tissue that is ischemic but not yet infarcted, and may be salvageable with intervention.3,4

**Angiography.** Transarterial catheter-based angiography remains the gold standard for evaluation of vascular pathology of the brain and spine. The current state of the art is biplane imaging to reduce dye load and facilitate interventional procedures. Digital subtraction technologies minimize bony interference in the resultant images. Bilateral carotid arteries and bilateral vertebral arteries may be injected and followed through arterial, capillary, and venous phases for a complete cerebral angiogram.

**Electroencephalography.** Electroencephalography (EEG) involves measuring weak electrical signals from the brain that are transmitted through the skull through electrodes that are applied to the scalp. The voltage fluctuations detected by EEG are thought to reflect summed membrane potentials from underlying brain tissue. Clinically, EEG is useful for detecting seizures, interictal markers of epileptogenic tissue, and widespread abnormalities in brain function, such as diffuse encephalopathy. EEG is also used in concert with electrical stimulation to detect sensory evoked potentials that can be useful for intraoperative mapping during cranial and spine surgery.

**Electromyography and Nerve Conduction Studies.** Electromyography and nerve conduction studies (EMG/NCS) are useful for assessing the function of peripheral nerves. EMG records muscle activity in response to a proximal stimulation of the motor nerve. NCS record the velocity and amplitude of the nerve action potential. EMG/NCS typically is performed approximately 3 to 4 weeks after an acute injury, as nerves distal to the injury continue to transmit electrical impulses normally until degeneration of the distal nerve progresses.

**Invasive Monitoring.** The most reliable monitor, always, is an alert patient with a reliable neurologic examination. If a reliable neurologic examination is not possible due to the presence of brain injury, sedatives, or paralytics, or if there is active and unstable intracranial pathology, invasive monitoring is required. There are several methods of monitoring intracranial physiology. The methods described in the following sections are bedside intensive care unit (ICU) procedures that allow for continuous monitoring. Both procedures involve making a small hole in the skull with a hand-held drill. They generally are placed in the right frontal region to minimize the neurologic impact of possible complications such as hemorrhage.

**External Ventricular Drain.** An external ventricular drain is also known as a ventriculostomy. A perforated plastic catheter is inserted into the frontal horn of the lateral ventricle. An uninterrupted fluid column through a rigid tube allows transduction of intracranial pressure (ICP). CSF also can be drained to reduce ICP or sampled for laboratory studies.

**Intraparenchymal Physiologic Monitoring.** Intraparenchymal monitors can be inserted into the brain through a threaded post locked securely into a burr hole, commonly referred to as a bolt. A bolt allows ICP monitoring with a fiber-optic pressure transducer, but it is smaller and less invasive than a ventriculostomy and may be associated with fewer complications, although the data do not clearly support this. Furthermore, a bolt can also be used to introduce probes to measure brain tissue oxygenation, brain temperature, and to perform microdialysis of parenchymal samples; however, the utility of these latter measures in clinical practice is still under investigation. Patients with severe brain injury due to trauma or aneurysmal hemorrhage may benefit from placement of these sensors in addition to a ventriculostomy to drain CSF for control of ICP. Such monitoring requires two twist-drill holes, which may be placed on adjacent or opposite sides of the head.

**NEUROLOGIC AND NEUROSURGICAL EMERGENCIES**

**Raised Intracranial Pressure**

ICP normally varies between 4 and 14 mmHg. Sustained ICP levels above 20 mmHg can injure the brain. The Monro-Kellie doctrine states that the cranial vault is a rigid structure, and therefore, the total volume of the contents determines ICP. The three normal contents of the cranial vault are brain tissue, blood, and CSF. The brain’s contents can expand due to swelling from traumatic brain injury (TBI), stroke, or reactive edema. Blood volume can increase by extravasation to form a hematoma, or by reactive vasodilation in a hypoventilating, hypercarbic patient. CSF volume increases in the setting of hydrocephalus. Figure 42-2 demonstrates the classic CT findings of hydrocephalus. The addition of a lesion, such as a tumor or abscess, also will increase ICP. The pressure-volume curve depicted in Fig. 42-3 demonstrates a compensated region with a small ΔP/ΔV, and an uncompensated region with large ΔP/ΔV.

In the compensated region, increased volume is offset by decreased volume of CSF and blood.

Increased ICP can injure the brain in several ways. Focal mass lesions cause shift and herniation. Temporal lesions push the uncus medially and compress the midbrain. This phenomenon is known as uncal herniation. The posterior cerebral artery (PCA) passes between the uncus and midbrain and may be occluded, leading to an occipital infarct. Masses higher up in the hemisphere can push the cingulate gyrus under the falx cerebri. This process is known as subfalcine herniation. The anterior cerebral artery (ACA) branches run along the medial surface of the cingulate gyrus and may be occluded in this case, leading to medial frontal and parietal infarcts. Diffuse increases in pressure
in the cerebral hemispheres can lead to central, or transtentorial, herniation. Increased pressure in the posterior fossa can lead to upward central herniation or downward tonsillar herniation through the foramen magnum. Uncal, transtentorial, and tonsillar herniation can cause direct damage to the brain stem. Figure 42-4 diagrams patterns of herniation.

Patients with increased ICP, or intracranial hypertension, often will present with headache, nausea, vomiting, and progressive mental status decline. Cushing’s triad is the classic presentation of hypertension, bradycardia, and irregular respirations. Focal neurologic deficits such as hemiparesis may be present if there is a focal mass lesion causing the problem. Patients with these symptoms should undergo an immediate head CT and rapid neurosurgical evaluation.

Initial management of intracranial hypertension includes airway protection and adequate ventilation. A bolus of mannitol up to 1 g/kg causes free water diuresis, increased serum osmolality, and extraction of water from the brain. The effect is delayed by about 20 minutes and has a transient benefit. Driving serum osmolality above 300 mOsm/L is of indeterminate benefit and can have deleterious cardiovascular side effects, such as hypovolemia that leads to hypotension and decreased brain perfusion. A ventriculostomy and/or craniectomy may be needed for definitive decompression.

It is critical to note that lethargic or obtunded patients often have decreased respiratory drive. This causes the partial pressure of arterial carbon dioxide (Paco₂) to increase, resulting in cerebral vasodilation and worsening of intracranial hypertension. This cycle causes a characteristic “crashing patient,” who rapidly loses airway protection, becomes apneic, and herniates. Emergent intubation and ventilation to reduce Paco₂ to roughly 35 mmHg can reverse this process.

Figure 42-2. Head computed tomography scan demonstrating hydrocephalus. The third ventricle (3rd) is widened and rounded, the anterior horns of the lateral ventricles are plump, and pressure-driven flow of cerebrospinal fluid into brain parenchyma adjacent to the ventricles is seen (arrowhead). This is known as transependymal flow of cerebrospinal fluid.

Figure 42-3. Pressure-volume curve demonstrating the effect of changing the volume of intracranial contents on intracranial pressure. Note the compensated zone, with little change of pressure with change of volume, and the uncompensated zone, with significant change of pressure with change of volume. (Adapted with permission from Ellenbogen RG, Abdulrauf SI, Sekhar LN: Principles of Neurosurgery, 3rd ed. Philadelphia, PA: Elsevier/Saunders; 2012.)
Brain Stem Compression

The posterior fossa (brain stem and cerebellum) requires special consideration because the volume of the posterior fossa within the cranial vault is small. Posterior fossa lesions such as tumors, hemorrhage, or stroke can cause mass effect that can rapidly kill the patient in two ways. Occlusion of the fourth ventricle can lead to acute obstructive hydrocephalus, raised ICP, herniation, and eventually death. This mass effect can also lead directly to brain stem compression (Fig. 42-5). Symptoms of brain stem compression include hypertension, agitation, and progressive obtundation, followed rapidly by brain death. A patient exhibiting any of these symptoms needs an emergent neurosurgical evaluation for possible ventriculostomy or suboccipital craniectomy (removal of the bone covering the cerebellum). This situation is especially critical, as expeditious decompression can lead to significant functional recovery.

Stroke

Patients presenting with acute focal neurologic deficits at a clearly defined time of onset (i.e., when the patient was last seen in a normal state of health) must be evaluated as rapidly as possible. An emergent head CT scan should be done. The study is often normal because CT changes from ischemic stroke may take up to 24 hours to appear (Fig. 42-6). A patient with a clinical diagnosis of acute stroke <4.5 hours old, without hemorrhage on CT, may be a candidate for thrombolytic therapy with tissue plasminogen activator (tPA). When a proximal large-vessel obstruction is suspected, patients should be evaluated for endovascular mechanical thrombectomy if therapy can be initiated within 6 to 8 hours of symptom onset. Intravenous tPA should be given regardless, but a noninvasive intracranial vascular study such as CT angiography should also be obtained in these cases. An emergent MRI is helpful but not always diagnostically necessary.

Seizure

A seizure is defined as an uncontrolled synchronous organization of neuronal electrical activity. A new-onset seizure often signifies an irritative mass lesion in the brain, particularly in adults, in whom tumors commonly present with seizure. Patients with traumatic intracranial hemorrhage are at risk for seizure. In addition to airway and ventilatory problems, a seizing patient is also at risk for neural excitotoxicity if the activity is prolonged, such as in status epilepticus. Any patient with a new-onset seizure should have imaging of the brain after the seizure is controlled and the patient is resuscitated.

TRAUMA

Trauma is the leading cause of death in children and young adults; however, the incidence of death and disability from trauma has been slowly decreasing. This decline is partly attributable to increased awareness of safety devices such as seat belts and motorist helmets. Nonetheless, trauma remains a major cause of morbidity and mortality, and it can affect every major organ system in the body. The three main areas of neurosurgical focus are: traumatic brain injury (TBI), spinal cord injury (SCI), and peripheral nerve injury.

Head Trauma

Glasgow Coma Scale Score. The initial assessment of the trauma patient includes the primary survey, resuscitation,
secondary survey, and definitive care. Neurosurgical evaluation begins during the primary survey with the determination of the GCS score (usually referred to simply as the GCS) for the patient. The GCS is determined by adding the scores of the best responses of the patient in each of three categories. The motor score ranges from 1 to 6, verbal from 1 to 5, and eyes from 1 to 4. The GCS therefore ranges from 3 to 15, as detailed in Table 42-2. Tracheal intubation or severe facial or eye swelling can impede verbal and eye responses. In these circumstances, the patient is given the score of 1 with a modifier, such as verbal “1T” where T = tube.

**Scalp Injury.** Blunt or penetrating trauma to the head can cause injury to the densely vascularized scalp, and significant blood loss can result. Direct pressure initially controls the bleeding, allowing close inspection of the injury. If a simple laceration is found, it should be copiously irrigated and closed primarily. If the laceration is short, a single-layer, percutaneous suture closure will suffice. If the laceration is long or has multiple arms, the patient may need debridement and closure in the operating room, with its superior lighting and wider selection of instruments and suture materials. Careful reapproximation of the galea will provide a more secure closure and better hemostasis.
Blunt trauma also can cause crush injury with subsequent tissue necrosis. These wounds require debridement and consideration of advancement flaps to cover the defect.

**Skull Fractures.** The usual classification system for bony fractures may be applied to the skull. The fracture may be characterized by skull X-rays or head CT. A closed fracture is covered by intact skin. An open, or compound, fracture is associated with disrupted overlying skin. The fracture lines may be single (linear); multiple and radiating from a point (stellate); or multiple, creating fragments of bone (comminuted). Closed skull fractures do not normally require specific treatment. Open fractures require repair of the scalp and operative debridement. Indications for craniotomy include depression greater than the cranial thickness, intracranial hematoma, and frontal sinus involvement. Skull fractures generally indicate that a significant amount of force was transmitted to the head and should increase the suspicion for intracranial injury. Fractures that cross meningeal arteries can cause rupture of the underlying vessels and subsequent epidural hematoma (EDH) formation.

Depressed skull fractures may result from a focal injury of significant force. The inner and outer cortices of the skull are disrupted, and a fragment of bone is pressed in toward the brain in relation to adjacent intact skull. The fragment may overlap the edge of intact bone, or it may plunge completely below the level of adjacent normal skull. The inner cortex of the bone fragments often has multiple sharp edges that can lacerate dura, brain, and vessels. Craniotomy is required to elevate the fracture, repair dural disruption, and obtain hemostasis in these cases (Fig. 42-7). However, fractures overlying dural venous sinuses require restraint. Surgical exploration can lead to life-threatening hemorrhage from the lacerated sinus.

Fractures of the skull base are common in head-injured patients, and they indicate significant impact. They are generally apparent on routine head CT, but they should be evaluated with dedicated fine-slice coronal-section CT scan to document and delineate the extent of the fracture and involved structures. If asymptomatic, they require no treatment. Skull base fractures requiring intervention include those with an associated cranial nerve deficit or CSF leak. A fracture of the temporal bone, for instance, can damage the facial or vestibulocochlear nerve, resulting in vertigo, ipsilateral deafness, or facial paralysis. A communication may be formed between the subarachnoid space and the middle ear, allowing CSF drainage into the pharynx via the Eustachian tube or from the ear (otorrhea). Extravasation of blood results in ecchymosis behind the ear, known as Battle’s sign. A fracture of the anterior skull base can result in anosmia (loss of smell from damage to the olfactory nerve), CSF drainage from the nose (rhinorrhea), or periorbital ecchymosis, known as raccoon eyes.

Copious clear drainage from the nose or ear makes the diagnosis of CSF leakage obvious. Often, however, the drainage may be discolored with blood or small in volume if some drains into the throat. In indeterminate cases, it is important to consider radiographic findings on the CT scan near the fracture that suggest CSF leak, such as pneumocephalus, subarachnoid, or intraparenchymal blood at the fracture site. The “halo” test assesses for a double ring when a drop of the fluid is allowed to fall on an absorbent surface, but it has been shown to have poor clinical utility. The fluid can be sent for β-2 transferrin testing, a carbohydrate-free isoform of transferrin exclusively found in the CSF; however, these tests often take 1 to 2 weeks to result and also can be difficult to incorporate into clinical practice.

![Figure 42-7](image-url)  
**Figure 42-7.** A. Bone-window axial head computed tomography (CT) of a patient who presented aphasic after being struck with the bottom of a beer bottle. CT demonstrates a depressed skull fracture in the left posterior temporoparietal area. B. Brain-window axial head CT demonstrating intraparenchymal hematoma caused by laceration of cortical vessels by the edge of the fractured bone. Arrowhead indicates traumatic subarachnoid hemorrhage in the sylvanian fissure.
Many CSF leaks will heal with elevation of the head of the bed for several days. An elevation of the head of the bed reduces the hydrostatic pressure of the CSF fluid column in the cranial vault, near the site of the defect. As such, when the CSF leak is in the lumbar thecal sac, the head of the bed should be flat so as to maximize hydrostatic pressure of the CSF fluid column at the cranial vault, away from the site of the defect. In addition, lumbar drain can be used to reduce CSF pressure. When there is a contraindication, to lumbar drain placement (such as an intracranial mass lesion or hematoma), an extraventricular drain should be used for CSF diversion. Although persistent CSF leaks have been shown to increase the risk of meningitis, there is no evidence supporting the use of prophylactic antibiotic use for preventing meningitis in patients with CSF leaks.

Traumatic cranial neuropathies generally can be managed conservatively, with documentation of the extent of impairment and signs of recovery. Patients with traumatic facial nerve palsies may benefit from a course of steroids, although their benefit is unproven. Patients with facial nerve palsy of abrupt onset, who do not respond to steroids within 48 to 72 hours, may be considered for surgical decompression of the petrous portion of the facial nerve. Patients also may present with delayed-onset facial nerve palsy. Again, steroids are used and surgery can be considered, with mixed results.

Closed Head Injury. Closed head injury (CHI) is the most common type of TBI and a significant cause of morbidity and mortality in the United States. There are two important factors that affect the outcome of CHI in general. The initial impact causes the primary injury, defined as the immediate injury to neurons from transmission of the force of impact. The long, delicate axons of the neurons can shear as they undergo differential acceleration or deceleration along their projecting pathways. Prevention strategies, such as wearing helmets, remain the best means to decrease disability from primary injury. Subsequent neuronal damage due to the sequelae of trauma is referred to as secondary injury. Hypoxia, hypotension, hydrocephalus, intracranial hypertension, thrombosis, and intracranial hemorrhage may all be mechanisms of secondary injury.

One focus of basic research in TBI, critical care medicine, and neurosurgical intervention is to decrease the effects of secondary injury.

The Brain Trauma Foundation’s most recent summary of management recommendations for TBI patients was published in 2016 and is endorsed by the American Association of Neurological Surgeons, Congress of Neurological Surgeons, and the World Health Organization. The guidelines standardize the care of these patients with the hope of improving outcomes. Level I recommendations are based on a body of high-quality evidence, such as large, well-received randomized controlled trials. Level II and III recommendations are based on moderate and low quality evidence, respectively. Some of the common patterns of CHI, including concussion, contusion, and diffuse axonal injury, are discussed in “Types of Closed Head Injury.”

Initial Assessment The initial evaluation of a trauma patient remains the same whether or not the primary surveyor suspects head injury. The first three elements of the ABCDs of resuscitation—airway, breathing, and circulation—must be assessed and stabilized. Hypoxia and hypotension are known to worsen outcome in TBI (due to secondary injury), making cardiopulmonary stabilization critical. Patients who cannot follow commands require intubation for airway protection and ventilatory control. The fourth element, assessment of “D,” for disability, is undertaken next. Motor activity, speech, and eye opening can be assessed in a few seconds and a GCS score assigned.

The following is an example of how a primary surveyor may efficiently assess disability and GCS: Approach the patient and enter his or her field of view. Observe whether the patient is visually attentive. Clearly command: “Tell me your name.” Then ask the patient to lift up two fingers on each side sequentially, and wiggle the toes. A visually or verbally unresponsive patient should be assessed for response to peripheral stimuli such as nail-bed pressure, or deep central painful stimulation, such as a firm, twisting pinch of the sensitive supraclavicular skin. Watch for eye opening and movement of the extremities, whether purposeful or reflexive. Assess the verbal response. The motor, verbal, and eye-opening scores may be correctly assigned using this rapid examination. An initial assessment of the probability of significant head injury can be made, assuming that pharmacologic and toxic elements have not obscured the examination. The surveyor must also take note of any external signs of head injury, including bleeding from the scalp, nose, or ear, or deformation of the skull or face.

Classification TBI can be classified as mild, moderate, or severe. For patients with a history of head trauma, classification is as follows: severe head injury if the GCS score is 3 to 8, moderate head injury if the GCS score is 9 to 12, and mild head injury if the GCS score is 13 to 15. Many patients present to emergency rooms and trauma bays with a history of TBI. A triage system must be used to maximize resource utilization while minimizing the chance of missing occult or progressing injuries.

TBI patients who are asymptomatic, who have only headache, dizziness, or scalp lacerations, and who did not lose consciousness, have a low risk for intracranial injury and may be discharged home without a head CT scan. Head-injured patients who are discharged should be sent home with reliable family or friends who can observe the patient for the first post-injury day. Printed discharge instructions, which describe monitoring for confusion, persistent nausea, weakness, or speech difficulty, should be provided to the caretaker. The patient should return to the emergency department for evaluation of such symptoms.

Patients with a history of altered consciousness, amnesia, progressive headache, skull or facial fracture, vomiting, or seizure have a moderate risk for intracranial injury and should undergo a prompt head CT. If the CT is normal, and the neurologic examination has returned to baseline (excluding amnesia of the event), then the patient can be discharged to the care of a responsible adult, again with printed criteria for returning to the emergency room. Otherwise the patient must be admitted for a 24-hour observation period.

Patients with depressed consciousness, focal neurologic deficits, penetrating injury, depressed skull fracture, or changing neurologic examination have a high risk for intracranial injury. These patients should undergo immediate head CT and admission for observation or intervention as needed.

Types of Closed Head Injury

Concussion A concussion is defined as temporary neuronal dysfunction following nonpenetrating head trauma. The head CT is normal, and deficits resolve over minutes to hours. Definitions vary; some require transient loss of consciousness, while others include patients with any alteration of mental status. Memory difficulties, especially amnesia of the event, are very
common. Concussions may be graded. One method is the Colorado grading system. Head trauma patients with confusion only are grade 1, patients with amnesia are grade 2, and patients who lose consciousness are grade 3. Studies have shown that the brain remains in a hypermetabolic state for up to a week after injury. The brain is also much more susceptible to injury from even minor head trauma in the first 1 to 2 weeks after concussion. This is known as second-impact syndrome, and patients should be informed that, even after mild head injury, they might experience memory difficulties or persistent headaches. Return to play guidelines after sports-related concussions are controversial and are under active debate.

**Contusion** A contusion is a bruise of the brain, and occurs when the force from trauma is sufficient to cause breakdown of small vessels and extravasation of blood into the brain. The contused areas appear bright on CT scan, as seen in Fig. 42-8. The frontal, occipital, and temporal poles are most often involved. The brain sustains injury as it collides with rough, bony surfaces. Contusions themselves rarely cause significant mass effect as they represent small amounts of blood in injured parenchyma rather than coherent blood clots. Edema may develop around a contusion, causing mass effect. Contusions may enlarge or progress to frank hematoma, particularly during the first 24 hours. Contusions also may occur in brain tissue opposite the site of impact. This is known as a contre-coup injury. These contusions result from deceleration of the brain against the skull.

**Diffuse Axonal Injury** Diffuse axonal injury (DAI) is caused by damage to axons throughout the brain, due to rotational acceleration and then deceleration. Axons may be completely disrupted and then retract, forming axon balls. Small hemorrhages can be seen in more severe cases, especially on MRI.

Hemorrhage is classically seen in the corpus callosum and the dorsolateral midbrain. DAI can be considered to be a severe form of a concussion, often with irreversible consequence. It can often explain a poor neurological examination (such as impaired arousal) in cases without clear radiographic signs of global brain injury, particularly when there is damage in structures, such as the pontine reticular activating system or bilateral thalami, that are necessary for arousal. In these cases, alternative explanations of poor arousal, such as a basilar thrombus, must also be investigated.

**Penetrating Injury** These injuries are complex and must be evaluated individually. The two main subtypes are missile (e.g., due to bullets or fragmentation devices) and nonmissile (e.g., due to knives or ice picks). Some general principles apply. If available, skull X-rays and CT scans are useful in assessing the nature of the injury. Cerebral angiography must be considered if the object passes near a major artery or dural venous sinus. Operative exploration is necessary to remove any object extending out of the cranium, as well as for debridement, irrigation, hemostasis, and definitive closure. Small objects contained within brain parenchyma are often left in place to avoid iatrogenic secondary brain injury. High-velocity missile injuries (from high-powered hunting rifles or military weapons) are especially deadly, because the associated shock wave causes cavitory tissue destruction of an area that is much larger than the projectile itself. Projectiles that penetrate both hemispheres or traverse the ventricles are almost universally fatal. Antibiotics are given to decrease the chances of meningitis or abscess formation; however, the evidence supporting the use of antibiotics following missile injury is weak and largely comes from retrospective case studies and expert opinion. Recent guidelines published in regard to preventing combat-related infections recommend antimicrobial therapy for 5 days or until resolution of the associated CSF leak, albeit with limited supporting evidence.

**Traumatic Intracranial Hematomas.** The various traumatic intracranial hematomas contribute to death and disability secondary to head injury. Hematomas can expand rapidly and cause brain shift and subsequent herniation. Emergent neurosurgical evaluation and intervention often are necessary.

**Epidural Hematoma** EDH is the accumulation of blood between the skull and the dura. EDH usually results from arterial disruption, especially of the middle meningeal artery. The dura is adherent to bone, and some pressure is required to dissect between the two. On head CT, the blood clot is bright, biconvex in shape (lentiform), and has a well-defined border that usually respects cranial suture lines. An EDH is typically found over the convexities but may rarely occur in the posterior fossa as well. EDH has a classic, three-stage clinical presentation that is probably seen in only 20% of cases. The patient is initially unconscious from the concussive aspect of the head trauma. The patient then awakens and has a “lucid interval,” while the hematoma subclinically expands. As the volume of the hematoma grows, the decompensated region of the pressure-volume curve is reached, ICP increases, and the patient rapidly becomes lethargic and herniates. Uncal herniation from an EDH classically causes ipsilateral third nerve palsy and contralateral hemiparesis.

Open craniectomy for evacuation of the congealed clot and hemostasis generally is indicated for EDH. In some cases, EDH can be caused from bony venous bleeding that is self-limited.

---

Figure 42-8. Severe bilateral contusions in the basal aspect of the frontal lobes, caused by the brain moving over the rough, irregular skull base during sudden cranial acceleration.
and may not require surgical intervention. Generally, patients who meet all of the following criteria may be managed conservatively: clot volume <30 cm\(^3\), maximum thickness <1.5 cm, and GCS score >8.\(^9\) Prognosis after successful evacuation is better for EDH than subdural hematoma (SDH). EDHs are associated with lower-energy trauma with less resultant primary brain injury. Good outcomes may be seen in 85% to 90% of patients, with rapid CT scan and intervention.\(^1\) In some cases, EDH can also be caused by dural venous sinus tears that rapidly expand and are typically associated with a high degree of morbidity when treated surgically.

**Acute Subdural Hematoma** An acute SDH is the result of an accumulation of blood between the arachnoid membrane and the dura. Acute SDH usually results from venous bleeding, typically from tearing of a bridging vein running from the cerebral cortex to the dural sinuses. The bridging veins are subject to stretching and tearing during acceleration/deceleration of the head because the brain shifts in relation to the dura, which firmly adheres to the skull. Elderly and alcoholic patients are at higher risk for acute SDH formation after head trauma due to brain atrophy.

On head CT scan, the clot is bright or mixed-density, crescent-shaped (lunate), may have a less distinct border, and does not cross the midline due to the presence of the falk. Most SDHs occur over the cerebral hemispheres, but they may also occur between the hemispheres or layer over the tentorium.

Open craniotomy for evacuation of acute SDH is indicated for any of the following: thickness >1 cm, midline shift >5 mm, or GCS drop by two or more points from the time of injury to hospitalization. Nonoperatively managed hematomas may stabilize and eventually reabsorb, or evolve into chronic SDHs.\(^1\) This management requires frequent neurologic examinations until the clot stabilizes based on serial head CT scans.

The prognosis for functional recovery is significantly worse for acute SDH than EDH because it is associated with greater primary injury to brain parenchyma from high-energy impacts. Prompt recognition and intervention minimizes secondary injury. The elderly patients with low admission GCS, or GCS drop by two or more points from the time of injury to hospitalization. Nonoperatively managed hematomas may stabilize and eventually reabsorb, or evolve into chronic SDHs.\(^1\) This management requires frequent neurologic examinations until the clot stabilizes based on serial head CT scans.

Nonoperatively managed hematomas may stabilize and eventually reabsorb, or evolve into chronic SDHs.\(^1\) This management requires frequent neurologic examinations until the clot stabilizes based on serial head CT scans.

**Chronic Subdural Hematoma** Chronic SDH is a collection of blood breakdown products that is at least 2 to 3 weeks old. Acute hematomas are bright white (hyperdense) on CT scan for approximately 3 days, after which they fade to isodensity with brain, and then to hypodensity after 2 to 3 weeks. A true chronic SDH will be nearly as dark as CSF on CT. Traces of white blood are often seen due to small, recurrent hemorrhages into the collection. These small bleeds may expand the collection enough to make it symptomatic. This phenomenon is referred to as an acute-on-chronic SDH. Figure 42-9 demonstrates the CT appearance of an acute-on-chronic SDH. Vascularized membranes form within the hematoma as it matures. These membranes may be the source of acute hemorrhage.

Chronic SDHs often occur in patients without a clear history of head trauma as they may arise from minor head injury. Alcoholics, the elderly, and patients on anticoagulation are at higher risk for developing chronic SDH. Patients may present with headache, seizure, confusion, contralateral hemiparesis, or coma.

A chronic SDH >1 cm or any symptomatic SDH should be surgically drained. Unlike acute SDH, which consists of a thick, congealed clot, chronic SDH typically consists of a viscous fluid with the texture and dark brown color reminiscent of motor oil. A simple burr hole can effectively drain most chronic SDHs. However, the optimal treatment of chronic SDH remains controversial.\(^19\) Recent data suggest that open craniotomy is effective at reducing recurrence, but may be associated with more short-term complications.\(^20\) Most authorities agree that burr hole drainage should be attempted first to obviate the risks of formal craniotomy.\(^21\) A single burr hole placed over the dependent edge of the collection can be made, and the space is copiously irrigated until the fluid is clear. A second, more anterior burr hole can then be placed if the collection does not drain satisfactorily due to containment by membranes. The procedure is converted to open craniotomy if the SDH is too congealed for irrigation drainage, the complex of membranes prevents effective drainage, or persistent hemorrhage occurs that cannot be reached with bipolar cautery through the burr hole. The required surgical prepping and draping are always performed to allow simple conversion to craniotomy, and the scalp incision and burr holes are placed to allow easy incorporation into larger skin flaps.

There are various strategies to prevent reaccumulation of blood. Subdural or subgaleal drains may be left in place for 1 to 2 days. Subdural drains have been shown to reduce the risk of recurrence, whereas corticosteroid use in this patient population has been associated with higher morbidity without benefit.\(^20\) Mild hydration and bedrest with the head of the bed flat may

![Figure 42-9. Head computed tomography scan of an elderly patient with progressing left hemiplegia and lethargy, demonstrating an acute-on-chronic subdural hematoma.](image-url)
encourage brain expansion. High levels of inspired oxygen may help draw nitrogen out of the cavity. Regardless of the strategy used, follow-up head CT scans are required postoperatively and approximately 1 month later to document resolution.

**Intraparenchymal Hemorrhage** Isolated hematomas within the brain parenchyma are most often associated with hypertensive hemorrhage or arteriovenous malformations (AVMs). Bleeding may occur in a contused area of brain. Mass effect from developing hematomas may present as a delayed neurologic deficit. Delayed traumatic intracerebral hemorrhage is most likely to occur within the first 24 hours. Patients with contusion on the initial head CT scan should be reimaged 24 hours after the trauma to document stable pathology. Indications for craniotomy include: any clot volume >50 cm³ or a clot volume >20 cm³ with referable neurologic deterioration (GCS 6–8) and associated midline shift >5 mm or basal cistern compression.

**Pneumocephalus** Pneumocephalus, or air in the intracranial cavity, is commonly seen in neurosurgical patients following head trauma or following intracranial surgery. Pneumocephalus requires a defect in the skull that allows air to enter the intracranial cavity. This may occur following may represent an iatrogenic defect created following cranial surgery or following head trauma. Approximately 66% of postcraniotomy CT scans demonstrate some extent of pneumocephalus. The identification of pneumocephalus following head trauma can offer important clues about the extent of injury, such as the presence of skull based fractures or a CSF leak. In rare cases, pneumocephalus can also be seen in association with skull based tumors or infections.

A tension pneumocephalus occurs when the intracranial air pocket is under tension which can result in life threatening herniation if left untreated. This is a neurosurgical emergency and requires an urgent neurosurgical consultation. Two radiographic features have been associated with a tension pneumocephalus (Fig. 42-10). First, the “Mount Fuji” sign, where the air pocket separates the frontal lobes and widens the inter-hemispheric fissure, mimicking the silhouette of Mount Fuji. Second, the “air bubble” sign, where there are multi-focal pockets of air throughout the subarachnoid cisterns, putatively within the subarachnoid space. These radiographic findings are helpful clues; however, the diagnosis of tension pneumocephalus also requires a worsening neurological exam consistent with increased intracranial pressure and impending herniation. A burr hole may be used to relieve intracranial pressure per the discretion of the neurosurgical team.

When not associated with tension dynamics, the clinical significance and management of pneumocephalus depends on the underlying mechanism. There are thought to be two major mechanisms by which pneumocephalus develops. First, the “ball valve” mechanism involves the passage of air into the intracranial cavity during periods of positive pressure, whereby the defect in the skull acts as a one-way valve. In these cases, management involves avoiding positive pressure ventilation, and laying the head of the bed flat to minimize air traveling upwards into the cranial cavity. Second, the “inverted bottle” mechanism involves air entering the intracranial space due to a negative pressure gradient created by the drainage of CSF. In most cases, drainage occurs through a traumatic or iatrogenic CSF leak, but it may also occur through ventricular or lumbar drainage. In these cases, management should be focused on minimizing CSF drainage through the defect. If the CSF leak is at the skull base, as is the case following basilar skull fractures, or those involving the mastoid air cells, then the head of bed must be elevated so as to reduce hydrostatic pressure in the ventricular CSF fluid column, and controlled CSF diversion can be performed using an extraventricular or lumbar drain (see “Skull Fractures” for further discussion). Definitive repair of the skull-based defect can also be considered, but this is often done on an elective basis. In general, nontension pneumocephalus will resolve on its own with time as it is resorbed into the blood stream. Supplemental 100% oxygen may be used to increase the rate of resorption by increasing the diffusion gradient of nitrogen-predominant intracranial air pocket and the blood stream.

**Management of Traumatic Brain Injury**

**General Medical Management** Several medical steps may be taken to minimize secondary injury and the systemic consequences of head injury. Patients with a documented CHI and evidence of intracranial hemorrhage or a depressed skull fracture should receive a 1 g Keppra loading dose, followed by 1 week of therapeutic maintenance Keppra, typically 500 mg twice a day. Antiseizure prophylaxis has been shown to decrease the incidence of early posttraumatic seizures. There is no evidence to support long-term use of prophylactic antiepileptic agents. Even though the clinical studies supporting early antiseizure prophylaxis used phenytoin, Keppra is typically used in clinical practice due to a more favorable side effect profile. Blood glucose levels should be closely monitored by free blood sugar checks and controlled with sliding scale insulin. Fevers also should be evaluated and controlled with antipyretics, as well as source-directed therapy when possible. Hyperglycemia and hyperthermia are toxic to injured neurons and contribute to secondary injury. Head-injured patients have an increased prevalence of peptic ulceration and GI bleeding. Peptic ulcers occurring in patients with head injury or high ICP are referred to as Cushing’s ulcers. Ulcer prophylaxis should be used. Compression stockings or athrombic pumps should be used when the patient cannot be mobilized rapidly for prophylaxis of deep venous thrombosis.

**Steroids and Traumatic Brain Injury** Per a level 1 recommendation (high-quality evidence) from the Brain Trauma Foundation, steroids are not recommended for the management of TBI or reduction of elevated ICP. Also, high-dose methylprednisolone is contraindicated in severe TBI. A large randomized controlled trial (CRASH; n = 9673, 6-month follow-up, 24
demonstrated an increased risk of 6-month mortality in severe TBI (GCS 3–8) that received methylprednisolone (47%), as compared to placebo (42%, \( P = 0.0024 \)). This effect was also present when analyzing TBI of all severity levels (25.7% methylprednisolone vs. 22.3% placebo, \( P = 0.0001 \)).

**Blood Pressure Management** Blood pressure management in TBI is a complex issue. On one hand, hypotension results in hypoperfusion that may worsen brain injury that occurs following TBI. On another hand, hypertension may result in expansion of intracranial hematomas that are often seen in TBI.

There is clear evidence from retrospective studies, that frank hypotension (SBP <90 mmHg) is associated with increased mortality in TBI, particularly in the prehospital setting and during resuscitation.\(^2\) A large retrospective cohort study (\( n = 15,733 \)) identified hypotension thresholds that were associated with an increased risk of mortality in patients with TBI of varying age.\(^3\) Based on these data, the Brain Trauma Foundation guidelines\(^10\) provide a level III (low-quality) recommendation that maintaining systolic blood pressures >100 mmHg (ages 50–69 years), or >110 mmHg (ages 15–49 years or >70 years) may be considered to reduce mortality and improve outcomes. More recently, a large retrospective study\(^3\) demonstrated a dose-dependent relation between the duration of prehospital hypotension and increased mortality in patients with TBI, such that a 10-point increase in systolic blood pressure across a broad range (40–119 mmHg) was associated with an 18.8% decrease in adjusted odds of in-hospital mortality. These results suggest that having a single “hypotension threshold” may not be sufficient in management of TBI and may require more aggressive management than currently employed. Furthermore, an important and underappreciated consideration in blood pressure management is the baseline blood pressure of the patient. Future studies should assess blood pressure management goals that are tailored to each individual patient’s baseline blood pressure.

On the other hand, hypertension in TBI may have implications for intracranial hematoma expansion. It is common in clinical practice to recommend that systolic blood pressures are maintained <160 mmHg to mitigate the risk of hematoma expansion. Evidence supporting this practice is largely extrapolated from non-TBI patients. A small retrospective study (\( n = 69 \))\(^4\) demonstrated an increased risk of postcraniotomy intracranial hematoma in patients with intraoperative hypertension (62% vs. 34% controls, \( P < 0.001 \)), and postoperative hypertension in the first 12 hours after surgery (62% vs. 25% controls, \( P < 0.001 \)). A recent large retrospective study in patients with anticoagulant-associated intracranial hematoma demonstrated that lowering SBP to less than 160 mmHg within 4 hours of admission was associated with a reduced risk of hematoma expansion (\( n = 691 \), 33.1% <160 mmHg vs. 52.4% in ≥160 mmHg; \( P < 0.001 \)).\(^5\) However, there are no specific recommendations from the Brain Trauma Foundation on a hypertension threshold to avoid in patients with traumatic intracranial hematoma.

**Anticoagulation Reversal and Prophylaxis** Patients with intracranial hematoma who are on anticoagulation for cardiovascular indications (atrial fibrillation, cardiac stents, or mechanical valves) or stroke prevention present a challenging population. Anticoagulation reversal is important to reduce the risk of hematoma expansion; however, anticoagulant reversal is also associated with thrombotic cardiovascular complications. A recent retrospective study in patients with nontraumatic, oral-anticoagulant–associated intracranial hematoma showed that lowering the INR to <1.3 within 4 hours of admission was an independent predictor of hematoma expansion (\( n = 853 \); 19.8% vs. 41.5% in INR of ≥1.3; \( P < 0.001 \)). Furthermore, this study showed that the risk of ischemic complications was greater in patients that were not restarted on oral anticoagulation as compared to those that were subsequently restarted (\( n = 719 \); 5.2% vs. 15%, no restart, \( P < 0.001 \)); however, they did not observe a significant increase in the risk of hemorrhage with anticoagulation restart (\( n = 719 \); 8.1%, vs. 6.6%, \( P = 0.48 \)). The median time to anticoagulation restart was 30 days after discharge (inter-quartile range 18–65), as such, these data do not speak to risks and benefits of restarting anticoagulation in the acute postbleed interval. It is important to note that the risks and benefits of restarting anticoagulation will vary based on the individual patient and the patient’s indications for anticoagulation (e.g., mechanical heart valve vs. atrial fibrillation). As such, close collaboration between the neurosurgery and cardiology teams are important in optimizing a management strategy for these patients.

Anticoagulation prophylaxis for prevention of venous thrombosis also involves a risk-benefit analysis. Per a level III (low-quality) recommendation of Brain Trauma Foundation Guidelines,\(^10\) anticoagulation prophylaxis with low-molecular-weight heparin or low-dose unfractionated heparin may be used to reduce the risk of venous thrombosis, even though it is associated with an increased risk of intracranial hematoma expansion. It may be reasonable to initiate prophylactic anticoagulation 24 hours after an intracranial hematoma is deemed to be stable. A single-center retrospective study (\( n = 236 \)) found that such a strategy was associated with a decreased risk of DVT (0% vs. 5.6% (\( n = 6 \)), \( P < 0.001 \)), but did not observe significant differences in the rates of pulmonary embolism (0.78% (\( n = 1 \)) vs. 3.74% (\( n = 4 \), \( P = 0.18 \)) or intracranial hematoma expansion (0.7% [1] vs. 2.8% [3], \( P = 0.3 \)). However, because of the low rate of clinical events observed in this series, the study may have been underpowered to identify small differences in pulmonary embolism or hematoma expansion.

**Indications for Invasive Intracranial Monitoring** In patients with severe TBI (GCS <8), the Brain Trauma Foundation guidelines endorse a level IIB recommendation (low-quality of evidence) for ICP and cerebral perfusion pressure (CPP) to reduce short-term mortality (within 2 weeks of hospitalization). They also provide level IIB recommendations for treating ICP >22 mmHg and treating CPP level between 60 and 70 mmHg to optimize outcomes. These recommendations are supported by a recent retrospective cohort study (\( n = 459 \))\(^6\) that identified ICP and CPP thresholds that best discriminated between survivors and nonsurvivors in severe TBI, and also between survivors with “poor” and “favorable” outcomes (Glasgow Outcome Scale 1–3 vs. 4–6). A large, multicenter randomized controlled trial performed in 6 hospitals in Ecuador and Bolivia did not support the claim that intracranial monitoring in severe TBI results in improved clinical outcomes. Chestnut et al in 2012 did not observe a significant difference in mortality or favorable outcomes (as assessed by the Glasgow Outcome Scale) when severe TBI patients were managed with an intracranial monitor (\( n = 56 \), or with imaging and clinical exam (\( n = 53 \), \( P = 0.43 \)). Advanced multimodal monitoring such as brain tissue oxygen (PbrO2) monitoring, jugular bulb monitoring of arteriovenous oxygen content difference (AVDO2), cerebral autoregulation with TCD, and micro dialysis are under active investigation. Only jugular bulb monitoring of AVDO2 is associated with a level III (poor-quality evidence) recommendation to guide management in severe TBI.
The Brain Tissue Oxygen Monitoring in TBI (BOOST) trials are actively investigating the added benefit of brain tissue oxygenation beyond intracranial pressure monitoring in severe TBI.  

**Decompressive Cranietomy for Severe TBI** Decompressive craniectomy can be performed to relieve intracranial pressure associated with diffuse cerebral edema in cases of severe TBI without mass lesions (e.g., extra-axial hematoma). This is a controversial issue as there is a paucity of high-quality evidence providing clear support for or against this intervention. The DECRAs trial (a multicenter, randomized, controlled trial, n = 155) compared bifrontal decompressive craniectomy to medical management for the treatment of patients with severe TBI and elevated intracranial pressure refractory to first-tier therapies (ICP >20 mmHg for at least 15 minutes within an hour). They found no significant difference in mortality at six months, and found that functional outcomes (as measured by the Extended Glasgow Outcome Scale) were worse in patients who underwent surgery. They found a clear improvement in ICP and number of days in the ICU in patients that underwent surgery as compared to medical management. Of note, they used an intention-to-treat analysis, such that 18% of patients in the medical management group underwent a delayed craniotomy as a life-saving procedure. More recently, the RESCUE-ICP trial\(^{16}\) (a multicenter, randomized, controlled trial, n = 408) compared decompressive craniotomy and ongoing medical care in patients with severe TBI (without mass lesions) with elevated ICP (>25 mmHg) refractory to first- and second-tier interventions (medical management and ventriculostomy). Patients were randomized to either receive a barbiturate infusion (medical group) or undergo decompressive craniotomy (surgery group; unilateral hemicraniectomy vs. bifrontal craniotomy depending on degree of bilateral swelling and surgeon discretion). Again, they used an intention-to-treat analysis such that 37% of patients of the medical group underwent decompressive hemicraniectomy. At 6 months, decompressive craniectomy in patients with traumatic brain injury and refractory intracranial hypertension resulted in lower mortality and higher rates of vegetative state, lower severe disability, and upper severe disability than medical care. The rates of moderate disability and good recovery were similar in the two groups. The recent Brain Trauma Foundation Guidelines offer a level II (moderate-quality) recommendation against performing a bifrontal decompressive hemicraniectomy to improve functional outcomes at 6 months in patients with severe TBI with diffuse injury and no mass lesions, and with elevated ICP that is medically refractory. They note that this procedure has been demonstrated to reduce time in the ICU and ICP. However, they have not made an updated recommendation since the results of the RESCUE-ICP trial have been published. 

The results of the DECRAs and RESCUE-ICP trials suggest caution and careful consideration prior to performing decompressive craniotomy in treating severe TBI without mass lesions. There is now evidence that this procedure can be lifesaving and reduce mortality at 6 months; however, it is not clear that the survivors have a favorable functional outcome (as grossly measured by the Extended Glasgow Outcome Scale). By improving ICP and reducing time in the ICU, it may hasten the recovery process by allowing patients to begin rehabilitation earlier. Also, several unanswered questions remain. For example, might outcomes be improved if decompressive craniectomy was performed earlier, prior to the patient developing refractory ICP, and presumably secondary brain injury? As such, the decision of whether or not to perform decompressive craniotomy must be carefully considered within the context of each individual patient’s clinical scenario, the patient’s available social support system, and the family’s disposition and goals of care.  

**Vascular Injury.** Trauma to the head or neck may cause damage to the carotid or vertebrobasilar systems. Generally, dissection refers to violation of the vessel wall intima. Blood at arterial pressures can then open a plane between the intima and media, within the media, or between the media and adventitia. The newly created space within the vessel wall is referred to as the false lumen. Tissue or organs supplied by dissected vessels may subsequently be injured in several ways. Expansion of the hematoma within the vessel wall can lead to narrowing of the true vessel lumen and reduction or cessation of distal blood flow. Slow-flowing or stagnant blood within the false lumen exposed to thrombogenic vessel wall elements may thrombose. Pieces of thrombus may then detach and cause distal embolic arterial occlusion. Also, the remaining partial-thickness vessel wall may rupture, damaging adjacent structures.

Traumatic dissection may occur in the carotid artery (anterior circulation) or the vertebral or basilar arteries (posterior circulation). Dissections may be extradural or intradural. Intradural dissection can present with subarachnoid hemorrhage (SAH). Traditional angiography remains the basis of diagnosis and characterization of arterial dissection. Angiographic abnormalities include stenosis of the true lumen, or “string-sign,” visible intimal flaps, and the appearance of contrast in the false lumen. Four-vessel cerebral angiography should be performed when suspicion of dissection exists.

Historically, patients with documented arterial dissection have been anticoagulated with heparin and then warfarin to prevent thromboembolic stroke. Trauma patients often have concomitant absolute or relative contraindications to anticoagulation, complicating management. Antiplatelet therapy is often implemented in lieu of full anticoagulation, however, there is no randomized clinical trial comparing the two therapies.\(^{37}\) Consider surgical or interventional techniques for persisting embolic disease and for vertebral dissections presenting with SAH. Surgical options include vessel ligation and bypass grafting. Interventional radiology techniques include stenting and vessel occlusion. Occlusion techniques require sufficient collateral circulation to perfuse the vascular territory previously supplied by the occluded vessel.  

**Carotid Dissection** Carotid dissection may result from neck extension combined with lateral bending to the opposite side, or trauma from an incorrectly placed shoulder belt tightening across the neck in a motor vehicle accident. Extension or bending stretches the carotid over the bony transverse processes of the cervical vertebrae, while seat belt injuries cause direct trauma. Symptoms of cervical carotid dissection include contralateral neurologic deficit from brain ischemia, headache, and ipsilateral Horner’s syndrome from disruption of the sympathetic tracts ascending from the stellate ganglion on the surface of the carotid artery. The patient may complain of a bruise.

Traumatic vessel wall injury to the portion of the carotid artery running through the cavernous sinus may result in a carotid-cavernous fistula (CCF). This creates a high-pressure, high-flow pathophysiologic blood flow pattern. CCFs classically present with pulsatile proptosis (the globe pulses outward with arterial pulsation), retro-orbital pain, and decreased visual acuity or loss of normal eye movement (due to damage
to cranial nerves III, IV, and VI as they pass through the cavernous sinus. Symptomatic CCFs should be treated to preserve eye function. Fistulae may be closed by balloon occlusion using interventional neuroradiology techniques. Fistulae with wide necks are difficult to treat and may require total occlusion of the parent carotid artery.

Vertebrobasilar Dissection  Vertebrobasilar dissection may result from sudden rotation or flexion/extension of the neck, chiropractic manipulation, or a direct blow to the neck. Common symptoms are neck pain, headache, and brain stem stroke or SAH. The risks and benefits of aspirin therapy are unclear when a vertebral dissection extends intracranially. The theoretically increased friability of the vessel wall may increase the risk of SAH when coupled with an anticoagulant agent. Consultation of a stroke neurologist is recommended in this situation.

Brain Death.  Brain death occurs when there is an absence of signs of brain stem function or motor response to deep central pain in the absence of pharmacologic or systemic medical conditions that could impair brain function.

Clinical Examination  A neurologist, neurosurgeon, or intensivist generally performs the clinical brain death examination. Two examinations consistent with brain death 12 hours apart, or one examination consistent with brain death followed by a consistent confirmatory study generally is sufficient to declare brain death (see following paragraphs). Hospital regulations and local laws regarding documentation should be followed closely.

Establish the absence of complicating conditions before beginning the examination. The patient must be normotensive, euvolemic, and oxygenating well. The patient may not be under the effects of any sedating or paralytic drugs.

Documentation of no brain stem function requires the following: nonreactive pupils; lack of corneal blink, oculocephalic (doll’s eyes), oculovestibular (cold calorics) reflexes; and loss of drive to breathe (apnea test). The apnea test demonstrates no spontaneous breathing even when Paco2 is allowed to rise above 60 mmHg.

Deep central painful stimuli are provided by bilateral forceful twisting pinch of the supraclavicular skin and pressure to the medial canthal notch. Pathologic responses such as flexor or extensor posturing are not compatible with brain death. Spinal reflexes to peripheral pain, such as triple flexion of the lower extremities, are compatible with brain death.

Confirmatory Studies  Confirmatory studies are performed after a documented clinical examination consistent with brain death. A study consistent with brain death may obviate the need to wait 12 hours for a second examination. This is especially important when the patient is a potential organ donor, as brain-dead patients often have progressive hemodynamic instability. Lack of cerebral blood flow consistent with brain death may be documented by cerebral angiography or technetium radionuclide study. A “to-and-fro” pattern on transcranial Doppler ultrasonography indicates no net forward flow through the cerebral vasculature, consistent with brain death. An electroencephalogram (EEG) documenting electrical silence has been used but generally is not favored because there is often significant artifact which impairs interpretation.

Spine Trauma  The spine is a complex biomechanical structure. The spine provides structural support for the body as the principal component of the axial skeleton, while protecting the spinal cord and nerve roots. Trauma may fracture bones or cause ligamentous disruption. Often, bone and ligament damage occur together. Damage to these elements reduces the strength of the spine and may cause instability, which compromises both supportive and protective functions. Spine trauma may occur with or without neurologic injury.

Neurologic injury from spine trauma is classified as either incomplete or complete. If there is some residual motor or sensory neurologic function below the level of the lesion, as assessed by clinical examination, the injury is defined as incomplete. A patient with complete neurologic dysfunction persisting 24 hours after injury has a very low probability of return of function in the involved area.

Neurologic injury from spine trauma may occur immediately or in delayed fashion. Immediate neurologic injury may be due to direct damage to the spinal cord or nerve roots from penetrating injuries, especially from stab wounds or gunshot wounds. Blunt trauma may transfer sufficient force to the spine to cause acute disruption of bone and ligament, leading to subluxation, which is a shift of one vertebral element in relation to the adjacent level. Subluxation decreases the size of the spinal canal and neural foramina and causes compression of the cord or roots. Such neural impingement can also result from retropulsion of bone fragments into the canal during a fracture. Transection, crush injury, and cord compression impairing perfusion are mechanisms leading to SCI. Delayed neurologic injury may occur during transportation, examination of an improperly immobilized patient, or during a hypotensive episode.

The Mechanics of Spine Trauma  Trauma causes a wide variety of injury patterns in the spine due to its biomechanical complexity. A mechanistic approach facilitates an understanding of the patterns of injury, as there are only a few types of forces that can be applied to the spine. Although these forces are discussed individually, they often occur in combination. Several of the most common injury patterns are then presented to illustrate the clinical results of these forces applied at pathologically high levels.

Flexion/Extension  Bending the head and body forward into a fetal position flexes the spine. Flexion loads the spine anteriorly (the vertebral bodies) and distracts the spine posteriorly (the spinous process and interspinous ligaments). High flexion forces occur during front-end motor vehicle collisions, and backward falls when the head strikes first. Arching the neck and back extends the spine. Extension loads the spine posteriorly and distracts the spine anteriorly. High extension forces occur during rear-end motor vehicle collisions (especially if there is no headrest), forward falls when the head strikes first, or diving into shallow water.

Compression/Distraction  Force applied along the spinal axis (axial loading) compresses the spine. Compression loads the spine anteriorly and posteriorly. High compression forces occur when a falling object strikes the head or shoulders, or when landing on the feet, buttocks, or head after a fall from height. A pulling force in line with the spinal axis distracts the spine. Distraction unloads the spine anteriorly and posteriorly. Distraction forces occur during a hanging, when the chin or occiput strikes an object first during a fall, or when a passenger submarines under a loose seat belt during a front-end motor vehicle collision.

Rotation  Force applied tangential to the spinal axis rotates the spine. Rotation depends on the range of motion of intervertebral facet joints. High rotational forces occur during off-center...
impacts to the body or head or during glancing automobile accidents.

**Patterns of Injury.** Certain patterns of injury resulting from combinations of the previously mentioned forces occur commonly and should be recognized during plain film imaging of the spine. Always completely evaluate the spine. A patient with a spine injury at one level has a significant risk for additional injuries at other levels.

**Cervical** The cervical spine is more mobile than the thoracolumbar spine. Stability comes primarily from the multiple ligamentous connections of adjacent vertebral levels. Disruption of the cervical ligaments can lead to instability in the absence of fracture. The mass of the head transmits significant forces to the cervical spine during abrupt acceleration or deceleration, increasing risk for injury.

**Jefferson Fracture** A Jefferson fracture is a bursting fracture of the ring of C1 (the atlas) due to compression forces. There are usually two or more fractures through the ring of C1. The open-mouth odontoid view may show lateral dislocation of the lateral masses of C1. The rule of Spence states that 7 mm or greater combined dislocation indicates disruption of the transverse ligament. The transverse ligament stabilizes C1 with respect to C2. Jefferson fractures dislocated <7 mm usually are treated with a rigid collar, while those dislocated 7 mm or greater usually are treated with a halo vest. Surgical intervention is not indicated.

**Odontoid Fractures** The odontoid process, or dens, is the large ellipse of bone arising anteriorly from C2 (the axis) and projecting up through the ring of C1 (the atlas). Several strong ligaments connect the dens to C1 and to the base of the skull. Odontoid fractures usually result from flexion forces. Odontoid fractures are classified as type I, II, or III. A type I fracture involves the tip only. A type II fracture passes through the base of the odontoid process. A type III fracture passes through the body of C2. Types II and III are considered unstable and should be externally immobilized or fused surgically. Surgery often is undertaken for widely displaced fractures (poor chance of fusing) and for those that fail external immobilization. Type I fractures usually fuse with external immobilization only.

**Hangman’s Fracture** Traditionally considered a hyperextension/distraction injury from placement of the noose under the angle of the jaw, hangman’s fractures also may occur with hyperextension/compression, as with diving accidents, or hyperflexion. The injury is defined by bilateral C2 pars interarticularis fractures. The pars interarticularis is the bone between superior and inferior facet joints. Thus, the posterior bony connection between C1 and C3 is lost. Hangman’s fractures heal well with external immobilization. Surgery is indicated if there is spinal cord compression or after failure of external immobilization.

**Jumped Facets—Hyperflexion Injury** The facet joints of the cervical spine slope forward. In a hyperflexion injury, the superior facet can “jump” over the inferior facet of the level above if the joint capsule is torn. Hyperflexion/rotation can cause a unilateral jumped facet, whereas hyperflexion/distraction leads to bilateral jumped facets. Patients with unilateral injury usually are neurologically intact. Those with bilateral injury, however, typically suffer from spinal cord damage, since the anteroposterior diameter of the spinal canal is compromised by bilateral injury, leading to spinal cord compression (Fig. 42-11).

**Thoracolumbar** The thoracic spine is stabilized significantly by the rib cage. The lumbar spine has comparatively large vertebræ. Thus, the thoracolumbar spine has a higher threshold for injury than the cervical spine. A three-column model is useful for categorizing thoracolumbar injuries.⁵⁹ The anterior longitudinal ligament and the anterior half of the vertebral body constitute the anterior column. The posterior half of the vertebral body and the posterior longitudinal ligament constitute the middle column. The pedicles, facet joints, laminae, spinous processes, and interspinous ligaments constitute the posterior column.

**Compression Fracture** Compression fracture is a compression/flexion injury causing failure of the anterior column only. It is stable and not associated with neurologic deficit, although the patient may still have significant pain (Fig. 42-12).

**Burst Fracture** Burst fracture is a pure axial compression injury causing failure of the anterior and middle columns. It is unstable, and perhaps half of patients have neurologic deficit due to compression of the cord or cauda equina from bone fragments retropropulsed into the spinal canal.

**Chance Fracture** Chance fracture is a flexion-distraction injury causing failure of the middle and posterior columns, sometimes with anterior wedging. Typical injury is from a lap seat-belt hyperflexion with associated abdominal injury. It often is unstable and associated with neurologic deficit.

**Fracture-Dislocation** Fracture-dislocation is failure of the anterior, middle, and posterior columns caused by flexion/distraction, shear, or compression forces. Neurologic deficit can result from retropulsion of middle column bone fragments into the spinal canal, or from subluxation causing decreased canal diameter (Fig. 42-13).

**Initial Assessment and Management.** The possibility of a spine injury must be considered in all trauma patients. A patient with no symptoms referable to neurologic injury, a normal neurologic examination, no neck or back pain, and a known mechanism of injury unlikely to cause spine injury is at minimal risk for significant injury to the spine. Victims of moderate or severe trauma, especially those with injuries to other organ systems, usually fail to meet these criteria or cannot be assessed adequately. The latter often is due to impaired sensorium or significant pain. Because of the potentially catastrophic consequences of missing occult spine instability in a neurologically intact patient, a high level of clinical suspicion should govern patient care until completion of clinical and radiographic evaluation.

The trauma patient should be kept on a hard, flat board with straps and pads used for immobilization. A hard cervical collar is kept in place. These steps minimize forces transferred through the spine and therefore decrease the chance of causing dislocation, subluxation, or neural compression during transport to the trauma bay. The patient is then moved from the board to a flat stretcher. The primary survey and resuscitation are completed. Physical examination and initial X-rays follow.

For the examination, approach the patient as described in “Neurologic Examination” earlier in this chapter. Evaluation for spine or SCI is easier and more informative in awake patients. If the patient is awake, ask if he or she recalls details of the nature of the trauma, and if there was loss of consciousness, numbness, or inability to move any or all limbs. Assess motor function by response to commands or pain, as appropriate. Assess pinprick, light touch, and joint position, if possible. Determining the anatomically lowest level of intact sensation can pinpoint the level of the lesion along the spine. Testing sensation in an ascending fashion will allow the patient to better discern the true stimulus
as opposed to determine when it is extinguished. Document muscle stretch reflexes, lower sacral reflexes (i.e., anal wink and bulbocavernosus), and rectal tone.

American Spinal Injury Association Classification. The American Spinal Injury Association provides a method of classifying patients with spine injuries. The classification indicates completeness and level of the injury and the associated deficit.

Figure 42-11. A. Lateral cervical spine X-ray of an elderly woman who struck her head during a backward fall. Arrowhead points to jumped facets at C5–C6. Note the anterior displacement of the C5 body with respect to the C6 body. B. Sagittal T2-weighted magnetic resonance imaging of the same patient, revealing compromise of the spinal canal and compression of the cord. Note the bright signal within the cord at the level of compression, indicating spinal cord injury. C. Lateral cervical spine X-ray of same patient after application of cervical traction and manual reduction. Note restoration of normal alignment. D. Lateral cervical spine X-ray after posterior cervical fusion to restabilize the C5–C6 segment of the spine.

A form similar to that shown in Fig. 42-14 should be available in the trauma bay and completed for any spine injury patient. The association also has worked to develop recommendations and guidelines to standardize the care of SCI patients in an effort to improve the quality of care.

Neurologic Syndromes. Penetrating, compressive, or ischemic cord injury can lead to several characteristic presentations
Figure 42-12. A. Lateral lumbar spine X-ray showing a compression fracture of L2. Arrowhead points to anterior wedge deformity. Note the posterior wall of the vertebral body has retained normal height and alignment. B. Axial computed tomography scan through the same fracture. Arrowhead demonstrates a transverse discontinuity in the superior endplate of the L2 body.

Figure 42-13. Sagittal reconstruction of an axial fine-slice computed tomography scan through the lumbar spine demonstrating a severe fracture-dislocation through the body of L2.

Based on the anatomy of injury. The neurologic deficits may be deduced from the anatomy of the long sensory and motor tracts and understanding of their decussations (Fig. 42-15). Four patterns are discussed. First, injury to the entire cord at a given level results in anatomic or functional cord transection with total loss of motor and sensory function below the level of the lesion. The typical mechanism is severe traumatic vertebral subluxation reducing spinal canal diameter and crushing the cord. Second, injury to half the cord at a given level results in Brown-Séquard syndrome, with loss of motor control and proprioception ipsilaterally and loss of nociception and thermoception contralaterally. The typical mechanism is a stab or gunshot wound. Third, injury to the interior gray matter of the cord in the cervical spine results in a central cord syndrome, with upper extremity worse than lower extremity weakness and various degrees of numbness. The typical mechanism is transient compression of the cervical cord by the ligamentum flavum buckling during traumatic neck hyperextension. This syndrome occurs in patients with preexisting cervical stenosis. Fourth, injury to the ventral half of the cord results in the anterior cord syndrome, with paralysis and loss of nociception and thermoception bilaterally. The typical mechanism is an acute disc herniation or ischemia from anterior spinal artery occlusion.

Studies. Anteroposterior and lateral plain films provide a rapid survey of the bony spine. Plain films detect fractures and dislocations well. Adequate visualization of the lower cervical and upper thoracic spine often is impossible because of the shoulder girdle. Complete plain film imaging of the cervical spine includes an open-mouth view to assess the odontoid process and the lateral masses of C1. Fine-slice CT scan with sagittal and coronal reconstructions provides good detail of bony anatomy and is good for characterizing fractures seen on plain films, as well as visualizing C7–T1 when not well seen on plain films. MRI provides the best soft tissue imaging. Canal compromise from subluxation, acute disc herniations, or ligamentous disruption is clearly seen. MRI also may detect EDHs or damage to the spinal cord itself, including contusions or areas of ischemia.
Indications for Screening for Vascular Injury with Cervical Spine Trauma

It is important to consider the presence of blunt cerebrovascular injury in patients with cervical spine trauma; however, the specific indications for obtaining a screening CT angiography study are controversial. Many trauma centers rely on the Denver Criteria. These criteria indicate that screening should be employed for a cervical vertebral body or transverse foramen fracture, subluxation, or ligamentous injury at any level, or any fracture at the level of C1–C3, among other indications such as concerning mechanism, Lefort mid-face fractures, or basilar fractures through the carotid canal. A recent single-center retrospective study (n = 1717 cervical spine fractures) found a higher risk of vertebral artery injury only in the setting of fractures of C1 and C2 (combined), those that involve the transverse foramen, or had significant subluxation. They did not find that “high-risk” cervical spine fractures as defined by the Denver Criteria were associated with an increased risk of blunt cerebrovascular injury. Based on these data, we feel that it is appropriate to use a more defined set of screening criteria as outlined by Lockwood et al to reduce cost and contrast-exposure in patients with cervical spine fractures.
Definitive Management

**Spinal-Dose Steroids** Several studies have investigated the use of methylprednisolone in acute spinal cord injury. The National Acute Spinal Cord Injury studies (NASCIS I, II, and III) provided some support for the view that administration of high-dose methylprednisolone in acute spinal cord injury results in improved neurologic outcomes. A post-hoc analysis performed as part of NASCIS II demonstrated improved neurologic outcomes if methylprednisolone was administered within 8 hours of injury. A post-hoc analysis in NASCIS III showed improved outcomes at 6 weeks and 6 months, but not 1 year when methylprednisolone was administered within 3 and 8 hours of injury. However, these findings are tempered by the fact that these benefits were modest and only demonstrated in post-hoc analyses, and by the high rate of medical complications associated with corticosteroid administration. All three NASCIS trials showed that methylprednisolone was associated with a higher rate of complications such as pneumonia, severe sepsis, and poor wound healing. A recent Cochrane review did not observe a significant increase in complications or mortality associated with methylprednisolone administration in acute spinal cord injury, but did observe a trend towards this effect. Despite the lack of clear evidence on this issue, the most recent acute spinal cord injury guidelines provide a controversial level I recommendation against the use of corticosteroids in acute spinal cord injury. Some authors have argued for the use of methylprednisolone within 8 hours of acute spinal cord injury in carefully selected patients (e.g., young males that are less prone to medical complications associated with corticosteroids). Thus, clear consensus on the use of spinal-dose steroids does not exist. A decision to use or not use spinal-dose steroids may be dictated by local or regional practice patterns, especially given the legal liability issues surrounding SCI. Patients with gunshot or nerve root (cauda equina) injuries, or those who are pregnant, <14 years old, or on chronic steroids were excluded from the NASCIS studies and should not receive spinal-dose steroids. In addition to steroids, hypothermia for SCI has also received attention. There is even less evidence supporting the use of this treatment, and thus, it is not currently recommended.

**Orthotic Devices** Rigid external orthotic devices can stabilize the spine by decreasing range of motion and minimizing stress transmitted through the spine. Commonly used rigid cervical orthoses include Philadelphia and Miami-J collars. Cervical collars are inadequate for C1, C2, or cervicothoracic instability. Cervicothoracic orthoses brace the upper thorax and the neck, improving stabilization over the cervicothoracic region. Minerva braces improve high cervical stabilization by bracing from the upper thorax to the chin and occiput. Halo vest assemblies provide the most external cervical stabilization. Four pins are driven into the skull to lock the halo ring in position. Four posts arising from a tight-fitting rigid plastic vest immobilize the halo ring. Lumbar stabilization may be provided by thoracolumbosacral orthoses. A variety of companies manufacture lines of spinal orthotics. A physician familiar with the technique should fit a halo vest. Assistance from a trained orthotics technician improves fitting and adjustment of the other devices.

**Surgery** Neurosurgical intervention has two goals: decompression of the spinal cord and nerve roots, and stabilization of the spine. When spinal cord injury is caused by a hyperflexion-distraction injury that results in cord compression and an unstable spine, both surgical decompression and fusion are typically required. However, in cases of a hypextension injury causing central cord syndrome due to chronic cervical stenosis, surgical decompression may be needed without the need for internal fixation. In cases where there significant anterolisthesis (subaxial cervical jumped or perched facets), reduction of the fracture may be important for both decompression and stabilization. However, in some cases, reduction of the fracture may not be sufficient for decompression, and further decompressive surgery may still be needed.

Several controversial topics require consideration here. First, the timing of surgery has been a controversial topic. In the past, it has been suggested that patients with incomplete injury, or a deteriorating exam warrant emergent decompression, whereas patients with complete injuries can undergo surgery in a nonemergent manner. It is important to appreciate the risks of taking a medically unstable patient to surgery, such as a polytrauma patient with hemorrhagic shock or a complete spinal cord injury patient in neurogenic shock. However, there are clear benefits to early surgical decompression: it can allow early mobilization, aggressive nursing care, and physical therapy. Furthermore, a recent prospective cohort study found that the odds of observing a two-point increase in ASIA grade at 6 months was higher in patients that underwent surgery within 24 hours, as compared to those that underwent surgery after 24 hours. These data suggest that a subpopulation of patients may significantly benefit from early surgery; however, the characteristics of these patients were not described, suggesting a heterogeneous population in terms of preoperative ASIA grade and imaging.

In general, spine trauma patients with complete neurologic deficit, without any signs of recovery, or those without any neurologic deficits who have bony or ligamentous injury requiring open fixation, may be medically stabilized before undergoing surgery. Surgical stabilization may be indicated for some injuries that would eventually heal with conservative treatment. Solid surgical stabilization may also allow a patient to be managed with a rigid cervical collar who would otherwise require halo-vest immobilization.

**Continued Care.** Regional SCI centers with nurses, respiratory therapists, pulmonologists, physical therapists, physiatrists, and neurosurgeons specifically trained in caring for these patients may improve outcomes. Frequently encountered ICU issues include hypotension due to neurogenic shock (due to loss of sympathetic tone) and aspiration pneumonia. The recent guidelines recommend maintaining MAPs >85 for 7 days after injury. Chronically, prevention and treatment of deep venous thrombosis, autonomic hyperreflexia, and decubitus ulcer formation are important. Many patients with cervical or high thoracic cord injuries require prolonged ventilatory support until the chest wall becomes stiff enough to provide resistance for diaphragmatic breathing. Patients with high cervical cord injuries (C4 or above) will often require permanent ventilatory support. Patients should be transferred to SCI rehabilitation centers after stabilization of medical and surgical issues.

**Peripheral Nerve Trauma**

The peripheral nervous system extends throughout the body and is subject to injury from a wide variety of trauma. Peripheral nerves transmit motor and sensory information from the CNS to the body. An individual nerve may have pure motor, pure sensory, or mixed motor and sensory functions. The key
information-carrying structure of the nerve is the axon. The axon transmits information from the neuronal cell body and may measure from <1 mm to >1 m in length. Axons that travel a significant distance are often covered with myelin, which is a lipid-rich, electrically insulating sheath formed by Schwann cells. Myelinated axons transmit signals much more rapidly than unmyelinated axons because the voltage shifts and currents that define action potentials effectively jump from gap to gap over the insulated lengths of the axon.

Axons, whether myelinated or unmyelinated, travel through a collagenous connective tissue known as [endoneurium]. Groups of axons and their endoneurium form bundles known as [fascicles]. Fascicles run through a tubular collagenous tissue known as [perineurium]. Groups of fascicles are suspended in mesoneurium. Fascicles and their mesoneurium run through another tubular collagenous tissue known as [epineurium]. The epineurium and its contents form the nerve.

There are four major mechanisms of injury to peripheral nerves. Nerves may be lacerated, stretched, compressed, or contused. Knives, passing bullets, or jagged bone fractures may lacerate nerves. Adjacent expanding hematomas or dislocated fractures may stretch nerves. Expanding hematomas, external orthoses such as casts or braces, or blunt trauma over a superficial nerve may compress or crush nerves. Shock waves from high-velocity bullets may contuse nerves. These mechanisms of injury cause damage to the various anatomic components of the nerve. The patterns of damage are categorized in “Types of Injury.”

Certain nerve segments are particularly vulnerable to injury. The following four characteristics make a nerve segment more vulnerable: proximity to a joint, superficial course, passage through a confined space, and being fixed in position.

**Types of Injury.** The traditional classification system for peripheral nerve injury is the Seddon classification. Seddon described three injury patterns as defined in the “Neurapraxia,” “Axonotmesis,” and “Neurotmesis” sections. The Seddon classification provides a simple, anatomically based approach to peripheral nerve injury.50

**Neurapraxia** Neurapraxia is defined as the temporary failure of nerve function without physical axonal disruption. Axon degeneration does not occur. Return of normal axonal function occurs over hours to months, often in the 2- to 4-week range.

**Axonotmesis** Axonotmesis is the disruption of axons and myelin. The surrounding connective tissues, including endoneurium, are intact. The axons degenerate proximally and distally from the area of injury. Distal degeneration is known as Wallerian degeneration. Axon regeneration within the connective tissue pathways can occur, leading to restoration of function. Axons regenerate at a rate of 1 mm per day. Significant functional recovery may occur for up to 18 months. Scarring at the site of injury from connective tissue reaction can form a neuroma and interfere with regeneration.

**Neurotmesis** Neurotmesis is the disruption of axons and endoneurial tubes. Peripheral collagenous components, such as the epineurium, may or may not be intact. Proximal and distal axonal degeneration occurs. The likelihood of effective axonal regeneration across the site of injury depends on the extent of neuroma formation and on the degree of persisting anatomic alignment of the connective tissue structures. For instance, an injury may damage axons, myelin, and endoneurium, but leave perineurium intact. In this case, the fascicle sheath is intact, and appropriate axonal regeneration is more likely to occur than if the sheath is interrupted.

**Management of Peripheral Nerve Injury.** The sensory and motor deficits should be accurately documented. Deficits are usually immediate. Progressive deficit suggests a process such as an expanding hematoma and may warrant early surgical exploration. Clean, sharp injuries may also benefit from early exploration and reanastomosis. Most other peripheral nerve injuries should be observed. EMG/NCS studies should be done 3–6 to weeks postinjury if deficits persist. Axon segments distal to the site of injury will conduct action potentials normally until Wallerian degeneration occurs, rendering EMG/NCS before 3 weeks uninformative. Continued observation is indicated if function improves. Surgical exploration of the nerve may be undertaken if no functional improvement occurs over 3 months. If intraoperative electrical testing reveals conduction across the injury, continue observation. In the absence of conduction, the injured segment should be resected and end-to-end primary anastomosis attempted. However, anastomoses under tension will not heal. A nerve graft may be needed to bridge the gap between the proximal and distal nerve ends. The sural nerve is often harvested, as it carries only sensory fibers and leaves a minor deficit when resected. The connective tissue structures of the nerve graft may provide a pathway for effective axonal regrowth across the injury.

**Patterns of Injury**

**Brachial Plexus** The brachial plexus may be injured in a variety of ways. Parturition or a motorcycle accident can lead to plexus injury due to dislocation of the glenohumeral joint. Attempting to arrest a fall with one’s hands can lead to a stretch injury of the plexus due to abrupt movement of the shoulder girdle. An apical lung (Pancoast) tumor can cause compression injury to the plexus. There are many patterns of neurologic deficits possible with injury to the various components of the brachial plexus, and understanding them all would require extensive neuroanatomic discussion. Two well-known eponymous syndromes are Erb’s palsy and Klumpke’s palsy. Injury high in the plexus to the C5 and C6 roots resulting from glenohumeral dislocation causes Erb’s palsy with the characteristic “bellhop’s tip” position. The arm hangs at the side, internally rotated. Hand movements are not affected. Injury low in the plexus, to the C8 and T1 roots, resulting from stretch or compression injury, causes Klumpke’s palsy with the characteristic “claw hand” deformity. There is weakness of the intrinsic hand muscles, similar to that seen with ulnar nerve injury.

**Radial Nerve** The radial nerve courses through the axilla, then laterally and posteriorly in the spiral groove of the humerus. Improper crutch use can cause damage to the axillary portion. The section of the nerve traversing the spiral groove can be damaged by humerus fractures or pressure from improper positioning during sleep. This classically occurs when the patient is intoxicated and is called “Saturday night palsy.” The key finding is wrist drop (i.e., weakness of hand and finger extensors). Axillary (proximal) injury causes triceps weakness in addition to wrist drop.

**Common Peroneal Neuropathy** The common peroneal nerve forms the lateral half of the sciatic nerve (the medial half being the tibial nerve). It receives contributions from L4, L5, S1, and S2. It emerges as a separate nerve in the popliteal fossa and laterally wraps around the fibular neck, after which it splits to
form the deep and superficial peroneal nerves. The superficial, fixed location at the fibular neck makes the common peroneal nerve susceptible to compression. The classic cause of traumatic peroneal neuropathy is crush injury from a car bumper striking the lateral aspect of the leg at the knee. Symptoms of common peroneal neuropathy include foot drop (weakness of the tibialis anterior), evasion weakness, and numbness over the anterolateral surface of the lower leg and dorsum of the foot. In contrast, a foot drop due to L5 radiculopathy spares evasion because the S1 fibers are intact. Surgical exploration of a common peroneal crush lesion is typically a low yield endeavor. Rare cases may be due to compressive fibers or adhesions that may be lysed, with the possibility of return of function.

**CEREBROVASCULAR DISEASE**

Cerebrovascular disease is the most frequent cause of new, rapid-onset, nontraumatic neurologic deficit. It is far more common than seizures or tumors. Vascular structures are subject to a variety of chronic pathologic processes that compromise vessel wall integrity. Diabetes, high cholesterol, high blood pressure, and smoking – common comorbidities in the general population – are important risk factors for vascular disease. These conditions can lead to vascular damage by such mechanisms as atheroma deposition causing luminal stenosis, endothelial damage promoting thrombogenesis, and weakening of the vessel wall resulting in aneurysm formation or dissection. These processes may coexist. For instance, a vessel containing an atheromatous plaque will have a decreased luminal diameter. The plaque also may have compromised endothelium, providing the opportunity for thrombus formation, which can lead to acute total occlusion of the remaining lumen. Aneurysms and dissection often occur in atheromatous vessels. Specific patterns of disease relevant to the cerebrovascular system include atheromatous and thrombotic carotid occlusion, brain ischemia from proximal embolic disease, vessel wall rupture leading to hemorrhage, and rupture of abnormal, thin-walled structures, specifically aneurysms and AVMs.

**Ischemic Diseases**

Ischemic stroke accounts for approximately 85% of acute cerebrovascular events. Symptoms of acute ischemic stroke vary based on the functions of the neural tissues supplied by the occluded vessel, and the presence or absence of collateral circulation. The circle of Willis provides extensive collateral circulation, as it connects the right and left carotid arteries to each other and each to the vertebrobasilar system. Patients with complete occlusion of the carotid artery proximal to the circle of Willis may be asymptomatic if the blood flow patterns can shift and provide sufficient circulation to the ipsilateral cerebral hemisphere from the contralateral carotid and the basilar artery. However, the anatomy of the circle of Willis is highly variable. Patients may have a congenitally hypoplastic or missing communicating artery with resultant bilateral ACA supply by one carotid, or the PCA may be supplied by the carotid artery rather than the basilar. Similarly, one vertebral artery is often dominant and the other is hypoplastic. These variations may make disease in a particular vessel more neurologically devastating than in a patient with full collateral circulation. Occlusion distal to the circle of Willis generally results in a stroke in the territory supplied by that particular artery.

Neurologic deficit from occlusive disease may be temporary or permanent. A patient with sudden-onset focal neurologic deficit that resolves within 24 hours has had a transient ischemic attack (TIA). A patient with permanent deficit has had a completed stroke.

**Thrombotic Disease**

The most common area of neurologically significant vessel thrombosis is the carotid artery in the neck. Disease occurs at the carotid bifurcation. Thrombosis of a carotid artery chronically narrowed by atheroma can lead to acute carotid occlusion. As discussed previously, this can be asymptomatic due to sufficient collateralization. The more common concern is thromboembolus. Intracranial arterial occlusion by local thrombus formation may occur, but it is rare compared to embolic occlusion.

**Management.** Complete occlusion of the carotid artery without referable neurologic deficit requires no treatment. A patient with new neurologic deficit and an angiographically confirmed complete carotid occlusion contralateral to the symptoms should be considered for emergent carotid endarterectomy. Surgery should be performed within 2 hours of symptom onset and should not be performed on obtunded or comatose patients. These restrictions significantly reduce the number of operative candidates. In nonemergent cases, the results of the large-scale North American Symptomatic Carotid Stenosis Trial (NASCET) demonstrated a stroke reduction benefit to surgical revascularization in patients with severe stenosis, defined as occlusion of 70% to 99% of the carotid. Practice guidelines recommend revascularization at this level of stenosis even if asymptomatic. Surgical options for these patients include both carotid endarterectomy and carotid stenting, which have been shown to produce equal outcomes over long-term follow-up.

**Embolic Disease**

Emboli causing strokes may originate from a number of sources, including: the left atrium in atrial fibrillation, a hypokinetic left ventricular wall segment, valvular vegetations, an atheromatous aortic arch, stenotic/atheromatous carotid bifurcations, or from the systemic venous system in the presence of a right-to-left shunt, such as a patent foramen ovale. The majority of emboli enter the anterior (carotid) circulation rather than the posterior (vertebrobasilar) circulation. Characteristic clinical syndromes result from embolic occlusion of various vessels within these circulations.

**Common Types of Strokes**

**Anterior Cerebral Artery Stroke** The ACA supplies the medial frontal and parietal lobes as it courses into the interhemispheric fissure. Due to its vascular supply of the motor cortex, ACA stroke characteristically results in contralateral leg weakness.

**Middle Cerebral Artery Stroke** The MCA supplies the lateral frontal and parietal lobes as it courses into the interhemispheric fissure. Due to its vascular supply of the motor cortex, ACA stroke characteristically results in contralateral leg weakness. MCA stroke results in contralateral face and arm weakness. Dominant-hemisphere MCA stroke causes language deficits due to its supply of Broca’s area, Wernicke’s area, and the white matter tracts that connect the two. Proximal MCA occlusion with ischemia and swelling in the entire MCA territory can lead to significant intracranial mass effect and midline shift (see Fig. 42-6), termed malignant MCA stroke.

**Posterior Cerebral Artery Stroke** The PCA supplies the occipital lobe. PCA stroke results in a contralateral homonymous hemianopsia (see Fig. 42-6).

**Posterior Inferior Cerebellar Artery Stroke** The PICA supplies the lateral medulla and the inferior half of the cerebellar
hemispheres. PICA stroke results in nausea, vomiting, nystagmus, dysphagia, ipsilateral Horner’s syndrome, and ipsilateral limb ataxia. The constellation of symptoms resulting from PICA occlusion is referred to as the lateral medullary or Wallenberg’s syndrome.

Management. Ischemic stroke management has two goals: reopen the occluded vessel and maintain blood flow to ischemic “penumbra” tissues bordering the vascular territory. Reopening the vessel has historically been attempted with recombinant tPA. tPA administration within 3 hours of the onset of neurologic deficit improves outcome at 3 months. In the setting of suspected ischemic stroke, a head CT must be performed immediately to differentiate ischemic from hemorrhagic stroke. Intracranial hemorrhage, major surgery within the previous 2 weeks, GI or genitourinary hemorrhage in the previous 3 weeks, platelet count less than 100,000/µL, and systolic blood pressure >185 mmHg are among the contraindications to tPA therapy.

In recent years, a paradigm shift in ischemic stroke management has occurred with the advent of endovascular mechanical thrombectomy. Though tPA can be effective for strokes of smaller vessels, it produces recanalization in only 20% of large vessel ischemic strokes, and even less for internal carotid artery occlusion. In mechanical thrombectomy, the intracranial circulation is accessed endovascularly, and stent-retriever devices can be deployed to definitively remove clot and stent open involved vessels. Initial investigations into the technology began in 1999 with varied success. Technological advances proceeded, and in 2015, large-scale clinical trials investigating mechanical thrombectomy for large vessel occlusion were published. The MR-CLEAN trial was one of these. In this trial, 500 patients were randomized to tPA and medical therapy vs. mechanical thrombectomy. The latter group had a significantly better 90-day outcome. A domino effect ensued in which four other similarly large-scale trials (e.g., REVASCAT) were terminated early.

Benefits to mechanical thrombectomy include less stringent criteria than tPA administration, focused therapy, and time windows between 6 and 12 hours in trials. Currently, mechanical thrombectomy is being used for large vessel occlusion within 6 hours of symptom onset for those patients not eligible for tPA, which accounts for about 10% of ischemic stroke. Its indications and associated technology continue to evolve. It should be noted that current guidelines still support tPA as first-line therapy even for those eligible for mechanical thrombectomy.

Patients not eligible for tPA or mechanical thrombectomy require hemodynamic optimization and neurologic monitoring. Admit such patients to the ICU stroke service for blood pressure management and frequent neurologic checks. Permissive hypertension allows for maximal cerebral perfusion. Systolic blood pressure >180 mmHg may require treatment, but the optimal mean arterial pressure goal is between 100 and 140 mmHg. Give normal saline solution without glucose (which could injure neurons in the penumbra due to osmotic fluid shift), and aim for normovolemia. A stroke patient who worsens clinically should undergo repeat head CT to evaluate for hemorrhage or increasing mass effect from swelling, which typically peaks 3 to 5 days after the stroke. Significant swelling from an MCA or cerebellar stroke may cause herniation and brain stem injury. A decompressive hemicraniectomy or suboccipital craniectomy can be a life-saving intervention for these select stroke patients. In studies of malignant MCA syndrome, decompressive hemicraniectomy showed favorable mortality and functional outcomes.

This treatment option, however, should be considered with the understanding of potentially poor functional recovery regardless of therapy. One study showed that less than half of malignant MCA patients who underwent decompressive hemicraniectomy returned home following rehabilitation, which is even fewer for those undergoing medical therapy.

Hemorrhagic Diseases

Intracranial hemorrhage from abnormal or diseased vascular structures accounts for approximately 15% of acute cerebrovascular events. Hypertension and amyloid angiopathy account for most intraparenchymal hemorrhages, although AVMs, aneurysms, venous thrombosis, tumors, hemorrhagic conversion of ischemic infarct, and fungal infections also may be the cause. The term intracranial hemorrhage is frequently used to signify intraparenchymal hemorrhage and will be used here. Intracranial hemorrhage causes local neuronal injury and dysfunction and also may cause global dysfunction due to mass effect if sufficiently large. The Intracerebral Hemorrhage (ICH Score) is commonly used to risk-stratify these patients, and it takes into account GCS, age, hemorrhage volume, presence of intraventricular hemorrhage, and location to predict mortality. AVM or aneurysm rupture (along with trauma, discussed previously in this chapter) result in subarachnoid hemorrhage (SAH) because the major cerebral and cortical blood vessels travel in the subarachnoid space, between the pia and the arachnoid membranes. SAH can cause immediate concussive-like neuronal dysfunction by exposure of the brain to intra-arterial pressure pulsations during the hemorrhage. Moreover, it can cause delayed ischemia from cerebral arterial vasospasm, which can present as acute worsening of the patient’s neurologic status days to weeks after the injury. Patients presenting with intracranial hemorrhages that do not follow typical patterns should undergo cerebral angiography or MRI to evaluate for possible underlying lesions, such as AVM or tumor.

Hemorrhagic stroke most commonly occurs within the basal ganglia or cerebellum. The patient is usually hypertensive on admission and has a history of poorly controlled hypertension. Such patients are more likely to present with lethargy or obtundation compared to those who suffer an ischemic stroke. Depressed mental status results from mass effect from the hematoma in deep structures, which can produce midline shift or herniation. Ischemic stroke does not cause mass effect acutely. Therefore, patients are more likely to present with normal consciousness and a focal neurologic deficit. Hemorrhagic strokes tend to present with a relatively gradual decline in neurologic function as the hematoma expands, rather than the immediately maximal symptoms caused by ischemic stroke. Table 42-3 provides a listing of relative incidences of intracranial hemorrhage by anatomic distribution.

Hypertension. Hypertension increases the relative risk of intracranial hemorrhage by approximately fourfold, likely due to chronic degenerative vasculopathy. Hypertensive hemorrhages often present in the basal ganglia, thalamus, or pons, and result from breakage of small perforating arteries that branch off of much larger parent vessels (Fig. 42-16).

Most hypertensive hemorrhages should be medically managed. The hematoma often contains intact, salvageable axons because the blood dissects through and along neural tracts, and surgical clot evacuation destroys these axons. Factors potentially favoring surgery include: superficial clot location, young age, nondominant hemisphere, rapid deterioration, and significant

mass effect. However, the most comprehensive randomized clinical trials to date did not show an overall improved outcome in surgically evacuated intracranial hemorrhage, except for the subgroup of patients with clot <1 cm from the cortical surface. More recent studies have assessed the role of minimally-invasive catheter evacuation of clot; these investigations are ongoing. Medical management remains the gold standard, however, and includes moderate blood pressure control, normalizing platelet and clotting function, phenytoin or levetiracetam for seizure prophylaxis, and electrolyte management. Intubate patients who cannot clearly follow commands to prevent aspiration and hypercarbia. Follow and document the neurologic examination and communicate with the family regarding appropriateness for rehabilitation vs. withdrawal of care.

**Amyloid Angiopathy.** The presence of pathologic amyloid deposition in the media of small cortical vessels compromises vessel integrity and tends to cause more superficial (lobar) hemorrhages than hypertensive intracranial hemorrhage. Amyloid laden vessels may hemorrhage multiple times. The superficial location of amyloid hemorrhages may make surgical evacuation less morbid compared to typical deep hypertensive hemorrhages. Nonetheless, medical management and family counseling should be approached similarly to patients with hypertensive hemorrhages.

**Figure 42-16.** A. Head computed tomography scan of a patient with left-sided weakness and progressive lethargy reveals a right basal ganglia hemorrhage (arrowhead). The blood clot is bright white. Hypodensity around the clot represents cerebral edema. There is blood within the ventricular system. B. Another patient with intraventricular extension of a basal ganglia hemorrhage. The patient developed right-sided weakness and then lethargy. Head computed tomography indicated hydrocephalus. A ventriculostomy was placed for cerebrospinal fluid drainage (arrowhead indicates cross-sectional view of the catheter entering the anterior horn of the right lateral ventricle).
The Hunt-Hess clinical grading system for subarachnoid hemorrhage (SAH) categorizes patients clinically (Table 42-5).

Cerebral Aneurysm. An aneurysm is a focal dilatation of the vessel wall and is most often a balloon-like outpouching, but may also be fusiform. Aneurysms usually occur at branch points of major vessels (e.g., internal carotid artery bifurcation), or at the origin of smaller vessels (e.g., posterior communicating artery or ophthalmic artery). Approximately 85% of aneurysms arise from the anterior circulation (carotid) and 15% from the posterior circulation (vertebrobasilar). Table 42-4 shows the percentage distribution of cerebral aneurysms by location. Aneurysms are thin walled and at risk for rupture. The major cerebral vessels, and therefore aneurysms, lie in the subarachnoid space. Rupture results in SAH. The aneurysmal tear may be small and seal quickly, or it may not. SAH may consist of a thin layer of blood in the CSF spaces, or thick layers of blood around the brain and extending into brain parenchyma, resulting in a clot with mass effect. Because the meningeal linings of the brain are sensitive with free nerve endings, SAH usually results in a sudden, severe “thunderclap” headache. A patient will classically describe “the worst headache of my life.” Presenting neurologic symptoms may range from mild headache to coma to sudden death. The Hunt-Hess grading system categorizes patients clinically (Table 42-5).

The World Federation of Neurological Surgery (WFNS) SAH Grading Scale is also used for this purpose. The Fisher Scale and a more recent modified form use head CT characteristics, described in the following section, to stratify patients based on risk of vasospasm-induced delayed cerebral ischemia. Both scales are used in conjunction as a quick way to communicate severity of aneurysmal SAH.

Patients with symptoms suspicious for SAH should have a head CT immediately. Acute SAH appears as a bright signal in the fissures and CSF cisterns around the base of the brain, as shown in Fig. 42-17. CT is rapid, noninvasive, and approximately 95% sensitive. In patients with suspicious symptoms but negative head CT, a lumbar puncture (LP) should be performed. An LP with xanthochromia and high red blood cell counts (usually 100,000/mL), which do not decrease between tubes 1 and 4, is consistent with SAH. Negative CT and LP essentially rules out SAH. Patients diagnosed with SAH require four-vessel cerebral angiography within 24 hours to assess for aneurysm or other vascular malformation. Catheter angiography remains the gold standard for assessing the patient’s cerebral vasculature, relevant anomalies, and presence, location, and morphology of the cerebral aneurysms. Figure 42-18A demonstrates the typical anteroposterior digital subtraction angiographic view of a cerebral aneurysm. Figure 42-18B shows the anatomy of the circle of Willis in a simplified graphic representation to assist in visualizing the locations of various cerebral aneurysms.

SAH patients should be admitted to the neurologic ICU. Hunt-Hess grade 4 and 5 patients require intubation and hemodynamic monitoring and stabilization. The current standard of care for ruptured aneurysms requires early aneurysmal occlusion. There are two options for occlusion. The patient may undergo craniotomy with microsurgical dissection and placement of a titanium clip across the aneurysm neck to exclude the aneurysm from the circulation and reconstitute the lumen of the parent vessel. The second option is to utilize an endovascular approach for treatment, which has traditionally taken the form of “coiling.” The patient is taken to the interventional neuroradiology suite for placement of looped titanium coils inside the aneurysm dome. The coils support thrombosis and prevent
options, as described earlier. Current guidelines favor endovascular therapy as the preferred first-line approach. The International Subarachnoid Aneurysm Trial researchers suggested that endovascular occlusion resulted in better mortality outcomes for certain types of cerebral aneurysms, although this trial was marred by poor selection and randomization techniques, and the validity of its conclusions have been questioned.\textsuperscript{63} Long-term outcomes may be better in younger patients with clipped aneurysms, as demonstrated in the Barrow Ruptured Aneurysm Trial (BRAT).\textsuperscript{64} However, this trial has a number of similar criticisms as well. Debate also continues regarding optimal care for unruptured intracranial aneurysms, with a recent large-scale study showing no clear benefit to open surgical vs. endovascular approaches.\textsuperscript{65}

SAH patients often require 1 to 3 weeks of ICU care after aneurysm occlusion for medical complications that accompany neurologic injury. In addition to routine ICU concerns, SAH patients are also at risk for cerebral vasospasm. In vasospasm, cerebral arteries constrict pathologically and can cause ischemia or stroke from 4 to 21 days after SAH. Current vasospasm prophylaxis includes maintenance of optimal perfusion with hypertension and mild hypervolemia, as well as administration of nimodipine, a calcium channel blocker that may decrease incidence and degree of spasm, though its mechanism is debated. Neurointerventional options for treating symptomatic vasospasm include intra-arterial papaverine or nicardipine, and balloon angioplasty for larger caliber vessels.

Aneurysmal SAH has an approximate mortality rate of 50\% in the first month. Approximately one-third of survivors return to pre-SAH function, and the remaining two-thirds have mild to severe disability. Most require rehabilitation after hospitalization.

Arteriovenous Malformations. AVMs are abnormal, dilated arteries and veins without an intervening capillary bed. The nidus of the AVM contains a tangled mass of vessels but no neural tissue. AVMs may be asymptomatic or present with SAH, intraparenchymal hemorrhage, or seizures. Small AVMs present with hemorrhage more often than large AVMs, which tend to present with seizures. Headache, bruit, or focal neurologic deficits are less common symptoms. AVMs hemorrhage at an average rate of 2\% to 4\% a year. Figure 42-19 demonstrates the angiographic appearance of an AVM in arterial and venous phases.

For unruptured AVMs, recent evidence from over two hundred patients supports medical management alone rather than intervention due to risk of stroke.\textsuperscript{66} Because AVM rupture can present radiographically as SAH, it is important to consider several management differences as compared to aneurysmal SAH. Definitive therapy for the AVM usually is delayed 3 to 4 weeks to allow the brain to recover from acute injury. There is less risk of devastating early rebleeding from AVMs, and vasospasm is much less common. Three therapeutic modalities for AVMs are currently in common use: microsurgical excision, interventional radiology or endovascular embolization, and stereotactic radiosurgery (SRS). AVMs that are large, near eloquent cortex, or that drain to deep venous structures are considered high grade and more difficult to surgically resect without causing a significant neurologic deficit. Radiosurgery can treat these lesions, although it is limited to lesions <3 cm in diameter and has a 2-year lag time (i.e., the AVM may bleed in the interval). Embolization reduces flow through the AVM. It is usually considered adjunctive therapy, but it may serve as the sole treatment for deep, inaccessible lesions.
TUMORS OF THE CENTRAL NERVOUS SYSTEM

A wide variety of tumors affect the brain and spine. Primary benign and malignant tumors arise from the various elements of the CNS, including neurons, glia, and meninges. Tumors metastasize to the CNS from many primary sources. Presentation varies widely depending on relevant neuroanatomy. Prognosis depends on histology and anatomy. Modern brain tumor centers use team approaches to CNS tumors, as patients may require a combination of surgery (including newer, more minimally invasive approaches), radiation therapy, chemotherapy, SRS, and research protocol enrollment for studies assessing the efficacy of newer approaches such as immunotherapy. Tumors affecting the peripheral nervous system are discussed in the “Peripheral Nerve” section.

Intracranial Tumors

Intracranial tumors can cause brain injury from mass effect, dysfunction or destruction of adjacent neural structures, swelling, or abnormal electrical activity (seizures). Supratentorial tumors commonly present with focal neurologic deficits, such as contralateral limb weakness, visual field deficit, headache, or seizure. Infratentorial tumors often cause increased ICP due to hydrocephalus from compression of the fourth ventricle, leading to headache, nausea, vomiting, or diplopia. Cerebellar hemisphere or brain stem dysfunction can result in ataxia, nystagmus, or cranial nerve palsies. Infratentorial tumors rarely cause seizures.

All patients with symptoms concerning for brain tumor should undergo MRI with and without gadolinium. Gadolinium-based contrast can identify locations of blood-brain barrier breakdown of tumors and, when used in conjunction with other MRI sequences, is essential in narrowing the differential diagnosis. Initial management of a patient with a symptomatic brain tumor generally includes dexamethasone for reduction of vasogenic edema, and phenytoin or levetiracetam if the patient has seized. Patients with significant weakness, lethargy, or hydrocephalus should be admitted for observation until definitive care is administered.

Metastatic Tumors

Cerebral metastases are the most common type of intracranial tumor. Prolonged cancer patient survival and improved CNS imaging have increased the likelihood of diagnosing cerebral metastases. The sources of most cerebral metastases are (in decreasing frequency): lung, breast, kidney, GI tract, and melanoma. Lung and breast cancers account for more than half of cerebral metastases. Metastatic cells usually travel to the brain hematogenously and frequently seed the gray-white junction due to characteristic blood vessel caliber change. Other common locations are the cerebellum and the meninges. Meningeal involvement may result in carcinomatous meningitis, also known as leptomeningeal carcinomatosis. MRI pre- and post-contrast administration is the study of choice for evaluation. Figure 42-20 demonstrates bilateral cerebellar metastases. These lesions are typically well circumscribed, round, and multiple. Such findings should prompt a metastatic work-up, including CT scan of the chest, abdomen, and pelvis, and a bone scan.

Management largely depends upon the primary tumor, overall tumor burden, patient’s medical condition, and location and number of metastases. The beliefs of the patient and family regarding aggressive care must be considered, with the primary goal of optimizing survival time while maintaining or improving neurological function. Neurosurgical intervention can be indicated for a number of reasons. Biopsy can be obtained to provide a tissue diagnosis and further direct therapy. Hydrocephalus from increased intracranial pressure due to intracranial tumor burden can be temporized via placement of a ventriculoperitoneal shunt. Craniotomy can be used for debulking of intracranial tumor burden or resection. Data from randomized controlled trials have supported the use of craniotomy for tumor resection plus whole-brain radiation therapy (WBRT) or stereotactic radiosurgery (SRS) for patients with a single surgically accessible metastatic lesion, compared to radiation therapy alone. In one randomized trial assessing surgery and WBRT vs. WBRT alone, local recurrence decreased and median...
survival increased from 15 to 40 weeks. For multiple metastases, it should be noted that craniotomy primarily for resection is typically not indicated unless all detectable metastases can be resected. It may however still be useful for symptomatic relief from a primary lesion. Recent data suggest that SRS (e.g., Gamma Knife) may be applied to multiple metastases in one session with improved outcome.

Glial Tumors

Glial cells provide the anatomic and physiologic support for neurons and their processes in the brain. Tumors arising from glial cells are termed gliomas, and they represent the most common primary brain tumor. The several types of glial cells give rise to distinct primary CNS neoplasms.

Astrocytoma. Astrocytoma is the most common primary CNS neoplasm. The term glioma often is used to refer to astrocytomas specifically, excluding other glial tumors. Astrocytomas are graded from I to IV. Grades I and II are referred to as low-grade astrocytoma or low grade glioma, grade III as anaplastic astrocytoma, and grade IV as glioblastoma multiforme (GBM). Prognosis varies significantly between grades I/II, III, and IV, but not between I and II. Median survival is 8 years after diagnosis with a low-grade tumor, 2 to 3 years with anaplastic astrocytoma, and roughly 1 year with a GBM. GBMs account for almost two-thirds of all astrocytomas, anaplastic astrocytomas account for two-thirds of the rest, and low-grade astrocytomas the remainder. Fig. 42-21 demonstrates the typical appearance of a GBM.

The great majority of astrocytomas infiltrate adjacent brain. Juvenile pilocytic astrocytomas and pleomorphic xanthoastrocytomas are exceptions. These tumors are circumscribed, low grade, and associated with a good prognosis. Histologic features associated with higher grade include hypercellularity, nuclear atypia, and endovascular hyperplasia. Necrosis is present only with GBMs; it is required for the diagnosis.

Gross total resection should be attempted for suspected astrocytomas. Motor cortex, language centers, deep or midline structures, or brainstem location may make this impossible without unacceptable, devastating neurologic deficit. Advanced imaging, such as diffusion tensor imaging (DTI) and functional MRI (fMRI), are seeing increased use as means of assessing peritumoral structure and function to guide surgical decision-making. However, some lesions may be in such precarious regions as to be limited to stereotactic needle biopsy specimen. Gross total resection followed by fractioned radiotherapy (FRT) improves survival for all grades, although radiation therapy may be delayed until recurrence in low-grade tumors. Alongside FRT, adjuvant chemotherapy with temozolomide was demonstrated in a randomized controlled trial to increase short-term survival rate. Bevacizumab, an anti-VEGF antibody, is another treatment option under investigation. There are various ongoing research studies for GBM adjuvant therapy; these should be discussed with the patient and family. Other options include Iotrex-containing balloons for conformal radiation brachytherapy (Glia-Site), placed in the resection cavity at the time of surgery.
for recurrence. Adjuvant therapy remains marginally effective; survival has changed little over the last several decades.

**Oligodendroglioma.** Oligodendroglioma accounts for approximately 10% of gliomas, arising from the oligodendrocytes that create myelin in the CNS. They often present with seizures. Calcifications and hemorrhage on CT or MRI suggest the diagnosis. Oligodendrogliomas are also graded from I to IV; grade portends prognosis. Prognosis is better overall than for astrocytomas. Median survival ranges from 2 to 7 years for highest and lowest grade tumors, respectively. Aggressive resection improves survival. Many oligodendrogliomas will respond to procarbazine, lomustine (CCNU), and vincristine (PCV) chemotherapy. A particular chromosomal deletion, 1p19q, has been associated with robust response to the chemotherapeutic agent temozolomide. Radiation has not been clearly shown to prolong survival.

Recent updates to brain tumor classification by the WHO (discussed in the following section) note that high-grade (at least II or III) oligodendrogliomas and astrocytomas are classified together as diffuse gliomas. In fact, more similarity is seen between high-grade astrocytomas and oligodendrogliomas than between high-grade astrocytomas and low-grade astrocytomas. Further discussion of this nosology is beyond the scope of this chapter, but implications for the future of neuro-oncology are discussed here.

**Ependymoma.** The lining of the ventricular system consists of cuboidal/columnar ependymal cells from which ependymomas may arise. Although most pediatric ependymomas are supratentorial, two-thirds of adult ependymomas are infratentorial. Supratentorial ependymomas arise from the lateral or third ventricles. The infratentorial tumors arise from the floor of the fourth ventricle (i.e., off the posterior brainstem). The most common symptoms are headache, nausea, vomiting, or vertigo, secondary to increased ICP from obstruction of CSF flow through the fourth ventricle. The tumors may grow out the foramina of Luschka to form a cerebellopontine angle mass. They may also spread through the CSF to form “drop mets” in the spinal canal. The two main histologic subtypes are papillary and anaplastic, the latter characterized by increased mitotic activity and areas of necrosis. Gross total resection often is impossible because the tumor arises from the brain stem. The goal of surgery is to achieve maximal resection without injuring the very delicate brainstem. Suboccipital craniotomy and midline separation of the cerebellar hemispheres allows access to tumors in the fourth ventricle. Postoperative radiation therapy significantly improves survival. Patients with CSF spread documented by LP or contrast MRI should also have whole-spine radiation plus focused doses to visualized metastases.

**Choroid Plexus Papilloma.** The choroid plexus is composed of many small vascular tufts covered with cuboidal epithelium. It represents part of the interface between blood and brain. The choroid cells create CSF from blood via ultrafiltration and release it into the ventricular system. Choroid plexus papillomas and choroid plexus carcinomas (rare, mostly pediatric) may arise from these cells. Papillomas usually occur in infants (typically supratentorial in the lateral ventricle) but also occur in adults (usually infratentorial in the fourth ventricle). Papillomas
are well circumscribed and vividly enhance due to extensive vasculature. Like ependymomas, adult choroid plexus papillomas usually present with symptoms of increased ICP. Treatment is surgical excision. Total surgical excision is curative; recurrent papillomas should be re-resected. Radiation and chemotherapy are not indicated for papillomas. Radiation is adjunctive to aggressive surgery for carcinomas, but the results are generally poor.

**Neural Tumors and Mixed Tumors**

Neural and mixed tumors are a diverse group that includes tumors variously containing normal or abnormal neurons and/or normal or abnormal glial cells. Primitive neuroectodermal tumors arise from bipotential cells, capable of differentiating into neurons or glial cells.

**Medulloblastoma.** Medulloblastoma is classically described as the most common type of primitive neuroectodermal tumor (PNET), although this term has been removed in the latest WHO classification of central nervous system tumors. Most occur in the first decade of life, but there is a second peak around age 30. Medulloblastoma is the most common malignant pediatric brain tumor. They are usually midline. Most occur in the cerebellum and present with symptoms of increased ICP. Histologic characteristics include densely packed small round cells with large nuclei and scant cytoplasm. They are generally not encapsulated, frequently disseminate within the CNS, and should undergo surgical resection followed by radiation therapy and chemotherapy.

**Ganglioglioma.** Ganglioglioma is a mixed tumor in which both neurons and glial cells are neoplastic. They occur in the first three decades of life, often in the medial temporal lobe, as circumscribed masses that may contain cysts or calcium and may enhance. The presenting symptom is usually a seizure, due to the medial temporal location. Patients have a good prognosis after complete surgical resection.

**Neural Crest Tumors**

Multipotent neural crest cells develop into a variety of disparate cell types, including smooth muscle cells, sympathetic and parasympathetic neurons, melanocytes, Schwann cells, and arachnoid cap cells. They migrate in early development from the primitive neural tube throughout the body.

**Miscellaneous Tumors**

**Meningioma.** Meningiomas are derived from arachnoid cap cells of the arachnoid mater. They appear to arise from the dura mater grossly and on MRI and are commonly referred to as dural-based tumors. The most common intracranial locations are along the falx (Fig. 42-22), the convexities (i.e., over the cerebral hemispheres), and the sphenoid wing. Less common locations include the foramen magnum, olfactory groove, and inside the lateral ventricle. Most are slow growing, encapsulated, benign tumors. Aggressive atypical or malignant meningiomas may invade adjacent bone or cerebral cortex. Previous cranial irradiation increases the incidence of meningiomas. Approximately 10% of patients with a meningioma have multiple meningiomas. Total resection is curative, although involvement with small perforating arteries or cranial nerves may make total resection of skull base tumors impossible without significant neurologic deficit. The Simpson grading scale is used to characterize the extent of resection. Small, asymptomatic meningiomas can be followed until symptomatic or until significant growth is documented on serial imaging studies.

Atypical and malignant meningiomas may require postoperative radiation. Patients may develop recurrences from the surgical bed or distant de novo tumors.

**Vestibular Schwannoma (Acoustic Neuroma).** Vestibular schwannomas predominantly arise from the superior half of the vestibular portion of the vestibulocochlear nerve (cranial nerve VIII) (Fig. 42-23). Commonly, patients present with progressive hearing loss, tinnitus, or balance difficulty. Large tumors may cause brain stem compression and obstructive hydrocephalus. Bilateral acoustic neuromas are pathognomonic for neurofibromatosis type 2 (NF2), a syndrome resulting from mutation of chromosome 22. NF2 patients have an increased incidence of spinal and cranial meningiomas and gliomas.

Vestibular schwannomas may be treated with microsurgical resection or SRS (Gamma Knife radiosurgery or linear accelerator technology). The main complication with treatment is damage to the facial nerve (cranial nerve VII), which runs through the internal auditory canal with the vestibulocochlear nerve. Risk of facial nerve dysfunction increases with increasing tumor diameter. SRS is preferred for tumors <3 cm, and microsurgical resection for those >3 cm (SRS can be supplemented for any residual tumor following resection).

**Pituitary Adenoma.** Pituitary adenomas arise from the anterior pituitary gland (adenohypophysis). Tumors <1 cm diameter are considered microadenomas; larger tumors are macroadenomas.
Pituitary tumors may be functional (i.e., secrete endocrinologically active compounds at pathologic levels) or nonfunctional (i.e., secrete nothing or inactive compounds). Functional tumors are often diagnosed when quite small, due to endocrine dysfunction. The most common endocrine syndromes are Cushing’s disease, due to adrenocorticotropic hormone secretion, Forbes-Albright syndrome, due to prolactin secretion, and acromegaly, due to growth hormone secretion. Nonfunctional tumors are typically diagnosed as larger lesions causing mass effects such as visual field deficits due to compression of the optic chiasm or panhypopituitarism due to compression of the gland. Figure 42-24 demonstrates a large pituitary adenoma. Hemorrhage into a pituitary tumor causes abrupt symptoms of headache, visual disturbance, decreased mental status, and endocrine dysfunction. This is known as pituitary apoplexy.

Symptomatic pituitary tumors should be decompressed surgically to eliminate mass effect and/or to attempt an endocrine cure. However, prolactin-secreting tumors (prolactinomas) usually shrink with dopaminergic therapy alone. First-line pharmacotherapy for small prolactinomas is cabergoline, a dopamine agonist that inhibits production and secretion of prolactin, and is preferred over bromocriptine for its superior side effect profile. Consider surgery for prolactinomas with persistent mass effect or endocrinologic dysfunction in spite of adequate dopamine agonist therapy. Most pituitary tumors are approached transsphenally via the transsphenoidal approach, and minimally invasive, endoscopic surgical techniques are being used increasingly.

**Hemangioblastoma.** Hemangioblastomas occur almost exclusively in the posterior fossa, with about 20% occurring in patients with von Hippel-Lindau (VHL) disease, a multisystem neoplastic disorder. Other tumors associated with VHL are renal cell carcinoma, pheochromocytoma, and retinal angiomas. Many appear as cystic tumors with an enhancing tumor on the cyst wall known as the mural nodule. Surgical resection is curative for sporadic (non-VHL associated) tumors. Pathology reveals abundant thin-walled vascular channels; internal debulking may be bloody. En bloc resection of the mural nodule alone, leaving the cyst wall, is sufficient.

**Lymphoma.** CNS lymphoma may arise either primarily in the CNS or secondarily from systemic disease. Recent rising incidence may be due to growing transplant and AIDS populations. Presenting symptoms include mental status changes, headache due to increased ICP, and cranial nerve palsy due to lymphomatous meningitis (analogous to carcinomatous meningitis). Often, lymphoma appears hyperdense on CT due to dense cellularity. Most lesions typically enhance with contrast on MRI, and can be differentiated by diffusion restriction on diffusion-weighted sequences. Surgical excision is not indicated. A stereotactic needle biopsy specimen usually confirms the diagnosis. Subsequent treatment includes steroids, whole-brain radiation, and chemotherapy. Intrathecal methotrexate is an additional treatment option.

**Embryologic Tumors**

Embryologic tumors result from embryonal remnants that fail to involute completely or differentiate properly during development.

**Craniopharyngioma.** Craniopharyngiomas are benign cystic lesions that occur in the sellar region that occur most frequently in children. A second peak of incidence also exists around 50 years of age. Craniopharyngiomas arise from remnant embryonic tissue in the pituitary stalk. Calcification occurs in all pediatric and roughly half of adult craniopharyngiomas. Symptoms result from compression of adjacent structures, especially the optic chiasm. Pituitary or hypothalamic dysfunction or hydrocephalus may develop. Treatment is primarily surgical. Excision
is somewhat easier in children, as the tumor is often soft and easily suctioned. Adult tumors are often firm and adherent to adjacent vital structures. Visual loss, pituitary endocrine hypo-function, diabetes insipidus, and cognitive impairment from basal frontal injury are common complications.

**Epidermoid.** Epidermoid tumors are cystic lesions with stratified squamous epithelial walls from trapped ectodermal cell rests that grow slowly and linearly by desquamation into the cyst cavity. The cysts contain keratin, cholesterol, and cellular debris (Fig. 42-25). They occur most frequently in the cerebellopontine angle and may cause symptoms due to brainstem compression. Recurrent bouts of aseptic meningitis may occur due to release of irritative cyst contents into the subarachnoid space (Mollaret’s meningitis). Treatment is surgical drainage and removal of the cyst wall. Intraoperative spillage of cyst contents may lead to severe chemical meningitis and must be avoided by containment and aspiration.

**Dermoid.** Dermoids are less common than epidermoid tumors. They contain hair follicles and sebaceous glands in addition to a squamous epithelium. Dermoids may be found anywhere along the craniospinal axis. They are more commonly midline structures and are associated with more anomalies than epidermoids. They may be associated with trauma, as from a lumbar puncture that drags skin structures into the spine. Bacterial meningitis may occur when dermoids are associated with a dermal sinus tract. Treatment of symptomatic lesions is surgical resection, again with care to control cyst contents.

**Teratoma.** Teratomas are germ cell tumors that arise in the midline, often in the pineal region (the area behind the third ventricle, above the midbrain and cerebellum). They contain elements from all three embryonal layers: ectoderm, mesoderm, and endoderm. Teratomas may contain skin, cartilage, GI glands, and teeth. Teratomas with more primitive features are more malignant, while those with more differentiated tissues are more benign. Surgical excision may be attempted. However, the prognosis for malignant teratomas is very poor.

**Spinal Tumors**

Approximately 20% of CNS tumors occur in the spine, and a wide variety of spinal tumors exist. Unlike cranial tumors, the majority of spinal tumors are histologically benign. Understanding two major spinal concepts—stability and neural compression—facilitates an understanding of the effects of spinal tumors. Destruction of bones or ligaments can cause spinal instability, leading to deformities such as compression, kyphosis, subluxation, all of which harbor the potential for subsequent neural compression. Tumor growth in the spinal canal or neural foramina can cause direct compression of the spinal cord or nerve roots and cause pain and loss of function. Classically, the pain is worse at night. Anatomic categorization provides the most logical approach to these tumors. Certain tumors present in characteristic locations. An understanding of the anatomy leads to an understanding of the clinical presentation and possible therapeutic options.

**Extradural Tumors.** Extradural tumors account for approximately 55% of spinal tumors. This category includes tumors...
arising within the bony vertebral structures and from within the epidural space. Destruction of the bone can lead to instability and fractures, causing pain and/or deformity. Epidural expansion can lead to spinal cord or nerve root compression with myelopathy, radiculopathy, or a combination thereof.

**Metastatic Tumors** Metastatic tumors are the most common extradural tumors. Spinal metastases most commonly occur in the thoracic and lumbar vertebral bodies because the greatest volume of red bone marrow is found in these regions. The most common primary sources of spine metastases are lymphoma, lung, breast, and prostate. Other sources include renal, colon, thyroid, sarcoma, and melanoma. Most spinal metastases create osteolytic lesions. Osteoblastic, sclerotic lesions suggest prostatic cancer in men and breast cancer in women.

Patients with progressive neurologic dysfunction due to a metastatic lesion should undergo urgent surgery followed by radiation therapy. Patients with debilitating pain may undergo radiation therapy with close observation for neurologic deterioration. Preoperative neurologic function correlates with postoperative function. Patients may lose function over hours. These patients should be given high-dose IV dexamethasone, taken immediately to MRI, and then to the OR or radiation therapy suite. Indications for surgery include failure of radiation therapy, spinal instability, recurrence after radiation therapy, and the need for diagnosis in cases of unknown primary tumors. Most cases with significant bone involvement require both decompression and fusion. Bony fusion usually takes 2 to 3 months. Prognosis governs operative decisions. Surgery is unlikely to improve quality of life for patients with a life expectancy of 3 months or less, but it is likely to improve quality of life for patients with life expectancy of 6 months or more. Benefit for patients with 3- to 6-months’ life expectancy is unclear and requires frank discussion with the patient and family. Patients who are unlikely to tolerate general anesthesia, are already completely paralyzed, or who have very radiosensitive tumors such as multiple myeloma and lymphoma, should not generally undergo surgery.

**Management Principles of Spinal Cord Compression in Metastatic Cancer of the Spine** Spinal cord compression due to tumor burden is important to distinguish because it can, as with any other form of cord compression, cause paralysis and loss of bowel and bladder function. A randomized controlled trial demonstrated that patients with spinal cord compression from metastatic tumor have better outcomes with decompressive surgery and radiotherapy compared to radiotherapy alone. Patients with radiosensitive tumors, such as multiple myeloma and lymphoma, are excluded from this group. Another important tool in assessing these patients is the SINS (Spinal Instability Neoplastic Score). This scale grades the utility of operative intervention in metastatic cancer to the spine on the basis of pain, deformity, location, type of bone lesion, integrity of vertebral body, and posterior element involvement.

**Primary Tumors** Hemangiomas are benign tumors found in 10% of people at autopsy. They occur in the vertebral bodies of the thoracolumbar spine and are frequently asymptomatic. They are often vascular and may hemorrhage, causing pain or neurologic deficit. Large hemangiomas can destabilize the spine and predispose to fracture. Osteoblastic lesions include osteoid osteoma and osteoblastoma. The latter tends to be larger and more destructive. Aneurysmal bone cysts are nonneoplastic, expansile, lytic lesions containing thin-walled blood cavities that usually occur in the lamina or spinous processes of the cervicothoracic spine. They may cause pain or sufficiently weaken the bone to cause a fracture. Cancers arising primarily in the bony spine include Ewing’s sarcoma, osteosarcoma, chondrosarcoma, and plasmacytoma.

**Intradural Extramedullary Tumors** Intradural extramedullary tumors constitute approximately 40% of spinal tumors and arise from the meninges or nerve root elements. They may compress the spinal cord, causing myelopathy, or the nerve roots, causing radiculopathy. The most common intradural extramedullary tumors are typically benign, slow growing, and well circumscribed. Rare benign epidural masses include arachnoid cysts, dermoids, and epidermoids. Rare malignant epidural tumors include metastases and high-grade gliomas, or “drop” metastases from posterior fossa gliomas.

**Meningioma** Meningiomas arise from the arachnoidea mater. They appear to be dural based and enhance on MRI. An enhancing “dural tail” may be seen. They occur most commonly in the thoracic spine (Fig. 42-26) but also arise in the cervical and lumbar regions. Some spinal meningiomas grow into the

---

**Figure 42-26.** T2-weighted sagittal magnetic resonance imaging of the midthoracic spine demonstrating a well-encapsulated tumor arising from the dura posteriorly and compressing the spinal cord. Arrowhead points to dorsal location of the mass. The patient presented with worsening gait and lower extremity spasticity. Pathology demonstrated meningioma.
epidural space. Growth causes cord compression and progressive myelopathy with hyperreflexia, spasticity, and gait difficulties. Surgical excision is the treatment of choice. The surgeon often finds a clean margin between the tumor, dura, and spinal cord, allowing en bloc resection without damage to the cord.

**Schwannoma** Schwannomas are derived from peripheral nerve sheath Schwann cells. They are benign, encapsulated tumors that rarely undergo malignant degeneration. While two-thirds are entirely intradural, one-sixth are entirely extradural, and one-sixth have a classic “dumbbell” shape from intradural and extradural components. Symptoms result from radiculopathy, often presenting as pain or myelopathy. Symptomatic lesions should be surgically resected. The parent nerve root usually can be preserved. Patients with multiple schwannomas likely have NF2. In these patients, a careful neurologic examination is needed to determine which lesions are symptomatic and require resection.

**Neurofibroma** In contrast to schwannomas, neurofibromas tend to appear more fusiform and to grow within the parent nerve, rather than forming an encapsulated mass branching off the nerve. Neurofibromas are benign but not encapsulated. They present similarly to schwannomas, and the two may be difficult to differentiate on imaging. Salvage of the parent nerve is more challenging with neurofibromas. To improve the likelihood of total resection, thoracic and high cervical nerve roots may be sacrificed with minimal deficit. Patients with multiple neurofibromas likely have NFI, also known as von Recklinghausen’s neurofibromatosis. Resection for symptomatic lesions should be offered.

**Intradural Tumors.** Intradural tumors constitute approximately 5% of spinal tumors. They arise from within the parenchyma of the spinal cord. Common presenting symptoms are local dysesthesia, burning pain, radicular pain, sensory loss, weakness, or sphincter dysfunction. Patients with such symptoms should undergo MRI of the entire spine with and without enhancement.

**Ependymoma** Ependymomas are the most common intramedullary tumors in adults. There are several histologic variants. The myxopapillary type occurs in the conus medullaris or the filum terminale in the lumbar region and has the best prognosis after resection. The cellular type occurs more frequently in the cervical cord. Many spinal ependymomas have cystic areas and may contain hemorrhage. Surgical removal can improve function. A distinct tumor margin often exists, allowing safer excision. Postoperative radiation therapy after subtotal resection may prolong disease control.

**Astrocytoma** Astrocytomas are the most common intramedullary tumors in children, although they also occur in adults. They may occur at all levels, although more often in the cervical cord. The tumor may interfere with the CSF-containing central canal of the spinal cord, leading to a dilated central canal, referred to as syringomyelia (syrinx). Spinal astrocytomas are usually low grade, but complete excision is rarely possible due to the nonencapsulated, infiltrative nature of the tumor. As a result, patients with astrocytomas fare worse overall than patients with ependymomas.

**Other Tumors.** Other types of rare tumors include high-grade astrocytomas, dermoids, epidermoids, teratomas, hemangiomas, hemangioblastomas, and metastases. Patients usually present with pain. Prognosis generally depends on preoperative function and the histologic characteristics of the lesion.

### Future Directions

Future directions in the neurosurgical management of brain tumors are related to improved genetic characterization of brain tumors and technological advances. Regarding the former, the recent update of the World Health Organization classification of central nervous system tumors, alluded to earlier in this chapter, emphasizes an integrated classification approach utilizing both histologic and molecular characteristics. The addition of the latter feature underscores significant advances in the genetics of CNS tumors, which are being translated to treatment. Immunotherapy, for example, is an active area of research in the treatment of GBM. In this approach, immune cells such as T cells and dendritic cells are leveraged to target tumor-specific tissue. These approaches will play an important role as adjuvant therapy to neurosurgical approaches.

Recent advances in neurosurgical technology are being used to address previous operative limitations. Intraoperative fluorescein is being studied as a means of marking abnormal tissue that appears grossly normal in order to maximize resection and minimize recurrence. Indications for SRS are expanding and provide a noninvasive option that can be used as monotherapy or as supplemental therapy to operative intervention. Moreover, new minimally invasive techniques, such as MRI-guided laser interstitial thermal therapy (MRgLITT), are actively being studied for less morbid access to otherwise difficult-to-reach tumors.

### SPINE: BASIC CONCEPTS

The spine is a complex structure and is subject to an extensive array of pathologic processes, including degeneration, inflammation, infection, neoplasia, and trauma. Discussions of spine trauma, tumor, and infection are addressed separately in this chapter in the “Infection—Spine,” “Spinal Tumors,” and “Spine Trauma” sections. General concepts, common patterns of disease, and basic operative interventions are presented here.

The spine consists of a series of stacked vertebrae, intervening discs, and longitudinal ligaments. The vertebrae consist of the vertebral body anteriorly and the pedicles, articular facets, laminae, and spinous processes posteriorly. The intervertebral discs have two components. The tough, fibrous ring that runs around the outer diameter of the two adjacent vertebral bodies is known as the annulus fibrosus. The spongy material inside the ring of the annulus is known as the nucleus pulposus. The annulus and the nucleus provide a cushion between adjacent vertebral bodies, absorb forces transmitted to the spine, and allow some movement between the vertebral bodies. The ligaments stabilize the spine by limiting the motion of adjacent vertebrae.

**Stability**

Stability and neural compression are the two concepts critical to understanding the mechanics and pathologic processes affecting the spine.

**Future Directions**

Future directions in the neurosurgical management of brain tumors are related to improved genetic characterization of brain tumors and technological advances. Regarding the former, the recent update of the World Health Organization classification of central nervous system tumors, alluded to earlier in this chapter, emphasizes an integrated classification approach utilizing both histologic and molecular characteristics. The addition of the latter feature underscores significant advances in the genetics of CNS tumors, which are being translated to treatment. Immunotherapy, for example, is an active area of research in the treatment of GBM. In this approach, immune cells such as T cells and dendritic cells are leveraged to target tumor-specific tissue. These approaches will play an important role as adjuvant therapy to neurosurgical approaches.
intermediate mobility. The sacral spine is fused together and has no intrinsic mobility. The load borne by the lumbar spine is transmitted to the sacrum, and then the pelvis through the sacroiliac joints. The coccyx is the most inferior segment of the spine and has no significant contribution to load bearing or mobility.

A stable spine is one that can bear normally experienced forces resulting from body mass, movement, and muscle contraction, while maintaining normal structure and alignment. An unstable spine will shift or sublux under these forces. The determinants of spinal stability vary throughout the cervical, thoracic, and lumbar portions. In elementary form, stability depends on the structural integrity of the hard, bony elements of the vertebral column, as well as the tensile integrity and security of the supporting ligamentous attachments. Plain X-rays and CT scans are sensitive for detecting bony defects such as fractures or subluxation, while MRI better detects disruptions of the soft tissues, including ligaments and intervertebral discs. Specific patterns of abnormalities seen on imaging studies may suggest or diagnose spinal instability.

A common form of nontraumatic spinal instability is lumbar spondylolisthesis, which is typically a forward slippage of a lumbar vertebra relative to the lower vertebra on which it rests. This results from congenital or degenerative disruption of the pars interarticularis, the critical bridge of bone that spans adjacent facet joints. In the setting of a pars defect, there is no solid bony connection between the adjacent vertebrae. The spine is unstable and anterior listhesis (slippage) may result. Patients typically present with severe low back pain that is exacerbated with movement and load bearing (mechanical low back pain). Radiculopathy in this setting indicates neuroforaminal compression. Figure 42-27 demonstrates an L4 and L5 spondylolisthesis.

Neural Compression

Besides providing a stable, central element of the body’s support structure, the spine also protects the spinal cord and nerve roots as they pass through the neural foramina to form the peripheral nervous system. In a healthy spine, the spinal cord and nerve roots are suspended in CSF, free of mechanical compression. Pathologic processes that can lead to CSF space impingement and neural compression include: hypertrophic degenerative changes in the intervertebral discs and facet joints, expansion of epidural masses such as tumors or abscesses, and subluxation (i.e., slippage) of adjacent vertebral bodies. Subluxation may be due to trauma that exceeds the spine’s load-bearing capabilities and leads to structural failure, or chronic structural degradation by degenerative disease, infection, or tumor. Subluxation reduces the cross-sectional area of the central canal and the neural foramina (see Fig. 42-10B). Reduced central canal area can lead to myelopathy. Reduced neural foraminal area can lead to radiculopathy.

Myelopathy. Compression of the spinal cord can cause disturbance of function known as myelopathy. This dysfunction may be secondary to the direct effects of compression, cord ischemia due to reduced perfusion, or pathologic changes due to repeated cord trauma. These mechanisms lead to demyelination of the corticospinal tracts, which are long descending motor tracts. Corticospinal tract damage leads to upper motor neuron signs and symptoms, including hyperreflexia, spasticity, and weakness. These mechanisms also cause damage to the dorsal columns, which carry ascending proprioception, vibration, and two-point discrimination information. Loss of proprioception makes fine motor tasks and ambulation difficult.

Radiculopathy. Compression of the nerve roots causes disturbance of root function, known as radiculopathy. Characteristic features of radiculopathy include lower motor neuron signs and symptoms (hyporeflexia, atrophy, and weakness) and sensory disturbances such as numbness or tingling sensations (paresthesias), burning sensations (dysesthesias), and shooting (radicular) pain. Myelopathy and radiculopathy often present together in diseases that involve the central canal and the neural foramina. This combination can lead to lower motor neuron dysfunction at the level of disease, and upper motor neuron dysfunction below that level.

Patterns of Disease

Cervical Radiculopathy. The cervical nerve roots exit the central canal above the pedicle of the same-numbered vertebra and at the level of the higher adjacent intervertebral disc. For example, the C6 nerve root passes above the C6 pedicle at the level of the C5–C6 discs. The cervical nerve roots may be compressed acutely by disc herniation, or chronically by hypertrophic degenerative changes of the discs, facets, and ligaments. Table 42-6 summarizes the effects of various disc herniations. Most patients with acute disc herniations will improve without surgery. NSAIDs or cervical traction may help alleviate symptoms. Patients whose symptoms do not resolve or who have significant weakness should undergo decompressive surgery. The two main options for nerve root decompression are anterior cervical discectomy and fusion (ACDF) and posterior cervical foraminotomy (keyhole foraminotomy). ACDF allows more direct access to and removal of the pathology (anterior to the nerve root). However, the procedure requires fusion because discectomy causes a collapse of the interbody space and instability will likely occur. Figure 42-28 demonstrates a C6–C7 ACDF with the typical interposed graft and plating system. Keyhole foraminotomy allows for decompression without requiring
fusion, but it is less effective for removing centrally located canal pathology.

**Cervical Spondylotic Myelopathy.** The term *spondylosis* refers to diffuse degenerative and hypertrophic changes of the discs, intervertebral joints, and ligaments, which collectively result in spinal stenosis. Spinal cord dysfunction (myelopathy) due to cord compression from cervical spinal degenerative disease is therefore referred to as *cervical spondylotic myelopathy* (CSM). Classically CSM presents with spasticity and hyperreflexia due to corticospinal tract dysfunction, upper extremity weakness and atrophy from degeneration of the motor neurons in the anterior horns of the spinal gray matter, and loss of lower extremity proprioception due to dorsal column injury.

Figure 42-28. **A.** Anteroposterior cervical spine X-ray showing the position of an anterior cervical plate used for stabilization after C6–C7 discectomy. Patient presented with right triceps weakness and dysesthesias in the right fifth digit. Magnetic resonance imaging revealed a right paracentral C6–C7 herniated disc compressing the exiting C7 nerve root. **B.** Lateral cervical spine X-ray of the same patient clearly demonstrates the position of the plate and screws. The allograft bone spacer placed in the drilled-out disc space is also apparent.

Figure 42-29 demonstrates typical findings. Some patients complain of difficulty buttoning shirts, using utensils, and ambulating. Spondylosis is usually diffuse, so the usual treatment for CSM is multilevel (usually C3–C7) cervical laminectomy, although patients with disease localized over one to three levels may be candidates for anterior decompression and fusion. Fig. 42-30 demonstrates the postoperative appearance of a vertebral corpectomy and fusion for CSM. Thorough cervical laminectomy decompresses the cord posteriorly. Patients often have slow recovery due to the extensive chronic changes in the cervical cord and may benefit from rehabilitation programs. The other disease that classically presents with combined upper and lower motor neuron symptoms is amyotrophic lateral sclerosis (ALS). Care must be taken...
to avoid offering cervical laminectomy to a patient with undiagnosed ALS. Two findings help differentiate CSM from ALS: cranial nerve dysfunction such as dysphagia (not typically caused by cervical spine disease) and sensory disturbance (not found in ALS).

**Thoracic Disc Herniation.** Thoracic disc herniation accounts for <1% of herniated discs. A patient may present with radicular pain or sensorimotor changes in the lower extremities due to cord compression. A posterior approach via midline incision and laminectomy should be avoided because of the high incidence of cord injury from manipulation and retraction. Anterior approaches via thoracotomy minimize risk to the cord and allow excellent access to the disc. The radicular arteries running from the aorta to the thoracic cord should be spared, when possible, to avoid ischemia. Alternatively, a posterolateral approach is possible via resection of the rib head and facet joint. Finally, a transpedicular approach may be attempted for lateral disc herniations.73

**Lumbar Radiculopathy.** Lumbar nerve roots exit the thecal sac, pass over the higher adjacent disc space, and exit the canal under the pedicle of the same-numbered vertebra. Therefore, the L5 nerve root passes over the L4–L5 disc space and exits under the L5 pedicle (Fig. 42-31). Lumbar discs may herniate with or without a history of trauma or straining. Normally they cause lancinating (radicular) pain down the leg (Table 42-7). Most acute herniated lumbar discs improve symptomatically without surgery. Surgery is indicated for symptoms persisting more than 6 to 8 weeks, progressive motor deficit (e.g., foot drop), or for patients with incapacitating pain not manageable with analgesics. A recent randomized control trial (Spine Patients Outcome Research Trial [SPORT])74 did not observe significant differences between patients randomized to undergo surgery vs. conservative management when using an intent-to-treat analysis. Because of the high amount of bi-directional cross-over between the surgery and conservative group, a subsequent reanalysis of the data as observational cohort analysis, demonstrated improved functional outcomes in terms of pain and physical function, more so at 3 months than at 2 years.74 Discectomy is performed using a midline incision, partial removal of the overlying laminae (hemilaminectomy or laminotomy), identification of the thecal sac and nerve root, and extraction of disc fragments. Free-floating disc fragments may be found. Often, however, the herniated disc material is still contained within the annulus, requiring incision of the posterior longitudinal ligament and curettage of the disc space. After lumbar discectomy, approximately two-thirds of patients will have complete relief of pain, and up to 85% will have significant improvement.

**Neurogenic Claudication.** Neurogenic claudication is characterized by low back and leg pain that occurs while walking and is relieved by stopping, leaning forward, or sitting. It is normally caused by degenerative lumbar stenosis causing compression of the cauda equina. Neurogenic claudication must be distinguished from vascular claudication, which tends to resolve quickly with cessation of walking. There is typically no need to change position, and the pain follows a stocking distribution rather than a dermatomal distribution. Pallor and coldness of the feet, and normal neurologic examination are also typical, though diabetic patients may present a challenge with microvascular
neuropathy. Patients with neurogenic claudication have a slowly progressive course and may be surgical candidates when their pain interferes with their lifestyle. The usual surgery is an L3 to L5 lumbar laminectomy to decompress the nerve roots. A recent randomized control trial did not observe a significant difference in outcomes between surgical and conservative management of lumbar stenosis at 1 year. Thus, surgical management of lumbar stenosis should be reserved for patients that do not improve with physical therapy.

Cauda Equina Syndrome. Cauda equina syndrome is due to compression of the cauda equina and may result from massive disc herniation, EDH, epidural abscess, tumor, or subluxation from trauma. Patients with cauda equina compression often present with urinary retention, saddle anesthesia, or progressing leg weakness. Saddle anesthesia is numbness in the perineum, genitals, buttocks, and upper inner thighs. Patients with suspected cauda equina syndrome should undergo immediate MRI of the lumbar spine to evaluate for a surgical lesion. Mass lesions should be removed urgently via laminectomy to preserve sphincter function and ambulation.

Spine Fusion Surgery
Fusion surgery is often required for patients with spinal instability resulting from disease, surgical intervention, or both. Fusion procedures lock adjacent vertebrae together. Fusion occurs when the body forms a solid mass of bone incorporating the adjacent vertebrae, eliminating normal intervertebral movement. Stabilization and immobilization promote bony fusion. Internal instrumentation and external orthoses are often used to stabilize and immobilize the fused spinal segments.

Spinal Instrumentation
Internal fixation devices for spinal segmental immobilization have been developed for all levels of the spine. Most spinal instrumentation constructs have two elements. The first element is a device that solidly attaches to the vertebral bodies. Options include wires wrapped around laminae or spinous processes, hooks placed under the lamina or around the pedicles, or screws placed in the pedicles or the vertebral bodies. The second element is a device that traverses vertebral segments. Options include rods and plates that lock directly to the wires, hooks, or screws at each vertebral level. Spinal instrumentation devices are available for anterior and posterior fusion in the cervical, thoracic, and lumbar regions. Most modern spinal instrumentation devices are made of titanium to minimize problems with future MRI scanning (Fig. 42-32). All spinal instrumentation constructs will eventually fail by loosening or breaking if bony fusion does not occur.

Arthrodesis

Arthrodesis refers to the obliteration of motion or instability by incorporating the relevant components into a solid mass of bone. Arthrodesis must occur in any fused segment to have long-term stability. Failure of arthrodesis results in failed fusion, often in the form of a fibrous nonunion. The rates of successful fusion are higher in the cervical spine than the lumbar spine. Arthrodesis requires ingrowth of new bone formed by the patient’s osteoblasts across the unstable defect. Inserting graft material, such as autograft or allograft, into the defect provides a bridge for osteoblasts and promotes fusion. The term autograft refers to the patient’s own bone, often harvested from the iliac crest. Iliac crest bone graft is a source of both cortical and cancellous bone. Cortical bone provides structural support, while cancellous bone provides a matrix for bony ingrowth. The term allograft refers to sterilized bone from human tissue banks. Allografts also may be cortical, cancellous, or both. Allograft lacks the array of osteoinductive endogenous compounds intrinsic to autograft, although supplemental products such as demineralized bone matrix paste can be added to encourage new bone formation. Other techniques for increasing the rates of successful fusion are being developed, including the integration of osteoinductive bone morphogenetic proteins, known as BMPs, into the fusion constructs.

Dynamic stabilization refers to the creation of spinal stability without achieving a bony fusion. The concept applies to both cervical and lumbar motion segments. Artificial lumbar and cervical disc replacement therapies are recent developments in degenerative spine disease that address this concept. However, their use is limited to very select cases. Another motion preservation technique that may hold promise is segmental “soft” stabilization. In cases of degenerative spondylolisthesis, such systems in the lumbar spine allow for decompressive laminectomy without increasing slippage. In theory, adjacent level facets and discs are spared the stresses of a neighboring bony fusion moment arm.

Peripheral Nerve

Common pathologic processes that compromise function of the peripheral nervous system include mechanical compression, ischemia, inflammation, and neoplasia.

Peripheral Nerve Tumors

Most peripheral nerve tumors are benign and grow slowly. Significant pain increases the likelihood that the patient has a malignant tumor. Treatment for peripheral nerve tumors is surgical resection to establish diagnosis and evaluate for signs of malignancy. These tumors have various degrees of involvement with the parent nerve. Some can be resected with minimal or no damage to the nerve. Tumors that grow within the nerve often contain functioning fascicles. Total excision of these tumors requires sacrifice of the parent nerve. The choice of subtotal resection, nerve preservation, and observation, vs. total resection with nerve sacrifice depends on tumor histology and the function of the parent nerve.

Schwannoma. Schwannomas are the most common peripheral nerve tumors, also referred to as neurilemomas or neurinomas. Most occur in the third decade of life. These benign tumors arise from Schwann cells, which form myelin in peripheral nerves. The most characteristic presentation is a mass lesion with point tenderness and shooting pains on direct palpation. Spontaneous
or continuous pain suggests malignancy. Schwannomas tend to grow slowly and eccentrically on parent nerves. The eccentric location and discrete encapsulated nature of these tumors often allow total resection without significant damage to the parent nerve. Subtotal resection and observation is reasonable for schwannomas entwined in important nerves, as the incidence of malignant transformation is extremely low.

**Neurofibroma.** Neurofibromas arise within the nerve and tend to be fusiform masses, unlike schwannomas, which tend to grow out of the nerve. Neurofibromas often present as a mass that is tender to palpation. They usually lack the shooting pains characteristic of schwannomas. Neurofibromas are often difficult to resect completely without sacrifice of the parent nerve. Neurofibromas have a higher incidence of malignant transformation; therefore, patients with known residual tumors require close observation. Patients with NF1 often have multiple neurofibromas. These patients should be offered resection for symptomatic tumors. Risk of malignant degeneration is up to 10%. Malignant neurofibromas have the histologic characteristics of sarcoma.

**Malignant Nerve Sheath Tumors.** Malignant nerve sheath tumors include solitary sarcomas, degenerated neurofibromas, and neuroepitheliomias. Patients with malignant peripheral nerve tumors typically complain of constant pain, rather than pain only on palpation, and are more likely to have motor and sensory deficits in the distribution of the parent nerve. Treatment for these tumors is radical excision. This often requires sacrifice of the parent nerve. Invasion of nearby soft tissues may occur and necessitate wide resection or amputation in an attempt to prevent systemic metastasis.

**Entrapment Neuropathies**

Entrapment neuropathy presents as neurologic dysfunction in nerves passing through a pathologically small, fixed space. Nerve dysfunction may result directly from chronic, repetitive pressure on the nerve, or from ischemic damage due to impaired perfusion.75 Entrapment causing dysfunction of nerve signaling may be associated with numbness, paresthesias, weakness, or muscle atrophy. The two most common sites of entrapment neuropathy are the ulnar nerve at the medial aspect of the elbow and the median nerve at the wrist. Usually EMG/NCS demonstrate slowing across the entrapped segment of nerve. Mechanical peripheral nerve disorders resulting from trauma (brachial plexus disruption, radial nerve damage from humerus fractures, and common peroneal nerve crush injuries) are discussed in the section “Trauma.”

**Ulnar Neuropathy.** The ulnar nerve has contributions from the C7, C8, and T1 nerve roots, arises from the medial cord of the brachial plexus, and supplies most of the intrinsic hand muscles (interossei and third and fourth lumbricals) and sensation to the fourth and fifth digits. It passes posteriorly to the medial epicondyle at the elbow in the condylar groove. This segment is superficial and subject to external compression and repetitive minor impacts. Patients with ulnar entrapment at the elbow present with numbness and tingling in the medial palm, as well as the fourth and fifth digits. Motor deficits include weakness and wasting of the intrinsic hand muscles. Treatment for symptomatic ulnar entrapment neuropathy is surgical exploration and incision of the fibrous aponeurotic arch that overlies the nerve. A 6-cm curvilinear incision centered between the medial epicondyle and the olecranon allows exploration of up to 10 cm of nerve and lysis of compressive tissues.

**Carpal Tunnel Syndrome.** The median nerve has contributions from the C5 to T1 nerve roots, arises from the medial and lateral cords of the brachial plexus, and supplies the muscles of wrist and finger flexion and sensation to the palmar aspect of the first, second, and third digits. The median nerve passes through the carpal tunnel in the wrist, lying superficial to the four deep and four superficial flexor tendons. The transverse carpal ligament is a tough, fibrous band that forms the roof of the carpal tunnel. The ligament attaches to the pisiform and hamate medially and the trapezium and scaphoid laterally. Patients complain of numbness and tingling in the supplied digits, clumsiness, and worsening with sleep or repetitive wrist movement. Patients may notice wasting of the thenar eminence. Treatment for symptomatic carpal tunnel syndrome unresponsive to splinting, analgesics, and rest is surgical division of the flexor retinaculum. This often provides prompt relief of pain symptoms and slow recovery of numbness and strength.

**Autoimmune and Inflammatory Disorders**

These are not surgical diseases, but they merit brief mention as they are included in the differential diagnosis for new-onset weakness. Their characteristic presentations help distinguish them from weakness due to structural lesions.

**Guillain-Barré Syndrome.** Guillain-Barré syndrome is an acute inflammatory demyelinating polyradiculopathy often occurring after viral infection, surgery, inoculations, or mycoplasmal infections. Patients classically present with weakness ascending from the legs to the body, arms, and even cranial nerves. Symptoms usually progress over 2 to 4 weeks and then resolve. Care is supportive. Respiratory weakness may require ventilatory support.

**Myasthenia Gravis.** Myasthenia gravis is an autoimmune process in which antibodies form to the acetylcholine receptors of muscles, leading to fluctuating weakness. Most patients have either thymic hyperplasia or thymoma. The most common symptoms are diplopia, ptosis, dysarthria, and dysphagia. More severe cases have limb or respiratory involvement. Weakness worsens with repetitive movement. Treatment is with acetylcholinesterase inhibitors and possible thymectomy.

**Eaton-Lambert Syndrome.** Eaton-Lambert syndrome is an autoimmune process with antibodies to the presynaptic calcium channels. This is a paraneoplastic syndrome most commonly associated with oat cell carcinoma. Patients have weakness of proximal limb muscles that improves with repetitive movement. This diagnosis must prompt oncologic evaluation.

**INFECTION**

CNS infections of interest to neurosurgeons include those that cause focal neurologic deficit due to mass effect, require surgical aspiration or drainage because antibiotic therapy alone is insufficient, cause mechanical instability of the spine, or occur after neurosurgical procedures.

**Cranial**

**Osteomyelitis.** The skull is highly vascular and resistant to infections. Osteomyelitis of the skull may develop by contiguous spread from pyogenic sinus disease or from contamination by penetrating trauma. *Staphylococcus aureus* and *S epidermidis* are the most frequent causative organisms. Patients usually present with redness, swelling, and pain. Contrast head CT aids
diagnosis and shows the extent of involved bone, along with associated abscesses or empyema. Osteomyelitis treatment entails surgical debridement of involved bone followed by 2 to 4 months of antibiotics. Craniotomy wound infections are a special concern because performing a craniotomy creates a devascularized free bone flap susceptible to infection and not penetrated by antibiotics. These wounds must be debrided and the bone flaps removed and discarded. Subsequent care involves appropriate antibiotic therapy, observation for signs of recurrent infection off antibiotics, and return to the OR for titanium or methylmethacrylate cranioplasty 6 to 12 months later.

**Subdural Empyema.** Subdural empyema is a rapidly progressive pyogenic infection. The subdural space lacks significant barriers to the spread of the infection, such as compartmentalization or septations. Subdural empyemas usually occur over the cerebral convexities. Potential infectious sources include sinus disease, penetrating trauma, and otitis. Streptococci and staphylococci are the most frequent sources. Presenting symptoms include fever, headache, neck stiffness, seizures, or focal neurologic deficit. Neurologic deficit results from inflammation of cortical blood vessels, leading to thrombosis and stroke. The most common deficit is contralateral hemiparesis. Patients with suggestive symptoms should undergo rapid contrast CT scan. LP frequently fails to yield the offending organism and risks herniation due to mass effect. Typical treatment is wide hemicraniectomy, dural opening, and lavage. The pus may be thick or septated, making burr hole drainage or small craniotomy insufficient. Patients then require 1 to 2 months of antibiotics. Subdural empyema has 10% to 20% mortality risk and common chronic sequelae, including development of a seizure disorder and residual hemiparesis. However, many patients do make a good recovery.

**Brain Abscess.** Brain abscess is encapsulated infection within the brain parenchyma. It may spread hematogenously in patients with endocarditis or intracardiac or intrapulmonary right-to-left shunts, by migration from the sinuses or ear, or via direct seeding by penetrating trauma. Disorganized cerebritis often precedes formation of the organized, walled-off abscess. Patients may present with nonspecific symptoms such as headache, nausea, or lethargy, or with focal neurologic deficit such as hemiparesis. Alternatively, patients may present in extremis if the abscess ruptures into the ventricular system. Abscesses appear as well-demarcated, ring-enhancing, thin-walled lesions on CT scan and MRI, and often have associated edema and mass effect. Patients require antibiotic therapy after needle aspiration or surgical evacuation. Antibiotic therapy without surgical evacuation may be considered for patients with small, multiple, or critically located abscesses. Abscesses that are large, cause mass effect, decreased mental status, or that fail to decrease in size after 1 week of antibiotics, should be evacuated. Nonsurgical management still requires aspiration or biopsy specimen for organism culture and sensitivities. Blood and CSF cultures rarely give definitive diagnosis. Removal of an encapsulated abscess significantly shortens the length of antibiotic therapy required to eliminate all organisms. Common chronic sequelae after successful treatment include seizures or focal neurologic deficit.

**Spine**

**Pyogenic Vertebral Osteomyelitis.** Pyogenic vertebral osteomyelitis is a destructive bacterial infection of the vertebrae, usually of the vertebral body. Vertebral osteomyelitis frequently results from hematogenous spread of distant disease, but may occur as an extension of adjacent disease, such as psoas abscess or perinephric abscess. *S aureus* and *Enterobacter* spp. are the most frequent etiologic organisms. Patients usually present with fever and back pain. Diabetics, IV drug abusers, and dialysis patients have increased incidence of vertebral osteomyelitis. Epidural extension may lead to compression of the spinal cord or nerve roots with resultant neurologic deficit. Osteomyelitis presents a lytic picture on imaging and must be distinguished from neoplastic disease. Adjacent intervertebral disc involvement occurs frequently with pyogenic osteomyelitis, but rarely with neoplasia. Plain films and CT help assess the extent of bony destruction or deformity such as kyphosis. MRI shows adjacent soft tissue or epidural disease. Most cases can be treated successfully with antibiotics alone, although the organism must be isolated to steer antibiotic choice. Blood cultures may be positive. Surgical intervention may be required for debridement when antibiotics alone fail, or for stabilization and fusion in the setting of instability and deformity.

**Tuberculous Vertebral Osteomyelitis.** Tuberculous vertebral osteomyelitis, also known as *Pott’s disease*, occurs most commonly in underdeveloped countries and in the immunocompromised. Several features differentiate tuberculous osteomyelitis from bacterial osteomyelitis. The infection is indolent and symptoms often progress slowly over months. Tuberculosis rarely involves the intervertebral disc. The involved bodies may have sclerotic rather than lytic changes. Multiple nonadjacent vertebrae may be involved. The upper lumbar and lower thoracic vertebrae are most commonly affected. Diagnosis requires documentation of acid-fast bacilli. Treatment involves long-term antimycobacterial drugs. Patients with spinal instability or neural compression from epidural inflammatory tissue should undergo debridement and fusion as needed.

**Discitis.** Primary infection of the intervertebral disc space, or discitis, is most commonly secondary to postoperative infections. Spontaneous discitis occurs more commonly in children. *S aureus* and *S epidermidis* account for most cases. The primary symptom is back pain. Other signs and symptoms include radicular pain, fevers, paraspinal muscle spasm, and localized tenderness to palpation. Many cases will resolve without antibiotics, which generally are given for positive blood or biopsy specimen cultures or persistent constitutional symptoms. Most patients will have spontaneous fusion across the involved disc and do not need debridement or fusion.

**Epidural Abscess.** Epidural abscesses may arise from or spread to the adjacent bone or disc, so distinguishing between vertebral osteomyelitis or discitis and a spinal epidural abscess may be difficult. The most common presenting signs and symptoms are back pain, fever, and tenderness to palpation of the spine. The most significant risk of epidural abscess is weakness progressing to paralysis due to spinal cord or nerve root damage. Cord and root damage may be due to direct compression or to inflammatory thrombosis resulting in venous infarction. *S aureus* and *Streptococcus* spp. are the most common organisms. Meticillin-resistant *S aureus* now constitutes a significant proportion of these infections, as high as 40%. The source may be hematogenous spread, local extension, or operative contamination. MRI best demonstrates the epidural space and degree of neural compromise. Patients with spinal epidural abscess and neurologic compromise should undergo surgical debridement for decompression and diagnosis, followed by culture-directed therapy.
antibiotic therapy. Relative contraindications to surgery include prohibitive comorbidities or total lack of neurologic function below the involved level. Patients with no neurologic deficits and an identified organism may be treated with antibiotics alone and very close observation. However, this management strategy remains somewhat controversial because these patients can undergo rapid and irreversible neurologic decline. Most epidural abscesses can be accessed via laminectomy without fusion. Collections predominantly anterior to the cervical or thoracic cord may require anterior approach and fusion.

**FUNCTIONAL NEUROSURGERY**

**Epilepsy Surgery**
